Despite low-circulating GH levels in CI, the administration of exogenous GH is detrimental. Several large randomized controlled trials have studied the use of GH as an attempt to treat hypercatabolism, that is, commonplace among critically ill patients. Results of these trials consistently show

an increase in mortality in the group treated with GH, leading to recommendations against the use of GH in patients with CI.^{5,6} In another randomized trial in CI, the administration of insulin-like growth factor-1, an important downstream mediator of GH signaling, also failed to show clinical benefit.⁷

The replacement of testosterone or estrogen, which results from low LH and FSH, and replacement of thyroxine, which results from low TSH, remain controversial.⁸⁻¹⁰

The posterior pituitary releases 2 peptide hormones: antidiuretic hormone (ADH) and oxytocin. These hormones are synthesized in neuronal cell bodies located in the hypothalamus and transported within vesicles along the axons to the posterior pituitary for release into the bloodstream. Disorders of ADH secretion are discussed in the sections on diabetes insipidus (DI) and syndrome of inappropriate ADH secretion (SIADH).

PITUITARY FAILURE

Aside from the typical neuroendocrine stress response in CI, the loss of normal pituitary function due to direct insults of the hypothalamus or pituitary itself can lead to loss of end-organ gland dysfunction such as secondary hypothyroidism, adrenal insufficiency, or hypogonadism. Clinical scenarios that commonly interfere with normal pituitary function include head trauma, intracranial hemorrhage, and neurosurgery, especially following procedures that involve manipulation within the sella turcica such as resection of a pituitary adenoma, Rathke’s cleft cyst, or craniopharyngioma.^{11,12} Patients with any of these conditions may be suspected for pituitary insufficiency.

Pituitary function may be significantly compromised in postpartum women following large amounts of blood loss during delivery (Sheehan’s syndrome).¹² Inflammatory conditions, such as lymphocytic hypophysitis, histiocytosis X, or neurosarcooidosis, may involve the pituitary gland and result in hormonal insufficiencies; these conditions are relatively rare but should be considered and then excluded in appropriate at-risk CI patients.¹³ Some malignancies (eg, lymphoma and hypernephroma) can metastasize to the pituitary gland and cause significant endocrinopathy; these conditions should

TABLE 44–1 Anterior pituitary response to critical illness.⁴

Thyroid stimulating hormone (TSH)	Elevated briefly then suppressed during CI, elevated during recovery
Adrenocorticotrophic hormone (ACTH)	Elevated for first 3 days of CI, then suppressed
Luteinizing hormone (LH)	Suppressed
Follicle stimulating hormone (FSH)	Suppressed
Prolactin (PRL)	Elevated
Growth hormone (GH)	Suppressed

Data from Mechanick JI, Sacks HS, Cobin RH: Hypothalamic-pituitary axis dysfunction in critically ill patients with a low free thyroxine index, *J Endocrinol Invest* 1997 Sep;20(8):462-470.

also be included in the differential diagnosis when appropriate.

Pituitary apoplexy, which occurs after hemorrhage of an existing pituitary adenoma, is another possible cause for the sudden loss of pituitary function.¹² Patients typically have a sudden severe headache, nausea, near syncope, or changes in vision if there is any mass effect that compresses the optic chiasm.

Acute manifestations of pituitary insufficiency include hypotension secondary to adrenal insufficiency and either hyponatremia or hypernatremia from changes in ADH secretion. Patients with suspected pituitary insufficiency should be given stress dose corticosteroids and evaluated for the SIADH or DI that may develop acutely in pituitary insufficiency. In some patients, the administration of corticosteroids may unmask underlying DI by impairing the release of ADH by the posterior pituitary and by indirectly attenuating ADH function in the renal collecting ducts.¹⁴

Diagnosing endocrine deficiencies resulting from hypopituitarism includes measurement of the pituitary hormone(s) and end-organ hormone(s), for instance, TSH and thyroxine, or LH, FSH, and either testosterone in men or estradiol in women. In postmenopausal women, pituitary dysfunction may be queried by measuring LH and FSH, which are expected to be elevated 5 to 20 fold.¹⁵

If deficiencies exist, replacement of end-organ hormones, such as treatment with thyroxine, testosterone, or estrogen, can be considered. In general, these treatments should be withheld until the patient has been stabilized. In the case of hypothyroxinemia with suspected or known pituitary dysfunction, it is also critical to initiate stress dose corticosteroid treatment prior to L-thyroxine (T4) treatment. This strategy minimizes the risk of severe adrenal insufficiency because cortisol catabolism (and, therefore, requirement) is enhanced by augmenting thyroid hormone levels, metabolic rate, and energy expenditure.

ADRENAL INSUFFICIENCY

Insufficient cortisol production by the adrenal cortex is the hallmark of adrenal insufficiency. Primary adrenal insufficiency results when there is adrenal

pathology and secondary/tertiary (or “central”) adrenal insufficiency results when there is pituitary/hypothalamic pathology affecting ACTH secretion. Decreased aldosterone reserve, as part of primary adrenal insufficiency, may occur in CI in association with cortisol insufficiency, or more rarely, alone as selective aldosterone deficiency.¹⁶ Underproduction of the weak androgen dehydroepiandrosterone, produced mainly in the zona reticularis of the cortex, or underproduction of adrenal catecholamines, produced in the adrenal medulla generally do not contribute to the clinical scenario of adrenal insufficiency.

Cortisol, the main glucocorticoid hormone, exerts its numerous systemic functions by inducing tissue-specific gene expression. During times of physiologic stress, cortisol secretion increases. Patients with insufficient cortisol production may experience signs and symptoms as mild as headache, malaise, abdominal pain, nausea (generally without vomiting), myalgias, and/or lassitude with adrenal withdrawal (associated with steroid tapering and suppression of the hypothalamic-pituitary-adrenal [HPA] axis), to signs as severe as hypotension, incapacitating fatigue, severe hypoglycemia, hyponatremia (with hyperkalemia if primary adrenal insufficiency), and acidosis with adrenal insufficiency or crisis (associated with either primary or central adrenal insufficiency). Primary adrenal insufficiency can result from autoimmune, infectious, or hemorrhagic processes within the adrenal cortex, for example, Waterhouse–Friderichsen syndrome from meningococcal infection or adrenal vein thrombosis resulting from antiphospholipid antibody syndrome. Central adrenal insufficiency typically results from overly rapid tapering of corticosteroid dosing or increased stress in a patient who was recently tapered off of corticosteroids.

During CI, a form of central adrenal insufficiency (also termed “relative adrenal insufficiency” or “adrenal exhaustion” in the medical literature) may develop due to higher systemic cortisol requirements, effects of certain medications that inhibit cortisol synthesis, such as etomidate, and/or an impaired HPA axis during CI. The incidence of this form of central adrenal insufficiency has been reported between 10% and 30% of patients admitted

with septic shock.¹⁷ Note that this entity, though real and relevant, is still the subject of great interest among intensivists and changes in definitions and management are likely to change in the near future.

Adrenal insufficiency should be suspected in patients with unexplained or persistent hypotension, hypoglycemia, hyponatremia, or hyperkalemia. An absence of hyperglycemia, that is, expected as a stress response to CI may also be an indication of adrenal insufficiency.³ The diagnosis is made by cosyntropin (250 mcg) stimulation testing that includes 2 criteria to confirm normal adrenal function: (1) plasma cortisol levels should reach 18 µg/dL/h after administering recombinant ACTH; (2) plasma cortisol levels should increase by at least 9 µg/dL from baseline. If both of these criteria are met, patients should be considered to have normal adrenal function. Patients with severe adrenal insufficiency fail to meet either of these criteria. If only 1 of the 2 criteria is met, adrenal insufficiency may still be suspected based on clinical impression.¹⁷ Unfortunately, there are several legitimate caveats to this approach that account for overdiagnosis and underdiagnosis: (1) measured total cortisol levels may be falsely low due to typically suppressed levels of cortisol-binding globulin (generally paralleling suppressing of albumin), (2) inadequate normative data for different CI patient subsets, and (3) the appearance of cortisol resistance. Consequently, a free cortisol level may be helpful, but this test usually requires several days to obtain a result, rendering the test moot for emergent decision making. Thus, a clinical diagnosis is still paramount to guide management.¹⁸

Treatment of adrenal insufficiency in CI includes stress-dose corticosteroids, usually hydrocortisone at doses of 50 to 100 mg every 6 to 8 hours. In patients with suspected adrenal insufficiency, corticosteroid treatment should be empirically initiated, and may be discontinued later in the subgroup of patients that do not meet criteria after the results of cosyntropin stimulation or free cortisol testing become available. In the cases of septic shock refractory to fluid resuscitation, and in patients with acute respiratory distress syndrome, several studies demonstrate improvement in clinical outcomes with glucocorticoid therapy regardless of cosyntropin stimulation testing.¹⁸ Treatment with stress dose glucocorticoid therapy is currently recommended in

these groups of patients.¹⁸ Another approach that is more clinically oriented is to provide a lower dose of hydrocortisone (50 mg q 12) to patients suspected of relative adrenal insufficiency (pressor dependence without clear reason), while deferring specific adrenal biochemical testing and then taper empirically.¹⁸

Patients with adrenal insufficiency should continue to receive steroid treatment until hemodynamically stable. As the patient improves, the corticosteroid dose should be tapered over days to weeks based on clinical judgment, taking into account initial dosing level, dosing chronicity, and setting.

The administration of fludrocortisone, a pure mineralocorticoid, in conjunction with glucocorticoid therapy in patients with septic shock and adrenal insufficiency, was suggested by the results of 1 clinical trial.¹⁹ However, a subsequent study failed to show any benefit with the use of fludrocortisone in this population.²⁰

Several conditions that may mimic adrenal insufficiency should be considered if patients do not respond to corticosteroid therapy. Dysautonomia may occur in patients with chronic underlying neurologic disease, such as parkinsonism, which reduces sympathetic control of blood pressure and may lead to hypotension despite fluid resuscitation.²¹ Autonomic dysfunction may also be suspected and responsive to midodrine in patients on renal replacement therapy.²² Cortisol resistance, which may occur in preterminal patients or those with hepatic disease, may also lead to hypotension, but cortisol levels are often extremely high.²³

DIABETIC KETOACIDOSIS

Insulin signaling modulates a number of metabolic and growth pathways on the cellular level. In addition to the well-known function of insulin to stimulate glucose uptake in endothelial, muscle, and adipose tissues, a low level of basal insulin regulates β -oxidation of fatty acids. In patients with negligible insulin secretion, uncontrolled fatty acid β -oxidation leads to the generation of acidic ketone bodies, including acetone, acetoacetate, and β -hydroxybutyrate. Overproduction and accumulation of ketone bodies, especially β -hydroxybutyrate and acetoacetate that release hydrogen ions in

circulation, are the main causes of diabetic ketoacidosis (DKA).

DKA typically occurs in patients with type 1 diabetes that are newly diagnosed, acutely ill, or resulting from missed scheduled insulin doses.²⁴ Other patients at risk for DKA include those that have undergone surgical pancreatic resection, have pancreatic failure following episodes of pancreatitis, or patients with type 2 diabetes that have severely reduced pancreatic β -cell function during periods of extreme hyperglycemia (atypical or “Flatbush” diabetes).²⁵

Patients that develop DKA present with an anion gap acidosis, mental status changes, hyperglycemia, dehydration, and electrolyte abnormalities that commonly include hyponatremia, and initially, hyperkalemia. As DKA is treated with insulin, hypophosphatemia may develop, which can lead to muscle weakness and in extreme cases, respiratory failure. Without appropriate supportive treatments, severe neurologic deficits and death may occur in patients that develop DKA.²⁴

Treatment of DKA includes administration of insulin, intravenous fluids, and supportive measures. Additionally, an underlying cause for DKA should be investigated, which may include urinary tract infections or pneumonia, gastroenteritis, myocardial infarction, or simply nonadherence to insulin dosing.

Patients are stabilized with intravenous administration of regular insulin. A loading dose of 0.05 to 0.1 units/kg is recommended, followed by a continuous rate of 0.025 to 0.05 units/kg/h.²⁶ Normal saline is infused at the rate of 100 to 200 mL/h after a 1.5 to 2 L bolus. Electrolytes should be monitored at regular intervals, every 1 to 2 hours at first, then with declining frequency as the patient stabilizes. Potassium levels are typically elevated initially, but can decline to severely low serum levels as potassium shifts intracellularly with insulin and fluids treatment. Magnesium levels may also decline through a similar mechanism. As insulin drives cellular glucose uptake, glucose-6-phosphate is formed, consuming intracellular phosphate, and leading to passive inward diffusion of free phosphate and hypophosphatemia. Supplementation with potassium, phosphorus, and magnesium may need to be aggressive and should be administered to compensate for these changes.²⁶

Capillary blood glucose levels should also be monitored frequently, with adjustment of the insulin infusion as needed. If blood glucose levels normalize but the serum anion gap remains above 16 mEq/L, the insulin infusion should be continued, and a 5% to 10% dextrose infusion should be started. The overall strategy is to render patients as anabolic, thus the provision of dextrose in addition to insulin can help drive a positive nutritional balance in cellular metabolic pathways.

As the anion gap declines to levels consistently less than 16 mEq/L and arterial pH is greater than 7.30, patients should be considered for transition to subcutaneous insulin.²⁶ In many cases, the home insulin regimen can be restarted. For newly diagnosed type 1 diabetics, a good rule of thumb is to give 0.2 units/kg of long-acting insulin, such as glargine or detemir, and another 0.2 units/kg of rapid-acting insulin, divided into 3 premeal treatments daily. For patients with Flatbush diabetes, a combination of insulin and antihyperglycemic oral medication may be appropriate. Consultation with an endocrinologist can assist in determining the medication regimen for each individual patient.

HYPERGLYCEMIC HYPEROSMOLAR STATE

In contrast to DKA, which primarily occurs in type 1 diabetes, hyperglycemic hyperosmolar state (HHS), previously known as nonketotic coma, is more commonly seen in patients with type 2 diabetes.²⁴ Patients with type 2 diabetes have both systemic insulin resistance and impaired β -cell function, which, if not adequately treated, may lead to severely elevated blood glucose levels. HHS usually occurs during a period in which medication adherence has lapsed and uncontrolled blood glucose levels that reach extreme heights, often greater than 600 mg/dL, persist. These concentrations overwhelm renal glucose resorption, leading to hyperglycosuria and an osmotic diuresis occurs. Patients present with severe dehydration, with hyponatremia, polyuria, blurred vision, and acute weight loss. There may be a minimal production of ketones owing to a shift to lipid consumption for energy utilization, but this is generally not sufficient to cause acidosis.

If the dehydration and hyponatremia are severe enough, mental status changes may occur, necessitating admission to a closely monitored setting.

Treatment of HHS is generally supportive in nature. Intravenous fluids are given generously. Insulin should be administered, which may be given as an intravenous infusion or as subcutaneous basal/bolus injections. In patients admitted to the intensive care unit with mental status changes, an intravenous infusion of regular insulin is preferred.

As blood glucose normalizes and patients are able to take meals regularly, the insulin regimen should be converted to a combination of long-acting insulin with rapid acting bolus insulin administered with each meal. As a rule of thumb, 80% of the previous 24 hours intravenous insulin given can be used as a total daily subcutaneous insulin dose. This may be divided in half, and given as basal insulin; the remaining half can be divided into thirds and given as premeal rapid-acting insulin. This basal-bolus insulin administration strategy mimics normal pancreatic function and should be considered for optimal glycemic control in patients tolerating an oral diet, or for those on bolused tube feeding.²⁷ For patients on continuous enteral feeding, long-acting insulin, given 1 to 3 times per day is more suitable to match the infusion and absorption rate of dietary carbohydrates.

In addition, a multidisciplinary approach to the continued care of the patient may involve consultation with nutrition and diabetes educators and close follow up with the patient's diabetes specialist after hospital discharge.

THYROID FUNCTION

The vast majority of thyroid hormone produced by the thyroid gland is released into circulation as T₄ and is converted to triiodothyronine (T₃) or reverse T₃ (rT₃) by deiodinase enzymes in the liver and other target tissues. T₃, the active form of thyroid hormone, functions as a general regulatory signal of metabolism, whereas rT₃ is generally inactive metabolite of T₄. Nearly all cells and tissues contain thyroid hormone receptors that modulate gene expression and cellular metabolic function in response to T₃.

The controlled release of thyroid hormone occurs in several steps, which includes the secretion of TSH by the anterior pituitary and the secretion of

thyrotropin releasing hormone from the hypothalamus. Thyroid hormone activity is further modulated through control of the deiodination process during the systemic conversion of T₄ to either T₃ or rT₃.

In addition to the metabolic state of the individual, certain medications may influence the regulation of thyroid hormone function. Lithium affects T₄ synthesis and release, and deiodination.²⁸ Corticosteroids and β -adrenergic antagonists alter deiodination.²⁹ Amiodarone has several effects on thyroid function and is reviewed as follows.

NONTHYROIDAL ILLNESS

Both the hypothalamus activity and pituitary gland function are affected in CI. Patients commonly demonstrate a typical pattern of thyroid function blood tests that are associated with severity of CI rather than alteration in thyroid function. This phenomenon is known as nonthyroidal illness, or previously the "sick-euthyroid" syndrome.¹⁰ In this condition, TSH levels often decrease. T₄ levels may remain normal, but are usually decreased. T₃ levels decrease as conversion of T₄ to rT₃ increases. As a patient recovers, the TSH levels begin to rise and can become elevated above the normal range, as high as 15 to 20 mIU/L (milli-international units per liter). Consequently, thyroid function tests can be difficult to interpret in the setting of acute illness or hospitalization. Treatment of nonthyroidal illness with thyroid hormone replacement remains controversial and has not been shown to affect overall outcome.^{30,31}

THYROTOXICOSIS

In conditions that lead to excessive thyroid hormone production, hyperthyroidism or thyrotoxicosis develops. Patients may experience excessive warmth, diaphoresis, tachycardia, hyperreflexia, weight loss, hair loss, fine tremor and loose bowel movements. TSH levels are low, with normal to elevated free T₄ and T₃ levels.

In severe cases, thyrotoxic crisis may be classified under the Burch–Wartofsky scoring system (Table 44–2) as "Thyroid Storm."³² In addition to the classic symptoms of hyperthyroidism, patients may exhibit altered mental status, psychosis, fevers, nausea, vomiting, high-output heart failure,

TABLE 44–2 Burch–Wartofsky scoring system for thyrotoxic crisis.³²

Clinical Sign	Score	Clinical Sign	Score
Body Temperature		Congestive Heart Failure	
99°F-99.9°F (37.2°C-37.7°C)	5	Absent	0
100.0°F-100.9°F (37.8°C-38.2°C)	10	Peripheral edema	5
101.0°F-101.9°F (38.3°C-38.8°C)	15	Mild respiratory rates	10
102.0°F-102.9°F (38.9°C-39.3°C)	20	Pulmonary edema	15
103.0°F-103.9°F (39.4-39.9°C)	25	Gastrointestinal Symptoms	
104.0°F (40.0°C) or greater	30	Absent	0
		Nausea/vomiting/diarrhea	10
		Jaundice	20
Pulse (beats/min)		Central Nervous System	
90-109	5	Unaltered mental status	0
110-119	10	Mild agitation	10
120-129	15	Lethargy/delirium/psychosis	20
130-139	20	Seizure/coma	30
140 or greater	25	History of Precipitating Event	
Atrial Fibrillation		Absent	0
Absent	0	Present	10
Present	10		

A total score of 45 represents likely thyrotoxic crisis, 25 to 44 represents probable thyrotoxic crisis, and less than 25 is suggestive that thyrotoxic crisis is unlikely.

Adapted with permission from Klubo-Gwiedzinska J1, Wartofsky L: Thyroid emergencies, *Med Clin North Am.* 2012 Mar;96(2):385-403.

and unstable blood pressure. This may be precipitated by a large physiologic stressor, such as a myocardial infarction, surgery or other CI in a patient with long-standing, inadequately treated thyrotoxicosis.

Patients with severe thyrotoxicosis should be kept in a closely monitored setting and treated with stress-dose corticosteroids, β -adrenergic receptor blocking agents, and propylthiouracil (PTU) or methimazole, which prevent thyroidal synthesis and release of thyroid hormone. In this setting, PTU is given as a loading dose of 500 to 1000 mg orally or via nasogastric tube, followed by 200 to 250 mg

every 4 hours. As an alternative to PTU, methimazole is given as 60 to 80 mg daily.^{33,34}

The use of other agents such as lithium to prevent thyroid hormone release or cholestyramine to sequester T4 and T3 from portal circulation may be considered. Lithium may be given at doses of 300 mg every 6 hours.³³ Large amounts of potassium iodine may also be administered orally as 3 to 5 drops every 6 hours, which temporarily down regulates thyroid hormone synthesis and release, known as the Wolf–Chaikof phenomenon.³³ In the case of a patient with a nodular goiter, the administration of iodine should be omitted. This may lead to the undesired Jod–Basedow phenomenon, a condition in which exogenous iodine induces a surge in thyroxine production by an enlarged, nodular thyroid, that is, typically iodine avid.

Surgical resection of the thyroid gland may also be considered in several conditions such as if the patient remains hemodynamically unstable despite medical treatment, if any of the mentioned medical therapies are contraindicated, during pregnancy or other medical conditions that warrant rapid reversal of thyrotoxicosis. In such patients, plasmapheresis has also been suggested as a means of rapidly lowering circulating T4 and T3.³³ In severely thyrotoxic patients, medication half-lives can be affected; higher doses of medications, such as corticosteroids, antihypertensives, or antiseizure medications, may be required.

With supportive care, mortality rates between 10% and 75% have been reported after thyrotoxic crisis. Patients that survive often show marked improvement within 24 hours of hospitalization.³³ After stabilization, treatment of the underlying cause of thyrotoxicosis should be initiated. The most common cause is Graves' disease, in which autoantibodies activate the TSH receptor on thyrocytes.

Amiodarone toxicity may also induce thyrotoxic crisis through 1 of 2 mechanisms. In type 1 amiodarone-induced thyrotoxicosis, the high iodine content of the amiodarone preparation causes a Jod–Basedow phenomenon in patients with a nodular goiter. In type 2 amiodarone-induced thyrotoxicosis, the direct toxicity of amiodarone to thyrocytes induces subacute thyroiditis. Differentiating these 2 responses in the setting of severe thyrotoxicosis can be difficult because diagnostic testing with radioiodine thyroid uptake and scan can take several days to complete and the initiation of treatment

may be more urgent. Often both types of amiodarone-induced thyrotoxicosis are addressed with an empiric medical-treatment strategy that includes either methimazole or PTU, and a 2 to 3 months course of corticosteroids.

Other causes of thyrotoxicosis, which include subacute thyroiditis, a hot thyroid nodule, toxic multinodular goiter, and surreptitious use of T4 are less likely to induce thyrotoxic crisis. A thyroid uptake and scan can help to differentiate these conditions if the diagnosis is not clear.

MYXEDEMA COMA

In patients with less than the required thyroxine production, hypothyroidism ensues. Rarely, if left untreated for a prolonged timeframe, severe hypothyroidism may develop, leading to myxedema coma. These patients generally are unresponsive or have severely altered mental status, with cool, clammy skin, decreased body temperature, nonpitting edema, depressed respiratory drive and hypercapnia, bradycardia, and hypotension. A prolonged Q-T interval may increase risk of Torsades de pointes ventricular tachycardia.

The TSH is elevated, with low T3 and T4 levels. Supportive treatment should include the administration of intravenous fluids. Stress dose corticosteroids should also be given to anticipate a temporary adrenal insufficiency that develops as normal thyroid function is restored. After corticosteroids have been started, T4 may be administered. Initial doses should be given intravenously. Some authors favor giving a loading dose of 300 to 600 mcg T4, followed by a maintenance dose of 100 mcg daily.³⁵ Comparison studies show no difference in outcome, if lower doses are initiated.³⁶ The administration of T3 has also been suggested on the theoretical basis that conversion of T4 to T3 is impaired in severe illness. T3 may be given at a dose of 10 mcg every 8 to 12 hours, until consciousness is restored.³³ Once able to take medications orally, T4 may be given as an oral preparation during periods of fasting, separated by other medications that may impair absorption by at least 3 to 4 hours. Oral iron supplements, calcium supplements, and soy products can severely impair the absorption of T4.

Despite intensive supportive measures, mortality for myxedema coma remains at 20% to 25%.³³

DIABETES INSIPIDUS

The loss of ADH function either through impaired central production or by a lack of renal response to ADH signaling results in DI. Without ADH function, the distal collection tubules of the nephron are unable to adequately concentrate the urine that is produced. The dilute urine output often exceeds 300 mL/h and has an osmolality below 200 mOsm (Table 44–3). Consequently, patients lose a substantial amount of free water and experience an increased thirst sensation. Many patients with DI are able to compensate for renal losses by consuming adequate fluids, leading to the classic symptoms of polydipsia and polyuria. However, if a patient either does not have access to water or if their thirst mechanism is impaired, such as during CI, hypernatremia and dehydration may develop.

Common causes of DI include pituitary or other brain surgery, brain tumors, Sheehan’s syndrome, neurosarcoïd, histiocytosis X, and head trauma. DI can also result if the cells of the renal collecting ducts do not respond to circulating ADH, a condition known as nephrogenic DI.

DI is treated with desmopressin (DDAVP), a synthetic analogue of ADH which preferentially targets the renal vasopressin receptors. DDAVP may be given as oral, inhaled, and intravenous forms. During administration, plasma sodium levels and urine output should be closely monitored. The dose of DDAVP should be slowly titrated to avoid hyponatremia and to maintain a normal urine output.

TABLE 44–3 Clinical features of SIADH versus DI.

SIADH	DI
Hyponatremia	Normal or hypernatremia
Concentrated urine (> 600 mOsm)	Dilute urine (< 200 mOsm)
Urine sodium 40-70 mEq/L	Low urine sodium < 30 mEq/L

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE

A disproportionate release of ADH by the posterior pituitary can lead to SIADH, causing an inappropriate retention of free water and hyponatremia as the most common presenting finding. Patients with SIADH also exhibit highly concentrated urine and mildly elevated urine sodium levels ranging from 40 to 70 mmol/L (see Table 44–3). Common etiologies of SIADH include: pain, nausea, head trauma, meningitis, encephalitis, brain tumors, intracranial hemorrhage, pituitary, or other brain surgery as well as certain medications (selective serotonin uptake inhibitors, carbamazepine among others). ADH may also be synthesized ectopically in lung tumors, lymphomas, gastrointestinal tumors, and in association with pulmonary infections.

The mainstay of treatment for SIADH includes restriction of free water intake by the patient while the underlying cause is addressed. Daily weights and total volume taken in and put out should be recorded. ADH receptor blockers such as tolvaptan can also be given when fluid restriction fails to raise the plasma sodium adequately. The use of demeclocycline has fallen out of favor with the availability of ADH receptor blockers. In severe cases and in closely monitored settings, hypertonic saline can be administered.

In some patients at risk for SIADH with conditions affecting the central nervous system, cerebral salt wasting may develop. In this condition, high amounts of brain natriuretic peptide and possibly other factors are released from the CNS lead to excessive renal sodium losses and hyponatremia. Cerebral salt wasting may rarely be seen following head trauma, meningitis, encephalitis, and intracranial hemorrhage.³⁷ To differentiate from SIADH, urine sodium levels are inappropriately elevated. Treatment is with replacement of salt given either orally as sodium chloride tablets or intravenously as hypertonic saline.

CONCLUSION

In addition to the immune-neuroendocrine response, which is generally observed in all forms of CI, the specific disorders of pituitary insufficiency, adrenal

insufficiency, DKA, HHS, thyrotoxic crisis, myxedema coma, DI, and syndrome of inappropriate ADH response represent severe conditions of the endocrine system that can lead to CI. Patients with any of these conditions must be monitored closely, treated appropriately, with continued adjustment to the treatment regimen. Understanding the pathophysiology of each of these disorders allows for the anticipation of treatment strategies and improved and patient outcomes.

Oncologic Emergencies

Cristina Gutierrez, MD and
Stephen M. Pastores, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 Oncologic emergencies that may necessitate ICU admission include superior vena cava syndrome (SVCS), cardiac tamponade, malignant spinal cord compression, hypercalcemia, tumor lysis syndrome (TLS), and leukostasis.
- 2 SVCS is primarily caused by lung cancer and lymphoma. Sudden death is observed only when there is airway compromise or cerebral edema. Management is directed toward restoring the patency of flow in the SVC and stabilizing the airway.
- 3 Pericardial effusions from malignancies accumulate slowly and may result in large effusions. Lung, breast, melanoma, and lymphoma are the most common malignancies associated with pericardial tamponade. Emergent drainage or pericardial window is the treatment of choice for pericardial tamponade.
- 4 Early recognition of malignant spinal cord compression with physical exam, magnetic resonance imaging, and angiography is vital to restoring neurologic function.
- 5 Malignancy-associated hypercalcemia occurs in 20% to 30% of patients and is more common in solid tumors such as breast and lung cancer. Volume repletion with isotonic saline is the initial treatment of choice. Bisphosphonates, calcitonin, and corticosteroids are also useful treatments.
- 6 TLS is characterized by electrolyte and metabolic derangements from the breakdown of malignant cells. TLS can occur spontaneously or after chemotherapy, radiation, and treatment with corticosteroids. Aggressive hydration and correction of electrolyte abnormalities (hyperkalemia, hyperphosphatemia, hypocalcemia, and hyperuricemia) are keys to management.
- 7 Hyperleukostasis ($\text{WBC} > 50,000\text{--}100,000/\text{mm}^3$) is common in patients with acute myelogenous leukemia. Respiratory symptoms include dyspnea, hemoptysis, respiratory distress, and hypoxemia as well as neurologic including dizziness, headache, blurry vision, confusion, and stroke or intracranial hemorrhage. Treatment consists of leukapheresis, hydroxyurea, and chemotherapy.

INTRODUCTION

As the treatments for malignancies continue to improve, so does the long-term survival and prognosis of the oncologic patient. Consequently, an increasing number of patients with cancer face complications that can lead to severe illness and require admission to the intensive care unit (ICU). As in the general population, the majority of ICU admissions for patients with malignancy are due to sepsis and respiratory failure. Intensivists should be familiar with the specific issues relevant to the critically ill oncologic patient so that adequate treatment can be offered ([Table 45–1](#)). This chapter will focus on the classic clinical syndromes that represent oncologic emergencies: superior vena cava syndrome (SVCS), cardiac tamponade, spinal cord compression, tumor lysis syndrome, hypercalcemia, and leukostasis.

SUPERIOR VENA CAVA SYNDROME

Superior vena cava syndrome (SVCS) is a group of signs and symptoms that occur when there is obstruction of the SVC. Currently more than 85% to 90% of SVCS cases are associated with malignancy.¹ Ninety percent of malignant causes are due to lung cancer (nonsmall cell lung carcinoma—50%, small cell lung carcinoma—25%) and lymphoma (non-Hodgkin's lymphoma—10%).^{2,3} Once SVCS is present in the oncologic patient, life expectancy is not greater than 9 months, although these numbers can vary widely according to the type of malignancy.³

Findings on physical exam include facial plethora, neck and superficial chest vein distention, upper extremity edema, dyspnea, orthopnea, and presyncope. In the past, SVCS was considered a medical emergency; however, current data suggests that immediate death is only observed when there is airway compromise (laryngeal or vocal cord edema) or cerebral edema.^{2,4}

The diagnosis of SVCS is made clinically with support of imaging studies such as computed tomographic (CT) scan with contrast, magnetic resonance imaging (MRI), or venography. Imaging is used to evaluate the extent of obstruction, possible associated thrombosis, and vascular anatomy in case of any planned interventions.^{1,3}

Management of SVCS should be directed toward restoring the patency of flow in the SVC; all other treatments are considered supportive. Management of airway compromise requires oxygenation and rapid stabilization of the airway. Use of corticosteroids has been described but there are no randomized controlled trials suggesting that their use is beneficial.⁵ Moreover, the use of corticosteroids prior to any biopsy can alter the yield of pathologic diagnosis, especially if lymphoma is suspected.^{1,3} In patients with brain edema, quick restoration of vascular flow should be attempted because morbidity and mortality in these cases is extremely high. Diuretics to decrease edema should not be regularly used; intravascular depletion can adversely affect hemodynamics in these patients; and there is no data to support the effectiveness of diuretics.^{2,4}

In recent years, the use of intravascular stents for SVCS treatment has increased significantly. Stenting improves symptoms in the first 24 to 72 hours, making it the treatment of choice for patients with severe SVCS.^{5,6} Multiple studies have shown stenting to be efficient, safe, and cost-effective.^{5,6} Complications such as stent migration, stenosis, pericardial tamponade, and pulmonary embolism (PE) have been reported in less than 8% of cases.⁶ Prolonged use of anticoagulants for this population is controversial. Evidence of PE and risk for stent occlusion have made routine anticoagulation an appealing choice.⁷ However, bleeding complications are high and current data do not suggest improved outcomes when using routine anticoagulation.³

After stent placement, final treatment for SVCS should be guided toward management of the malignancy. Initiating treatment prior to diagnosis can obscure biopsy results in up to 48% of cases.³ Therefore, tissue biopsy, pathologic evaluation, and staging should be performed to define adequate treatment. Response to radiation and chemotherapy occurs only after 2 to 3 weeks of initiating treatment and symptoms improve in only 50% to 70% of cases.^{1,3} All treatments should be reviewed and their intent, either palliative or curative, should be clear to the clinicians.

CARDIAC TAMPONADE

Accumulation of fluid in the pericardial sac leads to elevated intrapericardial pressures, impaired ventricular filling, decreased preload, low cardiac

TABLE 45–1 **Oncologic emergencies.**

Oncologic-Related Causes		
Hemoptysis	Tumor related (primary vs metastatic, including germ cell tumors) DAH ^a (leukemias, multiple myeloma, HSCT, ^b pretransplant conditioning regimen, and other chemotherapies) Iatrogenic (biopsy) Infectious (aspergilloma, tuberculosis)	<ul style="list-style-type: none">• 30% of all causes of hemoptysis are related to malignancy• Reversal of causes of bleeding diathesis• Response to recombinant factor VIIa administration in cases of DAH has been reported
Status Epilepticus	Metastasis/primary malignancy Leptomeningeal disease Paraneoplastic syndromes PRES ^c Chemotherapy (cisplatin, cyclophosphamide, bevacizumab, busulfan, intrathecal methotrexate) Brain radiation HSCT Electrolyte disorders (hyponatremia and hypercalcemia)	<ul style="list-style-type: none">• Importance of recognizing underlying cause• Management of status should follow guidelines
Intracranial hemorrhage	Tumor related Leptomeningeal disease HSCT APML ^d undergoing chemotherapy Radiation Coagulopathy Leukostasis	<ul style="list-style-type: none">• Reversal of underlying coagulopathy• Role of prophylactic brain radiation in leukostasis is unclear• Higher incidence, and worse outcomes, in hematologic malignancies• No data supporting use of factor VII
Elevated ICP	Metastasis or primary malignancy Leukemic meningitis Superior vena cava syndrome	<ul style="list-style-type: none">• Steroids should be initiated in cases of tumor/metastasis• Radiation and surgery as intervention• Avoid lumbar puncture in the case of mass effect• Cautious use of mannitol

output, and shock, a clinical syndrome known as cardiac tamponade. Pericardial effusions secondary to malignancy usually accumulate slowly giving time for compensatory mechanisms against the elevated intrapericardial pressures. Thus, in the case of malignancy, cardiac tamponade usually occurs in the setting of large pericardial effusions. The most common malignancies associated with pericardial effusions are lung, breast, melanoma, and lymphoma.⁸ Primary malignancies of the pericardium, such as mesothelioma, are rare.⁸ In addition, treatment for malignancy—including radiation and some chemotherapy agents (eg, cytarabine, daunorubicin)—can cause pericarditis and secondary pericardial effusions.⁸ Prognosis of patients with malignant pericardial effusions is poor; at 6 months the survival rate is 45% and at 1 year the survival rate is 10% to 26%.⁹ Poor prognostic factors include the presence of primary adenocarcinoma of the lung, positive fluid cytology, and advanced malignancy.^{9,10}

The most common symptoms associated with cardiac tamponade are dyspnea, chest discomfort, and chest pain. Beck's triad—pulsus paradoxus, distant heart sounds, and jugular venous distention—is pathognomonic; however, it is present only in a minority of patients.¹¹ Electrocardiography (EKG) has always been used in the diagnosis of cardiac tamponade. Most specific (86%-99%) EKG signs of cardiac tamponade are low voltage, PR depression, and electric alternans; their sensitivity, however, can be as low as 8% to 42%.¹² Echocardiogram is the gold standard for the diagnosis of cardiac tamponade and should be performed emergently. Signs of tamponade include right ventricular collapse during diastole, exaggerated contraction of the right atrium during atrial systole, swinging motion of the heart, and mitral and tricuspid valve inflow variation with respiration.^{8,13}

Emergent drainage by either pericardiocentesis (guided by echocardiogram, fluoroscopy, or CT) or pericardial window is the treatment of choice. Pericardial window is recommended for patients who have a higher risk of recurrence such as those with adenocarcinoma of the lung.^{14,15} There is, however, no difference in overall survival or safety when performing any of these 2 procedures.¹⁵ Pericardial radiation and instillation of chemotherapy agents for recurrent effusions have been used safely;

however, no survival benefit has been demonstrated with these techniques.^{8,14}

After drainage of the effusion, symptoms and hemodynamic instability should improve dramatically. In a small percentage of patients, however, there can be persistent shock due to what is described as a “low cardiac output syndrome.”¹⁰ Management should be supportive as resolution is usually gradual; however, it has been associated with a poor prognosis in some studies.¹⁰

MALIGNANT SPINAL CORD COMPRESSION

Spinal lesions occur in 50% of patients with osseous metastasis.¹⁶ Of these, almost 10% of patients develop malignant spinal cord compression (MSCC).^{16,17} Hematologic spread is the most common mechanism of spinal cord involvement. Metastatic solid tumors of the lung, breast, and prostate cancer are the most common malignancies associated with MSCC.¹⁸ Non-Hodgkin's lymphoma, multiple myeloma, renal cancer, sarcomas, and unknown primary tumors are less common causes.^{18,19}

Early recognition of MSCC is vital because restoration of neurologic function and prognosis is directly related to the degree of initial neurologic damage.^{17,19} Pain is the first symptom in 83% to 90% of cases and studies suggest that 60% of cancer patients complaining of back pain have compression of the epidural space.^{18,20,21} Thus, in the setting of metastatic disease and back pain, there should be a high suspicion for MSCC. Motor deficits, ranging from weakness to paralysis, are present in 35% to 68% of cases.^{17,20} Sensory deficits are usually not recognized by the patients but are present on physical exam in 70% of cases.²⁰ Autonomic dysfunction and loss of sphincter tone is a poor prognostic factor for recovery as this presents late in the progression of the disease.^{17,18,20}

The gold standard and most cost-effective method for diagnosis of MSCC is MRI.¹⁸ Metastatic lesions to the spine are usually widespread, therefore, a whole spine MRI should be performed in all patients with suspected MSCC.¹⁸ Angiography is useful for hypervascular tumors (sarcoma, melanoma, thyroid, and renal cancer) in which presurgical embolization can be considered.^{19,21}

Prognosis after MSCC is poor and survival after diagnosis of MSCC is usually 3 to 6 months.^{16,17} The goal of treatment is to decrease pain and preserve neurologic function; therefore, a high suspicion and early recognition is important to improve outcomes.^{18,19} Scoring systems that include functional status, type of tumor, number of bone and visceral metastases, degree of neurologic dysfunction, and response to radiotherapy are intended to evaluate prognosis and guide therapy.^{17,18} Due to the wide variety of available scores, it is important that treatment is guided by a multidisciplinary team that can assess risks and benefits in an individual manner.

First-line treatment of MSCC are corticosteroids as they have been shown to reduce pain and improve neurologic function.²² Corticosteroids should be administered promptly to decrease spinal cord edema and in some cases, such as lymphoma, to reduce tumor burden.¹⁸ Administration should be prior to radiotherapy, for a total of 10 days, and low doses seem to be as efficacious as megadoses.²²

Radiation therapy is also widely used for the treatment of MSCC. It is recommended for patients who are unable to tolerate surgical procedures, have a short life expectancy, have diffuse spinal disease, symptoms present for longer than 48 hours, or those with a known tumor sensitivity to radiotherapy.^{17,20} This mode of treatment is known to reduce pain, tumor size, and preserve neurologic function.¹⁷

Surgical decompression is indicated in patients with progression of tumor and symptoms while undergoing radiation, significant cord compression, medically intractable pain, radioresistant tumors, and evidence of spinal instability.²⁰ Published meta-analysis and randomized controlled trials (RCTs) have shown that surgical intervention in combination with radiotherapy improves neurologic function, pain control, and survival when compared to radiation alone.^{16,18,21} Despite these encouraging results, it is important to take into account the patient's overall status and prognosis before undergoing any surgical procedure.^{17,18}

Spinal stereotactic radiosurgery, percutaneous vertebroplasty, and kyphoplasty are being considered as more localized and less invasive methods of treatment of MSCC. Although some studies have shown promising results, they are still not widely used and are still considered experimental.^{18,19,21}

Overall, MSCC should be readily recognized in the oncologic population. Management and diagnosis should be immediate, multidisciplinary, and tailored to every patient's diagnosis and overall prognosis.

HYPERCALCEMIA

Malignancy-associated hypercalcemia (MAH) occurs in approximately 20% to 30% of patients and is more common in solid tumors such as breast and lung cancer.²³⁻²⁵ Patients with hematologic malignancies such as Hodgkins disease, non-Hodgkins lymphoma, adult T-cell leukemia/lymphoma, and multiple myeloma can also rarely present with MAH.^{23,24,26} MAH can be divided into humoral, osteolytic, and calcitriol-associated hypercalcemia. Humoral hypercalcemia is the most common presentation of MAH. The main mediator is parathyroid hormone-related protein (PTHrP) which is mostly released by solid tumors but has also been described in cases of non-Hodgkins lymphoma and multiple myeloma.^{23,24,26} Osteolytic MAH, observed in 20% of cases, is associated with increased osteoclastic activity secondary to bone metastasis.^{24,26} Less than 1% of MAH is mediated by calcitriol production in hematologic malignancies such as lymphomas.^{24,27} While these distinctions exist, many cases of MAH are multifactorial. MAH is a marker of poor prognosis and median survival time after its presentation is less than 35 days.^{25,28}

Symptoms of hypercalcemia include muscular cramping, constipation, dehydration, polyuria, changes in mental status, and cardiac dysrhythmias. The severity of symptoms is usually associated with the degree of hypercalcemia, and central nervous system symptoms are usually present with calcium levels above 14 mg/dL.²⁴ Initial workup for hypercalcemia should include measurements of ionized calcium, PTH, PTHrP, and 25-hydroxy vitamin D levels.²⁵

Volume repletion should be the initial goal of hypercalcemia as hydration decreases tubular reabsorption of calcium by the renal tubules.²³ Loop diuretics to promote calciuresis are no longer recommended because they do not consistently decrease calcium levels and are associated with further volume depletion and electrolyte disorders.²⁹

Glucocorticoids, which inhibit calcitriol production, are effective in the treatment of lymphoma-related hypercalcemia.^{25,27}

Bisphosphonates, which block bone resorption by osteoclasts, are recommended for long-term treatment of hypercalcemia.²⁵ While one study showed zoledronic acid to be more efficient than pamidronate in immediate reduction of calcium levels, the difference seemed to dissipate after 1 week.^{24,30} Due to these findings any of the 2 medications can be used according to availability. However, if hypercalcemia is causing severe neurologic and cardiac symptoms, zoledronic acid should be considered as it is more effective in the short term. Renal failure can rarely occur when using bisphosphonates; administration should be avoided, or after discussion or risk benefits, if the glomerular filtration rate is less than 30 mg/dL.^{23,25,30}

Because bisphosphonates are effective only after 48 hours and hydration can only aid with calciuresis to a certain degree, other immediate measures such as calcitonin administration should be taken. Calcitonin decreases calcium levels by inhibiting osteoclasts and inducing calciuresis 2 hours after administration.^{23,30} Administration should be limited to 2 doses due to resistance and downregulation of its receptors.²⁸ Cinacalcet, a calcimimetic, rapidly decreases calcium levels in the setting of benign hyperparathyroidism; its role in MAH, however, is limited only to occasional case reports.²⁵ Denosumab, a monoclonal antibody that inhibits osteoclast activity, is used in patients with refractory MAH as long-term treatment; its use in the acute setting is also limited and it is not recommended on a regular basis.²⁵

As previously mentioned, although hypercalcemia can be reversible and treated with current medications, it is usually associated with poor long-term prognosis. Palliation and goals of care should be discussed with these patients even if their outcome after ICU admission is excellent.

TUMOR LYSIS SYNDROME

Tumor lysis syndrome (TLS) is characterized by electrolyte and metabolic derangements which occur after rapid breakdown of proliferating malignant cells. TLS can be spontaneous in rapidly growing

tumors or present after treatment with chemotherapy, corticosteroids, or radiation.^{31,32} TLS has an incidence of 5% to 10% and is typically associated with acute leukemias particularly acute lymphoblastic leukemia (ALL) and highly aggressive lymphomas, such as Burkitt's lymphoma.^{31,32} TLS can also rarely occur with solid malignancies and usually occurs weeks after chemotherapy treatment is initiated.³²

Electrolyte abnormalities associated with TLS include hyperkalemia, hyperphosphatemia, hypocalcemia (due to binding of phosphorus to calcium), and hyperuricemia. Clinical findings include vomiting, diarrhea, cramping, lethargy, seizures, cardiac arrhythmias, and shock. Acute kidney injury (AKI) in TLS is caused by deposition of uric acid and calcium phosphate crystals in the kidney tubules.³¹ Early recognition and prevention are extremely important as all of these symptoms and complications progress rapidly and can lead to death.

Recognition of high-risk patients and early detection should be the foundation of TLS management. Common risk factors for TLS include: pre-existing hyperuricemia, large tumor burden, rapidly growing malignancies, fluid depletion, and renal dysfunction.³²⁻³⁴ Patients can be characterized into low, intermediate, and high risk for TLS according to their malignancy, laboratory findings, and presence of pre-existing kidney disease.^{31,33} This stratification improves early recognition and serves as a guide for treatment. Moreover, laboratory criteria developed by Cairo and Bishop have helped with the diagnosis and classification according to severity of TLS.^{34,35} In their definition, elevations above 25% from baseline of uric acid, potassium, phosphorus, and calcium were included. When 2 or more laboratory abnormalities, 2 days before or 7 days after cytotoxic treatment are present, this is indication of TLS.³⁵ In addition to these laboratory abnormalities, the presence of AKI, seizures, or arrhythmias classifies the disorder as clinical TLS which carries a higher mortality and should be treated aggressively.^{31,34}

Supportive care of patients at risk for TLS should be initiated with aggressive hydration to maintain a urine output of 100 mL/h. Close monitoring of electrolytes, lactate dehydrogenase, and uric acid levels are necessary on days prior and after cytoreduction. Alkalinization of urinary pH has been shown to increase phosphate and xanthine (a uric

acid metabolite) precipitation in the renal tubules, therefore, administration of sodium bicarbonate is no longer recommended.^{31,34} Diuretics in the setting of oliguria can be administered, however, there is no evidence of improved outcome after its use.³² Indications for hemodialysis in TLS include signs of uremia, volume overload, persistent hyperkalemia, and acidosis. It is also recommended that patients with severe hyperphosphatemia and symptomatic hypocalcemia be initiated on hemodialysis.^{31,34} Prophylactic or early hemodialysis, however, has not been studied for TLS.³⁴

Two agents are used in the management of TLS: allopurinol (a xanthine oxidase inhibitor that blocks uric acid production) and rasburicase (a recombinant urate oxidase that degrades formed uric acid into allantoin which is easily excreted in urine).³⁶ Allopurinol should be started 2 days prior to initiation of cytotoxic treatment in patients at risk for TLS and can be administered both orally and intravenously with the same effectiveness.^{31,32} Studies have shown that rasburicase can reduce uric acid levels as fast as 4 hours after the initial dose and treatment required averages 3 days.³⁶ However, due to its costs and availability, the decision to administer rasburicase should probably be limited to high-risk or severe cases and after further discussion with the oncologist. Secondary effects reported with rasburicase include hypersensitivity, methemoglobinemia, and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency.^{32,36}

Current guidelines on management of TLS are based on the risks and severity of the syndrome.^{31,33,34} Although there are no studies comparing outcomes of these different guidelines, they all facilitate early recognition of high-risk patients and initiation of early aggressive treatment.

LEUKOSTASIS

Hyperleukocytosis (WBC > 50,000-100,000/mm³), common in chronic leukemias, is considered a medical emergency and a sign of poor prognosis when found in acute leukemias.^{37,38} Leukostasis occurs when blasts aggregate in the microvasculature leading to endovascular damage, hypoperfusion, cytokine release, and secondary organ dysfunction.^{39,40} Incidence of leukostasis is 10% to 30% and is more

common in patients with acute myelogenous leukemia (AML) than ALL.³⁹ Mortality can be as high as 60% and independent risk factors such as age, creatinine, total bilirubin, and lactic dehydrogenase (LDH) levels have been associated with early death.^{37,41}

The diagnosis of leukostasis is challenging as its clinical presentation and radiologic findings cannot be differentiated from common infectious and hemorrhagic complications which affect patients with leukemia. Moreover, some cases have been diagnosed with WBC less than 100,000/mm³, making this diagnosis even more challenging.⁴¹ Most common symptoms associated to leukostasis are respiratory (hypoxemia, dyspnea, and hemoptysis) and neurologic (dizziness, headache, blurry vision, confusion, and stroke or intracranial hemorrhage). Other clinical findings may include extremity, bowel and cardiac ischemia, renal vein thrombosis, heart failure, and priapism.^{40,41} It is important to recognize that in the presence of both respiratory failure and neurologic symptoms, mortality can be as high as 90%.⁴⁰

For the past 2 decades there has been very little progress in the treatment of leukostasis. Current available treatment consists of cytoreduction with leukapheresis, hydroxyurea, and chemotherapy. Leukapheresis is initiated in cases of AML if WBC is more than 50,000/mm³, and in ALL if WBC is more than 250,000/mm³.^{39,41} Although leukapheresis is still used in many institutions, its timing, number of treatments, and target WBC are not well defined. Reasons for this include the fact that the effectiveness of leukapheresis is not associated with WBC reduction, and its use continues to be based mainly on case reports and retrospective studies.^{39,41} Hydroxyurea has comparable efficiency and outcomes to leukapheresis and should be used in all patients with leukostasis.³⁹

Early chemotherapy is the only treatment that has shown to improve mortality in the short term.⁴² Cranial irradiation was used in the past for neurologic symptoms and as prophylaxis to reduce intracranial hemorrhage; however, this is no longer recommended due to lack of effectiveness.⁴² Dexamethasone, which decreases cytokine production and suppresses adhesion markers, has been shown to be effective in acute promyelocytic leukemia; nevertheless, additional studies to look at its role in other hematologic malignancies is necessary.⁴⁰

Rheumatologic and Inflammatory Conditions in the ICU

Deborah Orsi, MD; Wilma Correa-Lopez, MD and John Cavagnaro, PA

KEY POINTS

- 1 ICU mortality can be as high as 55% and can reach 79% in the systemic lupus erythematosus (SLE) population.
- 2 Severe sepsis and septic shock represent in fact the primary reason for ICU admission in about half of the rheumatologic patients.
- 3 The clinical manifestations of autoimmune diseases itself can be very heterogeneous and virtually all organ systems can be affected.
- 4 Most common adult rheumatologic disease encountered by the intensivist are in order of frequency, according to the most recent literature, SLE, rheumatoid arthritis (RA), systemic vasculitis, and systemic sclerosis (SS).
- 5 Conditions associated with airway involvement include RA, granulomatosis with polyangiitis (GPA, former Wegener granulomatosis), relapsing polychondritis and SLE.
- 6 Among all the rheumatologic diseases SS seems to have the highest prevalence (80%) of pulmonary involvement.
- 7 Rheumatologic patients are at high risk of acute coronary syndromes due to premature atherosclerosis compared to age-match population.
- 8 Renal involvement occurs in roughly 30% of the overall rheumatologic patients.
- 9 Chronic steroids therapy used in the treatment of numerous rheumatologic conditions increase the risk of adrenal insufficiency in acutely critically ill patients.
- 10 No clear prognosticator of in-ICU mortality has been identified as applicable to single patient yet, but intuitively high Apache score, multiorgan failure, comorbidities, advanced age and pancytopenia were all associated with worse outcome.

INTRODUCTION

According to the most recent literature, about a third of rheumatologic patients admitted to the hospital will require admission in an intensive care unit (ICU). Their in-ICU mortality can be as high as 55% and can reach

79% in the systemic lupus erythematosus (SLE) population. Such a severe life threatening decompensation may be caused by multiorgan system failure related to disease flare or by the complications of immunosuppressive state or therapy, such as infection.¹⁻¹⁴

Severe sepsis and septic shock represent in fact the primary reason for ICU admission in about half of the rheumatologic patients. It is the first cause of mortality in SLE patients, therefore, it is crucial to recognize and aggressively treat any infectious process before attempting to achieve diseases control with immunosuppressive therapy.

An increasing number of patients will be recognized ex novo to have a rheumatologic condition during their ICU stay. Such diagnosis can be quite challenging for the intensivist and usually require a multidisciplinary approach.

Few diagnostic tests, that is, autoantibodies, are confirmatory and when negative do not rule out the disease if clinical criteria are met. On the other end of the spectrum, positive autoantibodies can be found in healthy individuals and in extrarheumatologic conditions (Table 46–1). The clinical manifestations of autoimmune diseases itself can be very heterogeneous and virtually all organ systems can be affected.

The most common adult rheumatologic disease encountered by the intensivist are in order of frequency, according to the most recent literature, SLE, rheumatoid arthritis (RA), systemic vasculitis, and systemic sclerosis (SS).

Acute respiratory failure appears to be the most common indication for ICU admission. It remains difficult to estimate from various studies whether related to disease flare involving the respiratory system or to primary pulmonary infectious process or both.

OVERVIEW OF CLINICAL
MANIFESTATIONS OF
RHEUMATOLOGIC DISEASES
BY ORGAN SYSTEMS

Severe Sepsis

Acute respiratory failure due to pneumonia appears to be the most common reason for ICU admission. Chronic inflammatory process and immunosuppressant therapy make rheumatologic patients extremely susceptible to severe infections. Fever and leukocytosis may not be present.

The most common microorganisms involved are the typical bacterial pathogens, therefore treatment for community or hospital acquired

TABLE 46–1 Autoantibodies and associated disorders.

Autoantibody	Associated Disease
RF	RA (80%), LES (10%), MCTD (50%-60%), Sjogren SD (80%-90%)
	Infections, chronic liver disease, pulmonary disease
	Cryoglobulinemia
Anti-CCP	RA
ANA types:	Also seen in subacute endocarditis, tuberculosis, hematologic Malignancy, chronic infectious disease, other nonconnective tissue Disease (Crohn, autoimmune hepatitis, cholangitis)
Anti-dsDNA	SLE
Anti-Sm	SLE
Anti SS-A	Sjogren SD (70%), SLE (30%), RA, scleroderma, and MCTD (rare)
Anti SS-B	SJOEGREN SD (60%), SLE (15%), RA, scleroderma, MCTD
Anti RNP	MCTD (95%), SLE (30%)
Anti-Scl-70	Diffuse scleroderma (20%-40%) discord
Anticentromere	Limited scleroderma (60%-90%), diffuse scleroderma (30%)
Anti-histone	Drug-induced SLE
Anti-RNA polymerase	Systemic sclerosis
Anti Jo-1	Polymyositis

RF, rheumatoid factor; anti-CCP, anticyclic citrulline peptide; MCTD, mixed connective tissue disease.

pneumonia should not be delayed. Cases of nonresolving pneumonia must raise suspicion for atypical bacterial infections, reactivation of tuberculosis, disseminated fungal disease (histoplasmosis, cryptococcosis, and aspergillus spp.), listeriosis, and Pneumocystis pneumonia.

Effort should be made to collect all the appropriate body fluids and specimens before initiation of antibiotics treatment. Bronchoalveolar lavage (BAL)

should be considered early on in the course of the disease.

Pneumocystis pneumonia prophylaxis should be considered for patient on immunosuppressant agents.

Airway Involvement

Inflammation within the airway, obstruction from inflammation, ankylosis of the cricoarytenoid joints or cervical spine can represent challenging airways for the intensivist.

Conditions associated with airway involvement include RA, granulomatosis with polyangiitis (GPA, former Wegener granulomatosis), relapsing polychondritis and SLE.

Occasionally obstruction caused by angioedema may be seen in its acquired form in lupus patients. Subglottid stenosis can be present in about 10% to 20% of patients with GPA. Relapsing polychondritis of both small and large airways can cause upper or lower airway obstruction due to recurrent cartilage inflammation and destruction. Patients with advanced cutaneous scleroderma may represent difficult airway if mouth opening is narrowed.

Upper airway problems may arise especially in patients with RA and ankylosing spondylitis if airway needs to be secured.

Atlantoaxial subluxation (C1-C2) may be present in RA male patients particularly in those with severe peripheral joint deformities, long disease duration and neck pain. Patients undergoing elective surgery should have cervical radiologic evaluation since subluxation can be asymptomatic and neck manipulation during intubation may be proven to be fatal. In emergent situations, fiberoptic intubation will be the preferred option.

Pulmonary Disease

Respiratory insufficiency is the leading causes of ICU admission. Its manifestation may be expression of autoimmune flare or infection. Interstitial lung disease (ILD), pleuritis, pleural effusion, pulmonary hemorrhage, and embolism can all be encountered in critically ill rheumatologic patients.

RA patients tend to have an increased rate of ILD, cryptogenic organizing pneumonia, obliterative bronchiolitis, and pleural involvement.

Pulmonary hemorrhage seems more prevalent in systemic vasculitis and when associated with SLE.

Among all the rheumatologic diseases SS seems to have the highest prevalence (80%) of pulmonary involvement. ILD (being the nonspecific interstitial pneumonia the most common) and pulmonary arterial hypertension are the most common features and both can coexist. These patients should be screened before symptoms appear since early intervention can slow the disease progression. Doppler echocardiography and right heart catheterization are necessary to estimate pulmonary arterial hypertension. Further lung injury from recurrent aspiration is frequently experienced in scleroderma patients due to an incompetent gastroesophageal sphincter.

Sjogren syndrome (SJ) and polymyositis-dermatomyositis also share a high rate of pulmonary involvement as shown in [Table 46-2](#).

Pleural involvement occurs frequently in RA and SLE patients. The pleural fluid exam is an exudates with low pH, low glucose with a lymphocytic predominance. The level of rheumatoid factor in the pleural fluid parallels that in the serum. Recurrent effusions may require a more definitive treatment (pleurodesis).

Pulmonary embolism and deep vein thrombosis may be the primary manifestation of an underlying prothrombotic state caused by a rheumatologic condition. Lifelong prophylactic anticoagulation is required since new evidence from population-based studies show a 2 to 3 fold increase of thromboembolic phenomena in these patients.

Loss of anticoagulants factor due to concomitant renal impairment can also contribute to a prothrombotic state.

Drug-induced lung toxicity, that is, methotrexate is usually a diagnosis of exclusion.

The general evaluation of pulmonary involvement should include a chest X-ray (CXR), ofentimes not sensitive and a high resolution computed tomography (CT) of the chest. The latter may show pulmonary nodules, ground glass opacity as well as reticular pattern and honeycombing. BAL can help in differentiating between exacerbation of rheumatic disease, infection, drug-induced respiratory failure and alveolar hemorrhage. BAL and lung biopsy can aid the diagnosis but both have no role in prognostication.

TABLE 46–2 Frequency of pulmonary complication in rheumatologic disease.

Clinical Manifestation	RA	SLE	SS	PM-DM	SJ	MCTD
ILD	3+	2+	4+	3	3	2
DAH	1	2	1	1	0	1
COP	2	1	1	3	1	1
OB	2	0	0	0	1	0
PLEFF	3	2	1	0	1	2
ASP PN	0	0	3	3	2	2
VASCUL	2	2	0	1	2	2
PULM HTN	1	2	4	1	0	2
RESP MUSC INVOL	1	2	0	2	0	1

Keys:1+ some, 4+ maximal
DAH, diffuse alveolar hemorrhage; PLEFF, pleural effusion; ASP PN, aspiration pneumonia; VASCUL, vasculitis; PULM HTN, pulmonary hypertension; RESP MUSC INVOLV, respiratory muscle involvement.
Modified with permission from Fischman AP, Elias JA, Fishman JA: Fishman’s Manual of Pulmonary Disease and Disorders, 3rd ed. New York: McGraw Hill; 2002.

Aggressive immunosuppressive therapy is warranted to decrease pulmonary inflammation and evolution into acute lung injury as well as multior-gan involvement.

Cardiovascular Disease

Pericardial involvement may affect 12% to 48 % of patients with lupus and as high as 35% in patients with RA. Acute pericarditis may rarely evolve into cardiac tamponade but its progression into chronic-ity may cause restrictive cardiomyopathy requiring surgical intervention.

Rheumatoid nodules can involve the myocar-dium and the heart valves causing embolic phe-nomena and conduction disturbances (RA, SS, and its variant CREST). Myocarditis in lupus and polymyositis-dermatomyositis patients may lead to overt heart failure.

Libman Sacks endocarditis occurs in about 10% of SLE patients. Its fibrinoid vegetations can cause severe valvular regurgitation (mitral and aortic valve most commonly) and thromboembolic phenomena especially if antiphospholipid (APL) syndrome is associated.

Rheumatologic patients are at high risk of acute coronary syndromes due to premature

atherosclerosis compared to age-match population. Within the rheumatologic diseases, patients affected by Kawasaki and systemic vasculitis are at the high-est risk due to the chronic inflammation of coronary arteries and associated arteritis.

Gastrointestinal Disease

Gastrointestinal hemorrhage is frequently encoun-tered in patients treated with corticosteroids and nonsteroidal anti-inflammatory drugs (NSAIDs). Stress ulcers may provoke brisk bleeding if coagu-lopathy and thrombocytopenia are associated.

Henoch–Schonlein purpura, SS, necrotizing vasculitis may all cause bleeding from ulceration of small vessels of small bowel or colonic mucosa.

Intestinal ischemia may result as a complica-tion of panarteritis nodosa, RA, SLE, and vasculiti-des, in general. T e clinical manifestation depends on the size and location of the vessel involved. Occasionally profuse bleeding, ulceration with per-foration can be seen.

Renal Involvement

Renal involvement occurs in roughly 30% of the overall rheumatologic patients. Lupus nephritis

remains the most feared complication of the disease and renal involvement can be detected in as high as 90% of patients before any overt clinical manifestations.

The spectrum of the glomerular involvement varies from minimal to advanced sclerosis. Urine analysis will show proteinuria more than 0.5 g/24 hours and red blood cell cast. Complement levels including C3 and C4 are decreased. Hypertensive crisis can be also present.

Renal biopsy should not be delayed since it can provide diagnosis, staging and therefore treatment. Aggressive immunosuppressive treatment is warranted for advanced stage of glomerulonephritis (GN, staged from I to V, being the III stage usually the initial time for treatment) to prevent further progression of injury and achieve remission. Treatment includes pulse steroids combined with IV or oral cyclophosphamide with possible mycophenolate and cyclosporine in case of refractory response. Occasionally plasma exchange may be instituted for rapid progressive GN. Some patient will recover while some will progress to end stage renal disease requiring dialysis. Renal transplant can be successful if good control of the active disease is achieved.

Scleroderma renal crisis occurs in about 15% of patient with SS. It is a medical emergency presenting with abrupt onset of hypertension and acute renal failure. It can precede the diagnosis of SS. Multisystem involvement with hypertensive encephalopathy, visual disturbances and seizure, pulmonary edema, myocarditis, microangiopathic anemia and thrombocytopenia may be all present. Urine analysis shows granular cast, mild proteinuria and hematuria.

Management includes early treatment with ACE inhibitor such as captopril and lisinopril titrate to decrease blood pressure while avoiding hypoperfusion. Steroids are generally avoided as they are linked to possible risk factor for the development of renal crisis.

Active RA can cause late stage amyloid nephropathy. NSAID, gold and penicillamine can also be responsible for nephritic disease.

Central Nervous System Disease

Primary angiitis of the central nervous system (PACNS), lupus, polyarteritis nodosa (PAN), giant cell arteritis (GCA), and SJ comprise the majority

of autoimmune conditions associated with central nervous system (CNS) vasculitis. Patients with primary angiitis will lack the manifestations and the positive inflammatory markers of systemic vasculitis. Symptoms can range from severe headache, seizure, stroke, cognitive impairment, psychosis.

Lupus psychosis is a common manifestation of SLE. Antipsychotic and control of active disease are the treatment of choice. Steroid use may confound as well as precipitate the clinical picture. Lumbar puncture may show mild elevated white blood cell with predominance of lymphocytes, elevated protein and low glucose.

Cerebral venous thrombosis can be seen in patient affected by APS either primary or secondary to lupus.

Headache, diplopia, and stroke in an elderly woman with elevated ESR should raise suspicion for GCA, although a normal ESR does not exclude it. Symmetric stiffness and proximal muscle pain may be expression of the frequently associated polymyalgia rheumatica. Infections and malignancy of the CNS should be ruled out first. Lumbar puncture, brain CT, cerebral magnetic resonance imaging (MRI), and angiographic studies should be performed. Angiogram may reveal arterial stenosis, occlusion, dilatation, or vessel beading.

Hematologic Disorder

A prothrombotic state and anemia of chronic disease are usually present in patient with rheumatologic disease. Microangiopathic anemia, thrombocytopenia and leukopenia may also represent the manifestation of a disease flare that scatters autoantibodies against the hematologic series. Suppressed bone marrow function may also develop from immunosuppressive therapy.

Leukopenia is a clinical defining feature of SLE and is seen in patients with RA complicated by Felty syndrome. Thrombotic thrombocytopenic purpura (TTP) is frequently associated with pediatric SLE. APS is an autoimmune condition characterized by antibodies against phospholipids binding plasma proteins and is clinically manifested by arterial or venous thrombosis. It can occur as a primary condition or associated with other rheumatologic diseases, usually SLE. The affected organ and the clinical manifestation depend on the vessel

involved and may manifest as focal neurologic deficit, transverse myelitis, seizure, pulmonary embolism, intra-alveolar hemorrhage, valvular disease, coronary thrombosis, recurrent miscarriages. A catastrophic APS is defined as a wide spread small vessel thrombosis with multiorgan failure. Mortality rate can reach up to 50%. Treatment with anticoagulation, high dose pulse glucocorticoids and plasma exchange with or without IVIG has been associated with 50% to 80% recovery rate.

Coagulation abnormality caused by autoantibodies anticlotting factors may be manifest as disseminated intravascular thrombosis, bleeding or both. Autoantibody antifactor VIII is the most common autoimmune coagulation disorder seen in SLE and RA. Cessation of bleeding will respond to porcine factor VIII which is antigenically different.

A rare but potentially fatal cause of pancytopenia is acute hemophagocytic syndrome, a condition more commonly seen in rheumatologic pediatric patients. It is frequently a diagnosis of exclusion in adults. Pancytopenia, hypertriglyceridemia, elevated transaminase and ferritin characterize the diseases. Overwhelming inflammatory response, coagulopathy, pulmonary involvement and encephalopathy are the most common clinical manifestations. Bone marrow examination is diagnostic. Treatments include high dose steroids, IVIG and cyclosporine.

Musculoskeletal Involvement

Muscular involvement is a characteristic feature of many connective tissue diseases although do not constitute usually an indication for ICU admission except when impairment of the respiratory dynamic is present. Rheumatic inflammatory myopathies can be confused with critical illness myopathy in debilitated patient with prolonged ICU stay.

Immobilization, steroids, and neuromuscular blocking agent are usually associated with the latter. Difficult weaning from mechanical ventilation may contribute further to increase in length of stay in these patients.

Endocrine/Adrenal Insufficiency

Chronic steroids therapy used in the treatment of numerous rheumatologic conditions increase the risk of adrenal insufficiency in acutely critically

ill patients. Refractory hypotension and severe electrolytes imbalance may be present.

Stress dose steroids should be initiated (200-300 mg IV daily in divided doses) during an acute illness or high metabolic state.

Vasculitides

The presence of inflammatory leukocytes in a vessel wall and the reactive damage caused to the wall structures define vasculitis. Attack by leukocytes leads to loss of vessel integrity causing bleeding, with subsequent obstruction of the blood vessel lumen ultimately leading to tissue ischemia and necrosis. What triggers this cascade of events is unclear, but it is likely multifactorial. The size and location of the affected vessel and the presence or absence of anti-neutrophil cytoplasmic antibodies (ANCA) form the basis of the current classification system. The affected organs, and thus the clinical presentation, depend on the presence of the target antigen in the particular organ, on the ability of the endothelial cell to respond to the antigenic presence by activating and recruiting the elements involved in initiating and sustaining the inflammatory cascade.

The American College of Rheumatology (ACR) 1990 criteria was proposed with the intent of facilitating the task of distinguishing the different types of vasculitides. The criteria do not include all the features of each particular form of vasculitis, but mainly focus on those that commonly identify the particular syndrome and to allow for comparable subjects to be included in studies and discussions. The 2012 International Chapel Hill Consensus Conference (CHCC) revised the nomenclature used to categorize the vasculitides. The accompanying tables represent a combination of both the ACR criteria and the CHCC nomenclature, as a general reference point. However, the focus of this discussion is the management of the patient with vasculitis who requires admission to the ICU. Patients with vasculitides are frequently admitted to the ICU because of complications of the immunosuppressive therapy used to control the disease, such as severe infections associated with organ dysfunction, or because of life-threatening manifestations of the disease, such as the pulmonary-renal syndrome. Most patients are admitted to the ICU with a pre-existent diagnosis of vasculitis, but in some cases their ICU admission

constitutes the presentation of the disease. Unfortunately, the clinical manifestations of many of the vasculitides are nonspecific and seen in a number of conditions that present with systemic involvement, for example, multiorgan dysfunction seen in conditions such as endocarditis, severe sepsis, meningococcemia, DIC, and TTP. A high index of suspicion is therefore paramount as vasculitides, if severe and untreated, can rapidly deteriorate into life-threatening scenarios.

A potentially devastating cause for admission to the ICU for the patient with vasculitis is hemoptysis. Patients with vasculitides are frequently admitted to the ICU with manifestations of the pulmonary-renal syndrome (PRS), the combination of pulmonary hemorrhage and glomerulonephritis. Although anti-GBM disease (Goodpasture's disease) and lupus are responsible for some of the cases of PRS, the small vessel vasculitides account for most. These include the ANCA-positive vasculitides, namely eosinophilic granulomatosis with polyangiitis (EGPA, formerly known as Churg-Strauss syndrome), GPA, and microscopic polyangiitis (MPA). Less common culprits of PRS are the ANCA-negative IgA nephropathy and Henoch-Schonlein purpura. The clinical presentation and diagnostic features of each of the syndrome are summarized in the accompanying tables.

Anti-GBM disease (formerly known as Goodpasture's disease) is an uncommon cause of PRS. It is not a vasculitis, but rather a disorder mediated by antibodies directed against the $\alpha 3$ chain of type IV collagen found in the glomerular basement membrane and the alveolar capillaries. The spectrum of anti-GBM disease includes patients with glomerulonephritis but without pulmonary hemorrhage, or "renal-limited anti-GBM antibody disease," and those with both glomerulonephritis and pulmonary hemorrhage. Patients present with glomerulonephritis, hemoptysis (could be episodic or acute and massive), and constitutional symptoms such as fever, weight loss, malaise, anorexia, and arthralgia. Hemoptysis may be the only presenting complaint, in association with normal renal function. However, rapidly progressive renal failure associated with hematuria is the most common presenting manifestation of anti-GBM disease. Urinalysis shows hematuria with dysmorphic red cells and red

cell casts, and proteinuria, usually non-nephrotic in range. Histologically there is crescent formation within glomeruli. CXR may be normal or may show bilateral alveolar infiltrates, mostly in the perihilar and lower lung areas, which resolve over a few days after cessation of bleeding. Diagnosis depends on the demonstration of anti-GBM antibodies in the appropriate clinical setting. About 20% to 30% of patients are also "ANCA positive," and their disease behaves more like a vasculitis. Renal biopsy is necessary for confirmation of the disease. It shows crescentic glomerulonephritis and linear deposition of IgG along the glomerular basement membrane. Early diagnosis and treatment are crucial in order to prevent progression to ESRD and dialysis dependence. Treatment, as soon as the diagnosis is suspected, involves a combination of steroids, cyclophosphamide, and plasmapheresis. Good outcomes are usually seen in patients with less than 30% crescents on renal biopsy. Prognosis in anti-GBM correlates with the level of renal injury at the time of presentation. Patients with more than 50% crescents on renal biopsy, with serum Cr more than 7 or requiring dialysis with 72 hours of presentation, have poor outcomes. In these patients the benefits of combined therapy are questioned, and many would not recommend it. In these patients, a short course of steroids and plasma exchange is recommended.

The general evaluation of a patient with suspected vasculitis should include routine tests for evaluation of organ dysfunction, such as renal, hematologic, and, liver function tests; ESR and CRP as markers of inflammatory states; ANCA; anti-GBM antibody, for exclusion of Goodpasture's syndrome, Hep B and Hep C serologies; HIV testing; complement levels (C3, C4, CH50; decreased in SLE and cryoglobulinemia), RA (when elevated suggests RA, cryoglobulinemia-associated vasculitis, and SJ); cryoglobulins (seen in mixed essential cryoglobulinemia and in certain forms of vasculitis); CPK to rule out myositis (associated with some vasculitides). Blood cultures should routinely be performed to rule out infection. A CXR, chest CT (if abnormal CXR findings or in cases of pulmonary manifestations not explained by CXR), UA, and EKG may be warranted. If indicated, a lumbar puncture should be performed. Patients with pulmonary hemorrhage usually have pulmonary capillaritis from small

vessel vasculitis secondary to GPA and MPA more often than to anti-GBM and cryoglobulinemic vasculitis; it is rare in EGPA and IgAV. Bronchoscopy is performed to rule out other causes of pulmonary hemorrhage, such as infection, malignancy, among others and to establish the presence of alveolar hemorrhage. Tissue biopsy is almost always necessary in order to confirm the presence of a vasculitis.

The management of the patient with PRS involves supportive care and the use of immunosuppressants. Airway management should follow the usual protocols used in the care of patients with respiratory failure, such as lung protective ventilation. The patient with GPA, however, may represent a special challenge due to the occasional occurrence of tracheal stenosis. Infections are a common cause of mortality among these patients, and their occurrence requires diligent surveillance, especially because of the increased risk afforded by the use of immunosuppressants.

Glucocorticoids are the mainstay of therapy in vasculitides. However, the use of cytotoxic agents in addition to steroids has improved the survival of this patient population. The challenge resides in identifying the patient in whom the benefit-risk assessment favors the additional risks of cytotoxic agents. The severity of vasculitis has not been identified as a prognostic marker, in contrast to the presence of respiratory failure, which has been associated with worse outcomes. ANCA titers are not uniformly reflective of disease severity. The revised 2011 Five Factors Score (FFS) has been used to assess the severity of vasculitis and to identify the patient whose survival can be favorably impacted by the addition of cytotoxic agents. In the FFS scoring system a point is given for the presence of each of the following:

- Cardiac involvement
- GI involvement
- Renal injury (peak serum Cr > 1.7 mg/dL)
- Age > 65
- Absence of ENT manifestations (in EGPA)

The 1996 version of the FFS system included proteinuria and CNS involvement. The score ranges from 0 (none of the factors are present) to 2 (2 or more factors are present). The greater the number of factors present, the worse the prognosis, with cardiac and GI involvement being the strongest negative prognostic

indicators. The patient with a FFS of 1 has a 26% 5-year mortality risk according to some series. Based on these findings, it follows that patients with FFS of 1 or greater, patients with cardiac and/or gastrointestinal manifestations, as well as the obvious subset of patients with refractory disease, would benefit from the concomitant use of cytotoxic agents.

In general, the treatment of systemic vasculitis entails an induction phase, which typically can last up to 1 to 2 months, and a maintenance phase, which can last 1 to 2 years, or longer. The induction phase uses high dose steroids (IV methylprednisolone 1 g daily for 3 to 5 days, replaced then by prednisone 1 mg/kg/d) and, when indicated, a cytotoxic agent, such as cyclophosphamide, IV or PO. Compared to oral cyclophosphamide, pulse IV cyclophosphamide, every 2 to 4 weeks, is associated with similar rates of induction but a higher risk of relapse. The use of IV cyclophosphamide allows a lower total cumulative dose, and therefore potentially leads to a lower incidence of adverse reactions, especially infectious. Azathioprine and methotrexate have been used in less severe cases of vasculitides and in patients intolerant of cyclophosphamide. These agents are also used after the induction phase with cyclophosphamide in some cases. In patients with life-threatening pulmonary hemorrhage or rapidly progressing glomerulonephritis, plasmapheresis can be used as an adjunct to immunosuppression, although it offers no mortality benefit. The role of plasmapheresis in ANCA-negative glomerulonephritis is not supported by data. IV IG can be considered in patients with a concurrent, serious infection, in whom cytotoxic agents carry a greater risk of adverse events. In terms of monitoring of the response to therapy, standardized risk scores, decreasing ANCA levels as in the case of GPA and microscopic polyangiitis, can be used to guide therapy aggressiveness and the transition from induction to maintenance phases of treatment. Prophylaxis against opportunistic infections, especially *Pneumocystis*, is indicated during the period of immunosuppression.

Mortality in patients with vasculitis admitted to the ICU ranges from 11% to 40%, mostly secondary to infections. Early deaths in patients with vasculitis are usually secondary to the disease itself, whereas late mortalities are usually attributed to infectious complications, usually as result of treatment ([Table 46–3](#)).

TABLE 46–3 Overview of vasculitides

Small Vessels Vasculitides	Clinical Features/Diagnosis	Treatment
Eosinophilic granulomatosis with polyangiitis, EGPA (previously known as Churg-Strauss vasculitis; allergic granulomatosis with angiitis)	<ul style="list-style-type: none">• Most commonly affected: lungs, followed by the skin. It can be generalized.• Atopy/nasal polyps/allergic rhinitis and worsening asthma, fever, rash, myalgia, arthralgia, weight loss, cough, dyspnea. Rare manifestations: chest pain (secondary to myocarditis, coronary artery involvement; rare), renal dysfunction (less common than in other ANCA-positive vasculitides; most common necrotizing crescentic GN), GI (mesenteric ischemia)• CXR: fleeting pulmonary infiltrates• Peripheral eosinophilia (> 10%)• Mono/polyneuropathy• + ANCA (40%-60%)• Biopsy: accumulation of eosinophils in extravascular areas	<ul style="list-style-type: none">• Glucocorticoids are the mainstay of therapy (most patients will respond to steroid monotherapy)• Immunosuppressants are recommended for severe and refractory cases• A Five Factors Score of 1 or more is associated with increased mortality and benefits from the combination of glucocorticoids and immunosuppressant, usually cyclophosphamide• Azathioprine or Methotrexate used commonly for maintenance of induction• Some reports of benefit of IVIG in refractory cases; not the case for plasma exchange
Granulomatosis with polyarteritis (GPA, formerly known as Wegener's)	<ul style="list-style-type: none">• Triad of upper airway disease (sinusitis, oral ulcers, or bloody or purulent nasal discharge), lower airway disease (lung infiltrates/nodules/cavities/hemorrhage, hilar adenopathy tracheal stenosis), and renal disease (hematuria, cell casts, non-nephrotic proteinuria, pauci-immune/RPGN). Some cases involve ocular manifestations, heart (pericarditis, myocarditis, conduction abnormalities), GI, CNS involvement• C-ANCA (PR3-ANCA) positivity seen in 65%; a minority are p-ANCA or MPO-ANCA positive 3. About 10% are ANCA negative• Biopsy: granulomatous inflammation of artery or perivascular area, necrosis	<ul style="list-style-type: none">• Glucocorticoids +/- cyclophosphamide (alternative: rituximab probably as effective as cyclophosphamide according to trials; methotrexate in cases with mild or no extrarenal disease)• Response to therapy and mortality correlate to ANCA titers• High rates of relapse• Plasmapheresis may be of benefit in patients with severe disease, especially in patients who also have anti-GBM antibodies• Response to therapy that includes glucocorticoids and cyclophosphamide is seen in more than 90% of patients
Microscopic polyangiitis	<ul style="list-style-type: none">• Pulmonary infiltrates/hemorrhage, rapidly progressive glomerulonephritis• p-ANCA positive (antimyeloperoxidase)• Considered to be part of the GPA spectrum	<ul style="list-style-type: none">• Same treatment as GPA
IgA vasculitis (Henoch–Schonlein purpura)	<ul style="list-style-type: none">• Palpable purpura, arthritis, glomerulonephritis, intestinal ischemia (colic-like abdominal pain)/GI bleeding, hematuria• 10% develop renal insufficiency, 5% progress to renal failure• Pulmonary disease rare• Deposits of IgA in renal or skin biopsy• No new medications	<ul style="list-style-type: none">• Usually self-limited• Steroids may be indicated in severe cases with extracutaneous manifestations

(Continued)

TABLE 46–3 Overview of vasculitides (Continued)

Small Vessels Vasculitides	Clinical Features/Diagnosis	Treatment
Cryoglobulinemic vasculitis	Purpura, arthralgias, Raynaud’s phenomenon, and glomerulonephritis (in severe cases) Low complement levels, cryoglobulins Immune deposits of cryoglobulins in walls of small vessels Seen in association to infections, such as Hep C, autoimmune and lymphoproliferative disorders	<ul style="list-style-type: none">• Steroids• Plasmapheresis may be considered in severe cases• Treat associated infection
Hypersensitivity vasculitis	History reveals a possible offending or new drug Palpable purpura, maculopapular rash Skin lesion biopsy shows neutrophils surrounding an arteriole or nodule	<ul style="list-style-type: none">• Discontinue offending drug• If more than skin involvement present, steroids may be indicated
Vasculitis secondary to connective tissue disorders	Vasculitis plus diagnosis of a CTD	
Vasculitis associated with viral infection		
Medium Vessel Vasculitides	Clinical Manifestations/Diagnosis	Treatment
Polyarteritis Nodosa	<ul style="list-style-type: none">• Peripheral neuropathy (mono- or polyneuropathy), testicular pain, livedo reticularis, myalgia, intestinal ischemia, renal ischemia with elevated BUN and creatinine, new onset diastolic BP > 90• Most are ANCA negative• Angio: aneurysmal dilatation of affected arteries• Biopsy: polymorphonuclear cells in the arterial wall• Secondary PAN: associated with CTD, such as RA, SLE; infections, such as HBV, HCV; and hairy cell leukemia	<ul style="list-style-type: none">• Monotherapy with glucocorticoids may be appropriate for patients with mild disease (no renal/neurologic/GI/cardiac involvement)• For severe cases: a combination of glucocorticoids and cyclophosphamide• IFN alpha is used in some cases of PAN associated with HCV and hairy cell leukemia• Plasmapheresis is of no benefit
Kawasaki Disease	<ul style="list-style-type: none">• Fever for 5 days or more, bilateral conjunctivitis, desquamating rash with erythema of palms and soles, mucositis, cervical lymphadenopathy, coronary artery aneurysms• Usually seen in children	<ul style="list-style-type: none">• High dose aspirin and IMG

Primary Central Nervous System Vasculitis	<ul style="list-style-type: none">• Noninfectious granulomatous vasculitis limited to the brain, leptomeninges, or spinal cord• Insidious onset of persistent headache/cognitive impairment (most common presenting complaints), focal neurologic findings, ICH, seizures, ataxia. SC presentation involves sensory/motor deficits, weakness, pain. Constitutional symptoms uncommon/ESR, CRP normal• Diagnosis requires:<ul style="list-style-type: none">• Acquired neuro deficit of unknown etiology, AND• Angiographic demonstration of CNS vasculitis, AND• No evidence of systemic vasculitis• Imaging: multiple ischemic lesions over wide spread regions• CSF analysis: elevated protein, elevated WBCs (LP crucial to exclude alternate diagnoses, esp infectious and malignant)• Angio: vasospasm, which is helpful, but nondiagnostic (sensitivity: 50%-60%, specificity 30%)• Cerebral/leptomeningeal biopsy: gold standard for diagnosis	<ul style="list-style-type: none">• Combination therapy with glucocorticoids and cyclophosphamide for induction. Azathioprine or mycophenolate used with steroid taper for maintenance of remission• 12-18 months adequate for most patients
Large Vessel Vasculitides	Clinical Presentation/Diagnosis	Treatment
Takayasu arteritis	<ul style="list-style-type: none">• Arthralgia, claudication, decreased pulsation of one or both brachial arteries, difference of at least 10 mm Hg in SBP between the limbs, bruit over subclavian arteries or abdominal aorta• Angio: narrowing or occlusion of aorta, its branches, or large arteries of upper or lower extremities (not secondary to atherosclerosis, fibromuscular dysplasia)• Affects the aorta and its primary branches• Pulmonary arteries affected in 70% of cases, leading to pulm HTN, pulm infarction	<ul style="list-style-type: none">• Steroids• Methotrexate or azathioprine added to resistant cases
Giant cell arteritis	<ul style="list-style-type: none">• Fever, headache, polymyalgia rheumatica, claudication of jaw, scalp tenderness, vision disturbances• Late sequelae: aortic dilatation and aneurysm	<ul style="list-style-type: none">• High dose steroids

CONCLUSION

Overall rheumatologic critically ill patients have very high in-ICU mortality, therefore, early diagnosis and treatment should be sought in order to significantly impact mortality and morbidity. It is necessary to distinguish up front a disease flare versus an infectious process since initiation of immunosuppressive therapy may be fatal in severe septic patients. Aggressive treatment with high dose steroids, disease modifying antirheumatic-cytotoxic drugs and new biological agents must be tailored individually to achieve remission in case of active disease. Adjuvant measures such as plasma exchange and intravenous immunoglobulin are used for nonresponsive patients or for life threatening conditions. No clear prognosticator of in-ICU mortality has been identified as applicable to single patient yet, but intuitively high Apache score, multiorgan failure, comorbidities, advanced age and pancytopenia were all associated with worse outcome.

Skin Complications

Bonnie Koo, MD; John K. Nia, MD and Annette Czernik, MD

KEY POINTS

- 1 Dermatologic diagnoses are associated with longer ICU stays compared to patients with normal skin.
- 2 Any systemic infection can have cutaneous manifestations that are often nonspecific.
- 3 There are no mucosal lesions with Staphylococcal scalded skin syndrome distinguishing it from Stevens–Johnson syndrome/toxic epidermal necrolysis.
- 4 Necrotizing fasciitis is often mistaken for cellulitis. A key feature of necrotizing fasciitis is pain out of proportion to the clinical exam on initial presentation.
- 5 Meningococcemia should be considered in any patient with fever and petechial rash.
- 6 When suspecting a drug eruption a drug chart with medications and time courses is extremely helpful in identifying the causative medication.

INTRODUCTION

About 10% of ICU patients have a dermatologic diagnosis, which are associated with longer ICU stays compared to patients with normal skin.¹ This chapter will focus on skin disorders seen in the ICU setting ranging from common relatively benign disorders to life-threatening diseases. One should not hesitate to consult a hospital dermatologist to assist in the diagnosis, workup, and management of these patients.

COMMON DISORDERS

See [Table 47–1](#); [Figures 47–1](#) and [47–2](#).

Skin Infections

Any systemic infection can have cutaneous manifestations that are often nonspecific. The discussion

will be focused on life-threatening infections with distinctive skin findings.

Staphylococcal Scalded Skin Syndrome

Introduction

Staphylococcal scalded skin syndrome (SSSS) is caused by an exfoliative toxin producing staphylococcal species which bind and cleave desmoglein 1, an adhesion molecule that binds keratinocytes. This explains the clinical manifestation of widespread flaccid bullae and exfoliation. Although primarily a disease of infants and young children, adults with renal failure or immunosuppression are at risk for developing SSSS. The initiating event in adults is often a staphylococcal pneumonia or bacteremia.

TABLE 47–1 Common dermatoses in the ICU setting.

Diagnosis	Clinical Features	Workup and Dif erential Diagnosis	Treatment
Contact dermatitis	Sharply demarcated, erythematous, vesicular, patch or plaque with borders corresponding to the area of contact. Chronic forms are lichenified.	Fungal, scabies, cellulitis, and eczema. No specific workup needed; rule out other conditions.	Discontinue contact with offending agent. Topical steroids (fuocinonide 0.05% ointment) to provide relief and hasten resolution.
Miliara crystallina	Small, fragile, and clear vesicles on the face and trunk appearing as “drops of water.”	Consider folliculitis. No specific workup needed; rule out other conditions.	Minimize heat and occlusion to the area.
Miliara rubra	Erythematous macules sometimes with punctate vesicles on the neck and posterior trunk or other dependent areas.	Folliculitis vs infectious such as candida. No specific workup needed; rule out other conditions.	Minimize heat and occlusion to the area. Topical steroids may be used to relieve pruritus as well as oral sedating antihistamines such as hydroxyzine.
Cutaneous candidiasis	Bright erythematous patches that are often accompanied by satellite papules and pustules and maceration often in skin folds.	Seborrheic dermatitis, contact dermatitis, and inverse psoriasis. KOH preparation or fungal culture can be done but rarely performed as lesions are typically classic.	Keep affected areas dry. Topical antifungals such nystatin powder and/or clotrimazole cream twice a day.

Clinical Features

SSSS begins with widespread erythema beginning on the head and intertriginous areas which then generalize within 48 hours. T ere is often a preceding prodrome of fever, malaise, and skin tenderness. T e skin then takes on a wrinkled appearance due to the superficial flaccid bullae with subsequent exfoliation

(Figure 47–3). T ere are no mucosal lesions distinguishing it from Stevens–Johnson syndrome/toxic epidermal necrolysis (SJS/TEN).

Workup and Dif erential Diagnosis

SSSS is a clinical diagnosis. Since the condition is due to distant foci of infection, skin cultures are

FIGURE 47–1 Contact dermatitis. Typical geometric shape due to adhesive tape.

FIGURE 47–2 Miliara crystallina. Clear vesicles on the back.

FIGURE 47–3 Staphylococcal scalded skin syndrome. Peeling of the hands.

generally negative. However, blood cultures may be positive. A skin biopsy can be useful and will show disadhesion of keratinocytes due to cleavage of desmoglein 1. Other conditions to consider are extensive sunburns, toxic shock syndrome (TSS, staphylococcal), SJS/TEN, and autoimmune blistering dermatoses.

Treatment

Patients generally require supportive skin care which may best be handled in a burn unit. Parenteral antibiotics with beta-lactamase-resistant penicillins such as dicloxacillin or cephalexin should be given. Clindamycin reduces toxin production and is, therefore, recommended.

Toxic Shock Syndrome

Introduction

Toxic shock syndrome (TSS) is a severe, multisystem disease characterized by fever, hypotension, and multiorgan involvement with skin findings. There are 2 types: (1) classic TSS caused by staphylococcus and (2) streptococcal TSS (sTSS) which is more severe and has a mortality rate of up to 50%. Both tend to affect young healthy adults. Classic TSS was previously associated with tampon use but most recently is associated with surgical (particularly nasal) packing and abscesses, whereas, sTSS is associated with disruption of the skin barrier due to lacerations or bites. Both are due to elaboration of toxins that stimulate massive cytokine release.

Clinical Features

Classic TSS begins with a sudden onset of headache, fever, malaise, myalgias, vomiting, and diarrhea. TSS can rapidly progress to hypotension and frank shock. Patients generally also have generalized erythema and/or a scarlatiniform exanthema. Conjunctivitis, a red tongue, mucosal involvement and the hands and feet may also be involved.

sTSS often begins with severe pain in an extremity. sTSS is usually due to an invasive soft tissue infection but up to 50% of patients may have only severe extremity pain as the initial symptom. Other nonspecific symptoms such as fever, malaise, myalgias, and diarrhea may also be present. Unlike classic TSS, widespread erythema is often not present. The disease progresses very rapidly with multiorgan failure ensuing in 48 to 72 hours. Disseminated intravascular coagulation (DIC) and acute respiratory distress syndrome may also develop. In both types, desquamation of the hands and feet occur a few weeks after disease onset.

Workup and Differential Diagnosis

Because this condition can progress very rapidly a high index suspicion is needed. Blood cultures and cultures of any visible skin wounds or skin infections should be performed but are often negative in both TSS and sTSS. Laboratory findings may include an elevated creatinine and an elevated white blood count. Other conditions to consider are SSSS and TEN.

Treatment

Supportive care and intensive monitoring are the hallmarks of treatment. Hypotension may require aggressive intravenous fluid resuscitation and vasopressors. In addition parenteral clindamycin should be considered since it reduces toxin load, otherwise a beta-lactamase-resistant penicillin should be given. Surgical packing, if present, should be removed. The use of intravenous immunoglobulin (IVIG) may neutralize toxin.

Necrotizing Fasciitis

Introduction

Necrotizing fasciitis (NF) is a rapidly progressive and life-threatening disease of the subcutaneous fat and fascia. Prompt recognition with surgical intervention and parenteral antibiotics are the mainstay

of treatment. Risk factors for NF include diabetes mellitus, immunosuppression, renal failure, peripheral vascular disease, recent surgery and intravenous drug use. NF may also follow penetrating injuries. Mortality is up to 40%. It is generally caused by a polymicrobial infection including streptococci, staphylococci, *E. coli*, *Bacteroides*, and *Clostridium*.

Clinical Features

NF begins with severe pain, erythema and edema often in an extremity. Initially the skin is taut and shiny. As the condition evolves, the skin then becomes gray-blue with progression to frank necrosis. Hemorrhagic bullae may also form (Figure 47–4). As necrosis of the fascia ensues, a characteristic, malodorous, watery discharge is produced. Anesthesia is a late finding from destroyed nerves. Patients are toxic appearing with fevers, chills, and symptoms of septic shock. A key feature of this condition is pain out of proportion to the clinical exam on initial presentation. Fournier's gangrene refers to NF of the perineum and genitalia that rapidly spreads to the anterior abdominal wall.

Workup and Differential Diagnosis

NF is often mistaken for cellulitis. However, the patient's condition continues to rapidly deteriorate and characteristic skin changes ensue despite antibiotic therapy. Initial evaluation should include a complete white blood cell count, creatinine, electrolytes, and C-reactive protein. Blood cultures and culture

of any visible drainage should also be done. NF can be confirmed with MRI but this may not be practical and often a CT scan or echo will show fascial edema.

Treatment

Broad spectrum parenteral antibiotics should be started immediately as workup is in progress and tailored as the causative organism(s) are identified. Surgical debridement is the mainstay of treatment. Amputation may be necessary.

Meningococemia

Introduction

Meningococemia is a severe presentation of an infection by *Neisseria meningitidis*. Infections can range from mild upper respiratory infections to meningitis to purpura fulminans. Functional complement is necessary to fight *N. meningitidis*.

Clinical Features

Up to 1/3 of patients with acute meningococemia will present with a petechial eruption on the trunk and extremities (Figure 47–5). These lesions can progress to large purpuric lesions that are often retiform with a characteristic gunmetal grey color centrally. Bullae may form within these lesions. More extensive and severe skin lesions portend the onset of purpura fulminans.

Patients will have fever and hypotension. Other complications include arthritis, myocarditis, and meningeal symptoms. Of note, meningeal symptoms

FIGURE 47–4 Necrotizing fasciitis. Confluent bullae. Note the grey-tan color.

FIGURE 47–5 Meningococemia. Petechial macules on the lower extremity.

are usually absent in the severe cutaneous presentations of meningococemia.

Workup and Differential Diagnosis

Diagnosis is made by confirmation of the organism by culture or gram stain. Blood cultures and CSF fluid should be sampled. Other laboratory findings are generally nonspecific except an elevated white blood cell count. Patients with extensive petechial or purpuric lesions should be evaluated for the development of DIC.

Meningococemia should be considered in any patient with fever and petechial rash. Rocky Mountain spotted fever and West Nile virus and other causes of meningitis also need to be considered.

Treatment

Treatment for acute meningococemia is high dose intravenous penicillin. Third generation cephalosporins may also be used. Unfortunately, in severe cases, patients may deteriorate rapidly despite aggressive IV antibiotic therapy. All close contacts require prophylaxis with ciprofloxacin or rifampin.

DRUG ERUPTIONS

Drug eruptions are common in the hospitalized patient. The majority of them are relatively benign. When suspecting a drug eruption a drug chart with medications and time courses is extremely helpful in identifying the causative medication. Any medication can cause a drug eruption but the most common offenders are antibiotics (aminopenicillins, cephalosporins, macrolides), sulfonamides, and anticonvulsants.

Morbilloform Drug Eruptions

Introduction

Morbilloform eruptions are the most common type of drug eruptions and follow a benign course. They occur 7 to 12 days after the start of a new medication. The eruption may develop sooner on rechallenge.

Clinical Features

The rash begins as erythematous macules on the trunk that soon generalizes symmetrically (Figure 47–6). The lesions then become more confluent and slightly raised. Morbilloform eruptions

FIGURE 47–6 Morbilloform drug eruption. Symmetric erythematous macules and papules on the trunk.

last 1 to 2 weeks and may be associated with a low grade fever.

Workup and Differential Diagnosis

Morbilloform drug eruption is a clinical diagnosis. A high index of suspicion and recent initiation of culprit medications is often present. There may be a peripheral eosinophilia and mildly elevated white blood cell count. Most importantly, it needs to be watched for possible evolution to a more serious drug eruption such as acute generalized exanthematous pustulosis (AGEP), DRESS, SJS and TEN. Viral exanthems clinically mimic morbilloform eruptions. Skin biopsy is relatively nonspecific but findings such as eosinophils and the presence of interface changes is highly suggestive of a drug eruption.

Treatment

Aside from discontinuing the medication no specific treatment is needed. Topical steroids may be used but will generally not hasten recovery.

Acute Generalized Exanthematous Pustulosis

Introduction

Acute generalized exanthematous pustulosis (AGEP) is characterized by an acute onset of widespread pustules and erythema. The most common causes of AGEP are the beta-lactam antibiotics and macrolides. It can occur as early as 24 hours after exposure to a few days. Other important causes of AGEP include calcium channel blockers and antimalarials.

Clinical Features

The rash begins as erythema, often edematous, usually starting on the face or intertriginous areas. Within days, widespread sterile nonfollicular pustules generalize (Figure 47–7) and are accompanied by high fever. The rash may be asymptomatic, mildly pruritic or burning. Although pustules mainly characterize the rash, blisters, targetoid lesions, and mucous membrane involvement may also occur. AGEP lasts 1 to 2 weeks and resolves with superficial desquamation.

Workup and Differential Diagnosis

The initial presentation may resemble a morbilliform eruption but will be easily distinguished once the pustules appear. High fever is characteristic. There is often an elevated white count. There are generally no other lab abnormalities but mild renal dysfunction, mild hypocalcemia, and mild eosinophilia can occur. Eliciting a personal or family history of psoriasis is helpful since AGEP cannot be clinically distinguished from pustular psoriasis. A skin biopsy will distinguish between the two. A careful review of medications and time course will often reveal the causative drug. AGEP can be distinguished from DRESS by the lack of other organ involvement.

Treatment

Aside from discontinuing the offending medication, treatment is supportive. Topical steroids (such

FIGURE 47–7 Acute generalized exanthematous pustulosis. Nonfollicular pustules studding edematous erythematous plaques.

as triamcinolone 0.1% cream) may be helpful if the rash is pruritic and antipyretics for fever.

Drug Reaction with Eosinophilia and Systemic Symptoms

Introduction

Drug reaction with eosinophilia and systemic symptoms (DRESS) is a drug eruption that involves at least one other organ system. The liver is the most commonly affected organ followed by the kidney. The underlying mechanism is most likely due to an impaired ability to detoxify certain drugs. DRESS occurs somewhat later than other drug eruptions at 2 to 6 weeks after starting the medication with a mean of 3 weeks.

DRESS was formally known as phenytoin hypersensitivity syndrome and the anticonvulsants are indeed the most common class of medications to cause DRESS. Other drugs include antibiotics (sulfonamides, minocycline, vancomycin), allopurinol, antiretrovirals, amlodipine, and nonsteroidal anti-inflammatory drugs (NSAIDs).

Clinical Features

The rash often begins as a morbilliform eruption but often becomes more edematous and violaceous appearing as it evolves. The face, upper trunk, and upper extremities are most often affected. A hallmark of DRESS is facial edema. Blisters, pustules, purpuric lesions, and an exfoliative dermatitis are other clinical manifestations of DRESS. The mucous membranes can be involved. Fever and lymphadenopathy is almost always present.

Workup and Differential Diagnosis

Laboratory workup for DRESS includes a complete white blood cell count with differential to look for eosinophilia, liver function tests and creatinine. Elevated Aspartate Aminotransferase (AST) and Alanine Aminotransferase (ALT) is often present (70%) and can evolve to a fulminant hepatitis. Kidney involvement is less common (11%). Myocarditis, pneumonitis, and even neurologic symptoms can occur but are fortunately uncommon to rare.^{2,3} Skin biopsy is relatively nonspecific.

Treatment

Discontinuing the offending medication is paramount. Depending on the degree of organ

involvement, systemic steroids starting at a dose of at least 1 mg/kg/d may be initiated and tapered slowly over at least a month. Few to several months may be needed. Some advocate the use of IVIG for severe DRESS. Antithyroid antibodies resulting in hypothyroidism can occur a few months after DRESS. A TSH should be checked 1 to 3 months afterward and periodically as indicated.

Stevens–Johnson Syndrome and Toxic Epidermal Necrolysis

Introduction

Stevens–Johnson syndrome (SJS) and TEN are rare, severe, potentially life-threatening drug reactions. The 2 conditions are best thought of as part of a clinical spectrum with SJS associated with milder disease with less than 10% affected body surface area (BSA), SJS-TEN overlap as intermediary disease with 10% to 30% affected BSA and TEN with greater than 30% affected BSA. They are clinically characterized by widespread skin detachment due to keratinocyte apoptosis.

SJS and TEN generally occur about 7 to 21 days after the medication is started. The most common culprits are sulfonamides (particularly trimethoprim-sulfamethoxazole), allopurinol, antibiotics, antiretrovirals, and NSAIDs. Certain risk factors have been identified and include certain Human Leukocyte Antigen types, decreased ability to detoxify drugs, and HIV infection. SJS has a mortality rate of up to 5% vs up to 30% in TEN.

Clinical Features

Initial symptoms include fever, eye pain, and dysphagia. A rash appears a few days later and begins on the trunk and progresses to involve the face and upper extremities. The palms and soles are often involved. The rash initially looks morbilliform then becomes more dusky appearing and/or purpuric. There is mucosal involvement and often appears as hemorrhagic crusting of the lips (Figure 47–8) and painful erosions in the mouth. Patients will often have dysuria. The Nikolsky sign is positive. As the lesions evolve even further they take on a characteristic gray hue with subsequent detachment of the epidermis. This is seen as fragile bullae that break easily revealing raw dermis (Figure 47–9).

FIGURE 47–8 Stevens–Johnson syndrome. Hemorrhagic crusting of the lips.

FIGURE 47–9A Stevens–Johnson syndrome. Vesiculobullous lesions with surrounding erythema on the palm.

FIGURE 47–9B Toxic epidermal necrolysis. Sloughing of the skin revealing raw dermis.

Workup and Differential Diagnosis

There is no specific laboratory workup for SJS/TEN. There may be electrolyte imbalance due to impaired skin barrier function. Creatinine should be followed regularly to monitor renal function. The clinical presentation is characteristic but a skin biopsy is diagnostic revealing full thickness epidermal necrosis.

Several risk factors that predict worse prognosis have been identified. The SCORTEN represents this prognostic scoring system (Table 47–2).⁴⁻⁶ Important conditions that need to be distinguished are pemphigus vulgaris, SSSS, and erythema multiforme major.

Treatment

Treatment of SJS/TEN is dependent on early diagnosis and immediate discontinuation of the offending medication. This reduces mortality by up to 30% per day for TEN. Next, supportive care and therapy (outlined below) is instituted. Supportive care is best undertaken in a burn unit familiar with the special needs of patients with SJS/TEN. Nutritional support

is paramount. Many patients will require a nasogastric tube due to dysphagia.

Specific treatment is controversial and evolving but for uncomplicated SJS, prednisone started at 1 mg/kg/d with a slow taper is often used. For SJS/TEN overlap and TEN, cyclosporine or IVIG is advocated. The author uses cyclosporine starting at 3 mg/kg/day IV or PO in divided BID doses. The data for using cyclosporine is promising. Higher doses of IVIG are used than for autoimmune bullous diseases. We recommend starting IVIG at 1 gm/kg/d for 3 days for a total of 3 g/kg. IVIG is thought to work via inhibition of Fas-Fas ligand mediated keratinocyte death.

For eye involvement, ophthalmology should be consulted. Steroid, antibiotic, and lubricating eye drops are often needed. Long-term sequelae include scarring leading to vision loss. The patient needs to be monitored for infection. Death is mainly due to infection from the impaired skin barrier due to *S. aureus* and *Pseudomonas aeruginosa*.

TABLE 47–2 SCORTEN. Risk factors to predict mortality risk in TEN.

Risk Factor	Point
Age > 40 years old	1
Malignancy	1
Heart rate > 120 beats/min	1

Detached skin > 20% body surface area	1
Serum bicarbonate > 20 mEq/L	1
Serum glucose > 250 mg/dL	1
Number of Risk Factors	Mortality Risk
0-1	3.2%
2	12.1%
3	35.3%
4	58.3%
5 or more	>90%

Purpura

Purpura is hemorrhage into the skin or mucous membranes. The differential diagnosis is extensive and a thorough review of these is outside the scope of this chapter. The two main morphological entities of interest are palpable purpura and retiform purpura. Palpable purpura generally presents as bright red and slightly raised lesions. Discussion will mainly be limited to leukocytoclastic vasculitis (LCV) as the leading clinical entity associated with palpable purpura.

Retiform purpura has a net-like pattern most easily seen at the edges of the lesion. This pattern is due to the pattern of occlusion of the affected vessels. This can be caused by infiltration of the vessel wall by organisms in immunocompromised patients, abnormal coagulation or embolic phenomenon.

Leukocytoclastic Vasculitis

Introduction

Leukocytoclastic vasculitis (LCV) refers to inflammation of predominantly small vessels in the dermis. It is usually idiopathic (~50%) but it can sometimes be attributed to other causes (Table 47–3). It is mediated by the deposition of immune complexes in the vessels. These immune complexes ultimately lead to the release of proteolytic enzymes from neutrophils producing vessel wall inflammation or vasculitis.

TABLE 47–3 Major causes of LCV.

Cause	Incidence	Common Agent/ Disease(s)
Idiopathic	50%	
Infectious	15%-20%	Bacterial: Group A beta-hemolytic streptococci Neisseria meningococcus Mycobacterium tuberculosis Viral: Upper respiratory infections Hepatitis C > B (including vaccines) Parvovirus B19 HIV Septic vasculitis: Infective endocarditis Neisseria meningitidis (acute) Neisseria gonorrhea Staphylococcus aureus Rickettsiae Disseminated fungal infections (immunocompromised patients)
Inflammatory	15%-20%	Autoimmune connective tissue diseases Inflammatory bowel disease
Medication	10%-15%	Allopurinol Bortezomib Cephalosporins (cefactor) Penicillins NSAIDs* Oral contraceptives Anticonvulsants Sulfonamides Minocycline Cocaine adulterated with levamisole
Malignancy	2%-5%	Plasma cell dyscrasias Lymphoproliferative disorders

*NSAIDs: nonsteroidal anti-inflammatory drugs.

Clinical Features

LCV generally presents as palpable purpura, flat purpuric or petechial lesions, or as urticarial lesions (Figure 47–10). Atypical presentations include pustules and targetoid lesions. They occur 7 to 10 days after the triggering event and tend to favor the extremities and dependent areas. Lower extremity edema may be present. Lesions are usually asymptomatic but may be associated with mild pruritus or burning. Up to 50% of patients will also have mild systemic symptoms such as fevers, myalgias, arthralgias, and weight loss.

Workup and Differential Diagnosis

When LCV is suspected clinically, laboratory workup should be directed at the suspected underlying cause. An initial screening workup could include a complete blood count with differential, ESR, C-reactive protein, blood and urine cultures, cryoglobulins, hepatitis B and C, ANA, C3, C4, ASO titer, and a chest X-ray. Anti-Neutrophil Cytoplasmic Antibodies (ANCA), further imaging, and a malignancy workup can also be considered. A skin biopsy will confirm the histopathologic diagnosis of vasculitis. Direct immunofluorescence may also be useful.

The main concern will be the presence of a systemic vasculitis or the possibility of cryoglobulinemia. There is no associated vasculitis with Type I cryoglobulinemia since it is due to occlusion of vessels and presents with retiform purpura. It is usually caused by an underlying lymphoproliferative disorder. Types II and III cryoglobulinemia, also known as the mixed cryoglobulinemias, are due to a

FIGURE 47–10 Leukocytoclastic vasculitis. Palpable purpura on the lower extremity.

vasculitic process and presents as palpable purpura. It is usually due to underlying hepatitis C infection and less likely due to HIV, autoimmune disease, or an underlying lymphoproliferative disorder.

Treatment

Most cases of LCV do not require treatment. Treatment should be directed at the underlying cause, if found. For mild, skin-limited disease, NSAIDs, and antihistamines may be used in addition to other supportive measures such as leg elevation and avoiding tight-fitting clothing. In more severe cases, one can consider a short course of systemic steroids starting at 1 mg/kg/d of oral prednisone. For systemic vasculitis, corticosteroids and other immunosuppressive therapies are the mainstay of treatment.

Calciphylaxis

Introduction

Calciphylaxis is a potentially fatal condition characterized by vessel calcification with necrosis of the skin and soft tissues. It primarily affects obese female patients with diabetes often in the setting of chronic renal failure. Its etiology is poorly understood.

Clinical Features

Calciphylaxis begins with livedoid racemosa, a net-like, mottled discoloration of the skin. The lesions are fixed, unlike the temporary lesions of livedo reticularis. As the lesions progress they become more purpuric (retiform) and necrotic (Figure 47–11). The

FIGURE 47–11 Calciphylaxis. Necrotic plaques on the lower extremity.

lesions are severely painful and are most common on the lower extremities. Fatty areas such as the abdomen, buttocks, and breasts are also often affected.

Workup and Differential Diagnosis

In the typical patient with diabetes and renal failure, the diagnosis is made easily. Laboratory workup should include serum calcium, phosphate, electrolytes, BUN, creatinine, PTH, and a coagulation factors including PT, aPTT, antithrombin III, proteins C and S, anticardiolipin, antiphospholipid. Other workup to consider is hepatitis C serologies, cryoglobulins, and ANCA to rule out an underlying vasculitis.

Skin biopsy should be taken from the area adjacent to necrosis, preferably an area with early erythema or purpura. An excisional biopsy will provide an adequate sample and should go deep to subcutaneous fat. Other considerations include warfarin necrosis and purpura fulminans.

Treatment

Treatment is mainly directed at correcting calcium dysregulation. This is accomplished with low calcium dialysis, phosphate binders, and possible parathyroidectomy. Intravenous sodium thiosulfate is also commonly used with variable success. Almost all patients will require analgesia for the pain.

Careful wound management with gentle debridement is recommended. Hyperbaric oxygen therapy can be considered for very painful ulcers. Unfortunately, necrotic lesions are very resistant to treatment and often provide a nidus of infection leading to sepsis. This is the leading cause of death in these patients. Even with optimal treatment, the mortality approaches 40% to 80%.

Purpura Fulminans

Introduction

Purpura fulminans is a severe, life-threatening condition due to 3 main etiologies: infection and DIC, postinfectious, and hereditary deficiency of protein C or S (neonatal). Of particular interest is the type caused by infection, usually due to bacterial sepsis but can also be caused by viruses. In the postinfectious kind, it is due to a transient deficiency of protein S due to consumptive processes. Mortality is high at 20% to 40%.

FIGURE 47-12 Purpura fulminans. Necrotic plaque with bullae formation in the antecubital fossa.

Clinical Features

Purpura fulminans presents with an acute onset of large purpuric to ecchymotic areas mainly on the distal extremities and acral surfaces. Its appearance can be gangrenous. The lesions enlarge rapidly and may have overlying hemorrhagic bullae (Figure 47-12). They are quite painful. It is invariably accompanied by fever, chills, shock, and often with DIC.

Workup and Differential Diagnosis

Laboratory workup should include blood and urine cultures, complete white blood cell count with differential, DIC workup.

Few conditions present with a sudden onset of large purpuric lesions. Rocky Mountain spotted fever may present with a purpura fulminans-like picture. In the setting of a patient with known connective tissue disease, the catastrophic antiphospholipid antibody syndrome can be considered.

Treatment

Treatment is mainly supportive but it should also be directed at the underlying cause, if found. Replacement therapy with fresh frozen plasma, platelets, protein, C, and/or antithrombin may be indicated. Heparin may be considered if the patient has a thrombotic process but needs to be used with caution. Surgical debridement of affected extremities may be necessary and amputation may sometimes be necessary.

Other Critical Skin Conditions

Erythroderma

Introduction—Erythroderma refers to generalized erythema and scaling. Erythroderma is most

commonly due to generalization of a pre-existing skin disease (psoriasis, atopic dermatitis, pemphigus foliaceus), drug reactions, or cutaneous T-cell lymphoma (Sezary syndrome). In approximately 25% of cases, no underlying etiology is found. Erythroderma has serious systemic complications including hypothermia and fluid and electrolyte imbalances.⁷

Clinical Features—Patients present with generalized erythema and scaling of more than 90% of the BSA (Figure 47-13). It is pruritic. Palmoplantar keratoderma may be a clue to underlying pityriasis pilaris rubra. The nails may shed. Eruptive pale seborrheic keratosis may be seen.

Patients are often febrile with chills. Extracellular fluid shifts lead to pedal, pretibial, and facial edema. Increased blood flow through the skin and the loss of a functioning cutaneous barrier lead to extreme

FIGURE 47-13 Erythroderma. Confluent bright erythema.

fluid loss and electrolyte abnormalities. Fluid loss leads to reflex tachycardia as well as disturbances in body temperature regulation (both hyperthermia and hypothermia may be seen). Patients with erythroderma may have secondary cutaneous infections, most commonly with staphylococcus aureus.

Workup and Differential Diagnosis—Increased ESR, anemia, and hypoalbuminemia are commonly seen in erythroderma. Electrolytes need to be monitored. Flow cytometry may be useful if Sezary syndrome is suspected.

A history of dermatologic conditions known to cause erythroderma is helpful as well as any recent new medication exposures. A skin biopsy of a primary skin lesion can often differentiate erythrodermic psoriasis, atopic dermatitis, pityriasis rubra pilaris, or bullous disease.⁸ However, in many cases a skin biopsy shows a nonspecific hypersensitivity reaction. Important conditions that need be distinguished include DRESS, SJS/TEN, and SSS.

Treatment—Supportive care and treatment of the underlying condition (if found) is the mainstay of treatment. Patients need to be monitored for fluid and electrolyte imbalances, temperature, secondary infections, and nutritional needs. Sedating antihistamines (hydroxyzine) can be used to relieve pruritus. Topical therapy can include wet dressings, low-potency corticosteroid ointments. Systemic corticosteroids at an initial dose of 1 to 2 mg/kg/d may be useful in idiopathic erythroderma and drug reactions. Psoriatic erythroderma is typically treated with cyclosporine, methotrexate, acitretin, or biologic agents. Systemic corticosteroids should not be used in psoriasis as they can cause generalized pustular psoriasis (GPP).

Generalized Pustular Psoriasis

Introduction—Generalized pustular psoriasis (GPP) is a rare, life-threatening form of psoriasis.⁹ Usually, patients have a history of stable plaque-type psoriasis that flares into rapidly progressive pustular disease. Known triggers that can lead to a pustular psoriasis include rapid tapering of systemic corticosteroids, hypocalcemia, infections, pregnancy, and irritation such as sunburn.

Clinical Features—GPP presents with erythema studded with pustules. Patients are often febrile and have chills. GPP appears commonly on the trunk,

extremities, face, and can potentially arise on nail beds resulting in onycholysis, lakes of pus with subsequent nail shedding.¹⁰

Workup and Differential Diagnosis—Initial workup should include a complete white count with differential, electrolytes, ESR and blood cultures. Patients will often have lymphopenia with leukocytosis and an elevated ESR. A skin biopsy can be considered if the patient does not have a pre-existing diagnosis of psoriasis or if the diagnosis is not clear. GPP cannot be clinically distinguished from AGEP. A biopsy will distinguish between the two.

Treatment—Supportive care, including intravenous fluid and temperature regulation is paramount in treating GPP. Intravenous antibiotics may be needed if the patient becomes infected. Specific GPP treatment is with acitretin (considered first line) or cyclosporine and less likely methotrexate due to slower onset of action. It is important to avoid oral corticosteroids unless absolutely necessary, due to withdrawal and worsening of psoriasis.

Pemphigus Vulgaris

Introduction—Pemphigus vulgaris (PV) is a life-threatening autoimmune skin blistering condition. It affects middle-aged adults. Patients frequently develop persistent oral mucosal and/or cutaneous erosions. Lesions may progress to involve the entire cutaneous surface. The condition runs a relapsing and remitting course over the course over many years.

Clinical Features—PV presents with superficial erosions or flaccid bullae that usually present on the scalp or oral mucosa (Figure 47–14). The blister roof is very

FIGURE 47–14 Pemphigus vulgaris. Oral erosions.

FIGURE 47–15 Pemphigus vulgaris. Eroded plaques.

fragile and often no intact blisters are seen at first presentation. Erosions associated with a collarette of the remains of the prior blister are common. Lesions occur in a seborrheic distribution—involving the central face, chest, and back (Figure 47–15). Involvement of the oral mucosa is associated with significant pain with oral intake. Cutaneous lesions may become superinfected—most commonly with *S. aureus*. However, superficial infections with candida or herpes virus have been reported as well.

Not uncommonly, patients will have a positive Nikolsky sign. This is a test of skin fragility—where firmly stroking the skin induces blister formation. This can be used as a test to determine adequate control of disease activity.

Workup and Differential Diagnosis—All patients must meet clinical, histologic, and immunologic criteria in order to establish the diagnosis. Clinically, the patients must present with a history of

chronic mucocutaneous erosions that on exam are consistent with those typically seen in pemphigus. A biopsy for H&E must demonstrate subcorneal or suprabasal acantholysis. Lastly, either direct or indirect immunofluorescence or ELISA autoantibodies to skin antigens must be present. Serum antibodies against intraepidermal adhesion molecules (ie, desmoglein 1 and 3) are present.

Serum may be sent to specialty laboratory (eg, Beutner Laboratories at <http://www.beutnerlabs.com>) to establish and monitor pemphigus titers. This may distinguish pemphigus from other immunobullous diseases in the differential diagnosis such as paraneoplastic pemphigus and bullous pemphigoid. **Treatment**—Prior to the onset of the use of systemic steroids in this condition—pemphigus was uniformly fatal. Treatment involves the use of systemic steroids in combination with a steroid sparing immunosuppressant agent such as mycophenolate mofetil. Steroids are slowly tapered over the course of months to years. In spite of this treatment regimen, a large cohort of patients may be inadequately controlled or develop complications related to treatment.

In recent years, the use of rituximab has shown significant promise.^{11,12} Rituximab is an anti-CD 20 antibody that targets pre-B cells for destruction. It removes B-cells destined to become pathogenic antibody producing plasma cells from the circulation. This is often used in combinations with high-dose IVIG. IVIG induces a rapid and selective decrease in pemphigus autoantibodies.¹³

The use of rituximab and IVIG earlier in the course of treatment is becoming increasingly commonplace. Well-designed studies regarding the use of these agents and the weight of their relative toxicities to conventional therapy are lacking.

Principles of Neurosciences Critical Care

Christopher Zammit, MD; Ko Eun Choi, MD and
Axel Rosengart, MD, PhD, MPH

More so than any other tissue or organ system, the nervous system is exquisitely sensitive to insults and injuries. The importance of timely recognition, diagnosis, stabilization, and treatment of acute neurologic processes to mitigate or prevent permanent injury, disability, and even death cannot be overemphasized. The most elite resuscitators will utilize “parallel processing” and ensure that the most time-dependent diagnostics and therapeutics are prioritized.

Neurocritical care (NCC) is a relatively new and rapidly developing subspecialty. Intensive care units (ICUs) dedicated to the care of those with neurologic disorders requiring critical care are rapidly increasing in number. The Neurocritical Care Society (NCS) was established in 1999, and held its first annual meeting in 2003. The United Council for Neurologic Subspecialties, which oversees NCC Fellowship accreditation and NCC certification, hosted its first certification examination in 2007. Most recently, leaders in NCC and Emergency Medicine collaborated to create an educational program establishing guidance on the care for patients during the first critical hours of a neurologic emergency, entitled Emergency Neurologic Life Support (ENLS). Similar to Advance Cardiovascular Life Support offered by the American Heart Association, ENLS Certification is provided to those completing the program.

The expansion in the size and organization of the field has led to advances in the technology available for neuromonitoring and strategies for neurologic resuscitation, making a full introduction to NCC concepts beyond the scope of this chapter, and more appropriately the mission of published textbooks on

NCC. This chapter will provide an initial framework for the recognition, diagnosis, stabilization, and treatment of acute neurologic illness, with focused discussion of specific disease processes, including, encephalopathy and coma, acute ischemic stroke (AIS), intracerebral hemorrhage (ICH), subarachnoid hemorrhage (SAH), neuromuscular disease (NMDz), seizures, and status epilepticus. Other NCC diseases and disorders, such as traumatic brain injury (TBI) and/or spinal cord injury, cardiac arrest (CA), intracranial pressure (ICP) management, fulminant hepatic failure, delirium, encephalitis, and meningitis, are covered elsewhere in this textbook.

COMA AND ENCEPHALOPATHY

Consciousness has two components, arousal or wakefulness and content or awareness. Deficits in arousal are the result of either a diffuse, bihemispheric insult to the cerebral cortices or a focal injury to the ascending reticular activating system (ARAS) (see [Figure 48A–1](#)). Categories of arousal, in decreasing order, include awake, drowsy, obtunded or lethargic, stuporous, and comatose. Drowsy implies that the patient is prone to long bouts of sleep and hypoactivity during hours when normally expected to be awake and engaged, but they are easily aroused and awake with simple stimulation, such as speaking to them. An obtunded or lethargic patient requires a greater degree of stimulation to maintain their engagement. They often require a loud voice or gentle tactile stimulation to arouse them to participate in conversation or perform requested tasks. Once engaged, they tend to respond slowly and are prone

FIGURE 48 A–1 Arousal structure and main neurotransmitter.

to disengagement once stimulation is no longer maintained. A stuporous patient will require more substantial stimulation to arouse them, such as rigorous tactile or noxious stimulation. At best, they are able to follow simple commands, but more complex tasks are not possible, and may only be capable of localizing to painful stimulation. A comatose patient is unable to purposefully engage their environment regardless of the degree of stimulation provided. The best response seen will be a facial grimace and/or stereotyped, posturing, or reflexive movements

of the extremities to noxious stimulation. In those with a TBI, a Glasgow Coma Scale (GCS) score of less than 9 (see “Physical Examination,” and [Table 48A–1A](#)) is often considered to be “coma” despite the possibility that the patient may be able to engage their environment (eg, motor GCS score of 5).

Awareness is a product of the entire neurologic system, both peripheral and central, and whose assessment is a composite of several neurologic functions, including motor, sensory, visual, language, concentration, attention, cognitive, executive,

TABLE 48 A–1 A Glasgow coma scale.

Eye Opening (E)	Verbal Response (V)	Motor Response (M)
4—Opens spontaneously ^a	5—Alert and oriented	6—Follows commands
3—Opens to voice	4—Disoriented and confused	5—Localizes to pain ^b
2—Opens to pain	3—Incoherent words	4—Withdraws from pain
1—None	2—Incomprehensible sounds, moaning	3—Flexion posturing
	1—None	2—Extension posturing
	“T” or “U”—If patient is intubated or has tracheostomy	1—None

^aThe patient should attend to the examiner in order to score a 4 on (E).

^bPatient should cross midline to address the noxious stimulus in order to score a 5 on (M).

social, behavioral, and emotional functions. Deficits in awareness are the result of focal neurologic injuries (eg, AIS or NMDz) or diffuse processes that disrupt neural networks (eg, TBI or hypoxic-ischemic encephalopathy after CA). Impairments in arousal, attention, or concentration can adulterate the assessment of awareness, which is most accurately performed in the awake, attentive, and focused patient.

Encephalopathy is a nonspecific term applied to patients with cerebral dysfunction and encompasses scores of possible diagnoses, each with their own requisite diagnostics and therapeutics. Other colloquialisms used to describe encephalopathic patients with overall lesser degrees of precision include “altered mental status,” “altered,” “delta MS,” “changed from baseline,” “clouded,” or “confused.” Clinical features of encephalopathy include abnormalities in arousal ranging from drowsy to hyperactive, with impairments in attention or concentration. A subset of encephalopathic patients will be delirious, which is best described as a heterogeneous acute confusional disorder that develops

over several hours to days, fluctuates with time, is not attributed to a neurocognitive disorder, and is the result of the exposure to xenobiotics, drug withdrawal, or an acute medical disorder. Disturbances in attention, awareness, and orientation that tend to worsen in the evening and nighttime are hallmark features of delirium. The diagnosis is clinical and outlined in the American Psychiatric Association’s Diagnostic and Statistical Manual, 5th edition. Further diagnostic considerations include the delirium etiology, duration of symptoms, and level of psychomotor activity (see [Table 48A–1B](#)). Please refer to other chapters in this textbook for a more in-depth discussion of delirium.

When evaluating patients with a change in their neurologic status, it is crucial that a broad differential be maintained that includes both primary medical and neurologic etiologies. As discussed further later, stupor or coma can be the result of many metabolic, toxic, infectious, and inflammatory conditions. Additionally, it is not uncommon for a patient with a primary neurologic insult (eg, AIS) to also be

TABLE 48A–1B Delirium diagnostic criteria, diagnostic and statistical manual, 5th ed.

Diagnostic criteria	<div><div>A. A disturbance in attention (ie, reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment).</div><div>B. The disturbance develops over a short period of time (usually hours to a few days), represents a change from baseline attention and awareness, and tends to fluctuate in severity during the course of a day.</div><div>C. An additional disturbance in cognition (eg, memory deficit, disorientation, language, visuospatial ability, or perception).</div><div>D. The disturbances in Criteria A and C are not better explained by another preexisting, established, or evolving neurocognitive disorder and do not occur in the context of a severely reduced level of arousal, such as a coma.</div><div>E. There is evidence from the history, physical examination, or laboratory findings that the disturbance is a direct physiological consequence of another medical condition, substance intoxication or withdrawal (ie, due to a drug of abuse or to a medication), or exposure to a toxin, or is due to multiple etiologies.</div></div>

suffering from an acute medical issue (eg, endocarditis or acute kidney injury). If a diagnosis still exists that can explain the patient’s presentation and would require time-dependent treatment, it is important that it be definitively excluded via the expeditious conduction of the appropriate diagnostics.

Historical Considerations

Encephalopathy and coma are not a specific disease or syndrome. They are a physical finding signifying central nervous system (CNS) dysfunction requiring a diagnosis. For acute changes, the last known normal time or last known well time must be established and distinguished from the time that the change was noticed or the patient was found to be abnormal. Dramatic neurologic changes (eg, acute coma) do not preclude preceding subtle changes or stuttering symptoms that should be actively pursued. Historical information should also be sought from a variety of resources including family, friends, neighbors, Emergency Medical Service (EMS) personnel, 911 communication specialists, police, and patient belongings (eg, timed and dated receipts, cell phone text messages, emails, calls, or social media interactions). Clues at the scene of patient discovery should also be sought for consideration of environmental, traumatic, or pharmacologic etiologies.

A catalog of prior medical problems, medications (and compliance), social habits, and hobbies, should be performed. Specific inquiries about use of anticoagulant, antiplatelet, and antiepileptic medications should be made, particularly with the widespread use of target specific oral anticoagulation, such as dabigatran, rivaroxaban, and apixaban. EMS interventions (eg, naloxone) and the patient’s response should also be gathered.

Physical Examination

The physical exam commences with observation of the patient prior to interaction to assess for spontaneous movements and general physical condition (eg, healthy, chronically ill, ashen, wasted, cachectic, and disheveled). Violent spontaneous clonic movements may resemble the tonic-clonic activity seen in generalized seizures, but consideration must be given as to whether it is extensor posturing resulting from an acute brainstem injury (eg, basilar

TABLE 48A–1C Odors suggestive of neurotoxin exposure.

Odor	Neurotoxin
Mothballs	Camphor
Garlic	Organophosphates, arsenic, thallium
Peanuts	Vacor
Carrots	Cicutoxin (water hemlock)
Wintergreen	Methyl salicylates
Fruity	Chlorinated hydrocarbons
Glue	Solvents, toluene
Rotten eggs	Dimercaptosuccinic acid, hydrogen sulfide
Shoe polish	Nitrobenzene
Smoke or fire	Carbon monoxide or cyanide

thrombosis). Detection of certain odors can provide clues to neurotoxin exposure (Table 48A–1C). Exposure of the patient will allow for the identification of occult injury, illness, or paraphernalia associated with or causative of the presentation.

Vital signs including heart rate, blood pressure (BP), respiratory rate (RR), and pattern, oxygen saturation (SpO₂), quantitative waveform capnography (wPetCO₂), core temperature, and blood glucose should be acquired. Bradycardia may indicate elevated supratentorial pressure in children and infratentorial (posterior fossa) pressure in adults. Tachycardia should be evaluated for possible cardioembolic inducing arrhythmias (eg, atrial fibrillation), which may be the cause or result of a cerebral insult. Hypertension is quite nonspecific, as it may be seen with pain, anxiety, anatomic irritation of the forebrain, insula, limbic system, hypothalamus, descending sympathoexcitatory pathway rostral to the medulla, or intracranial hypertension. Hypotension is suggestive of an injury to the descending sympathoexcitatory pathway (which is anywhere from rostral medulla through the upper thoracic spine). However, if the MAP is less than 60 mm Hg, hypovolemia, neurogenic stunned myocardium, or systemic illness should be considered. wPetCO₂ can detect hypercapnia (albeit with limited sensitivity),

TABLE 48A–1D Respiratory patterns in CNS disease.

Pattern	Description	Localization	Examples of CNS Disease
Cheyne-Stokes	Several large tidal volume breaths alternating with periods of apnea last 12-30 seconds	Bihemispheric or diencephalon	Bilateral cerebral infarcts, diencephalic shift, early transtentorial herniation, encephalopathy
Hyperventilation	Persistently elevated RR in the absence of metabolic demands, pulmonary disease, or stimulation xenobiotic	Bihemispheric	Bilateral infarcts, encephalopathy
		Brainstem chemoreceptors	SAH or meningitis
		Brainstem (rare)	Glioma or lymphoma
Apneusis	Large tidal volume breaths with breathing holding for 2-3 seconds at end-inspiration and end-expiration	Pons	Basilar artery stroke, transtentorial herniation
Cluster or ataxic	Frequent irregular breaths of varying regularity and tidal volume	Rostral medulla	Transtentorial herniation, cerebellar mass, hemorrhage, swelling
Apnea	No spontaneous breathing	More extensive medullary injury	Late transtentorial herniation, cerebellar mass, hemorrhage, swelling

CNS, central nervous system; RR, respiratory rate; SAH, subarachnoid hemorrhage.

while providing a continuous RR and tracing allowing for the demonstration of respiratory patterns localizable to specific cerebral anatomic locations (Table 48A–1D). Cushing’s triad of irregular breathing, bradycardia, and hypertension is an unreliable sign of elevated ICP in adults. If observed, it is much more likely to represent a posterior fossa process or an exceptionally progressed supratentorial process. Hyperthermia may be environmental, suggest infection or signify a toxidrome, such as neuroleptic malignant syndrome, serotonin syndrome, or thyrotoxicosis. Hypothermia may be environmental, or can be seen in sepsis, various intoxications, hypothyroidism, or pituitary apoplexy. A finger stick blood sugar should be obtained immediately to exclude (and potentially emergently treat) symptomatic hypoglycemia.

The following will emphasize the crucial aspects of the neurologic exam in the stuporous or comatose patient. Patients with mild impairments in arousal should undergo a usual neurologic assessment to include visual fields, cranial nerves, motor, language, coordination, reflexes, tone, and attention

(eg, counting backward from 20 to 1 or reciting the months of the year backward).

Level of Arousal (or Wakefulness)

As outlined earlier, a patient’s wakefulness can be placed into one of several categories. Clinically, the patient should be described by what they are able to do with a specific type of stimulation, rather than just the category of arousal. This is elicited by progressively escalating the stimulation by first speaking in a normal tone, then a loud voice, then tactile stimulation, then vigorous tactile stimulation (eg, jostling the patient), and finally applying noxious stimulation, and assessing for a response to verbal commands. During this evaluation, one must not assume that the patient is unconscious (eg, they may be locked in). Options for noxious stimulation include a trapezius pinch, nasopharyngeal irritation with a cotton swab, jaw thrust (if not prohibited by a traumatic injury), supraorbital pressure, sternal rub, or nail bed pressure. Grabbing and twisting of the skin or tissue folds is highly discouraged as this may lead to bruising, hematomas, and skin tears.

Prior to providing noxious stimulation, be sure to lift the patient's eyelids and ask him or her to look up/down, left/right to carefully evaluate for a locked-in state.

In acute trauma, the GCS is a validated score of arousal that can be rapidly calculated, with values ranging from 3 to 15. It has three components; eye opening, verbal, and motor function (see Table 48A–1A). A more recently introduced and validated coma scale is the FOUR (Full Outline of UnResponsiveness) Score, which ranges from 0 to 16 and include assessments of eye movements, motor function, respiratory pattern, and brainstem function (Table 48A–1H).

Several months to a year after cerebral injury patients may transition from states of depressed arousal to those with near intact arousal, but varying degrees of awareness impairment, such as vegetative state and minimally consciousness state (Figure 48A–2). These terms can be applied three months after a non-traumatic brain injury (eg, CA) and 1 year after a traumatic brain injury.

Motor Exam

The motor exam in comatose patients assesses appendicular movement, tone, and reflexes to

identify asymmetry and/or localize CNS injuries. It occurs simultaneous with the evaluation of arousal. Localization is produced via activation of the cortical inputs to the corticospinal tracts. Therefore, absence of localization is suggestive of cerebral hemispheric dysfunction or an injury along the corticospinal tracts. The careful inspection of nonlocalizing movements provides clues to the presence or absence of a diencephalic or brainstem lesion (Table 48A–1E). To elicit such movements, the stimulus should be sustained until it is clear that the full extent of movement has been observed. Failure to do so may falsely localize the lesion and mischaracterize the problem. If pathologic posturing is observed, the descriptors “flexor” and “extensor” are preferred over “decorticate” and “decerebrate” posturing, respectively.

Repeated identical movements (stereotyped) induced by a variety of stimuli are typical of those with dysfunction of the cerebral hemispheres or diencephalon. More extensive diencephalic lesions or rostral midbrain injury will produce *flexor* posturing in the upper extremities (ie, flexion of the fingers and wrist, forearm supination, elbow flexion, and

FIGURE 48A–2 State of consciousness by arousal and content.

TABLE 48A–1 E Physical exam findings in a comatose patients with brainstem dysfunction.

Anatomic Level	Mental Status	Pupillary Size and Position	Eye Movement	Motor Responses	Respiration
Diencephalon	Drowsy	Small (1-2 mm)	Normal	Abnormalities of flexion	Cheyne-Stokes
Midbrain	Coma	Fixed in mid position (4-5 mm) ^a	Dysconjugate	Abnormalities of extension	Hyperventilation
Pons	Coma	1 mm in primary pontine injury; fixed and 4-5 mm with prior midbrain injury ^a	Complete paralysis	Abnormalities of extension	Hyperventilation or apneusis
Medulla	Variable	Variable	Variable	Flaccid	Cluster, ataxic, or apnea

^aFixed and dilated pupil(s) will be seen if brainstem dysfunction is the result of lateral and/or downward compression forces (eg, uncal or transtentorial herniation).

shoulder adduction) and extensor posturing of the lower extremities (ie, extension of the knee, internal rotation and extension of the hip, and plantar flexion of the ankle). More caudal injuries will produce extensor posturing of the upper extremities (ie, shoulder adduction, elbow extension, and wrist pronation and flexion) and lower extremities. Extensor posturing can be elicited by trivial internal or external stimulation (eg, distended bladder or ventilator delivering a tidal volume), giving the appearance of spontaneous clonic movements, leading the clinician to falsely suspect they are epileptic in origin. Medullary brainstem lesions will produce flaccidity in all extremities. Opisthotonic posturing (ie, clenched teeth, arching of the spine) is an infrequently encountered manifestation of severe brainstem injury.

Tone and reflexes should be examined to discern between upper and lower motor neuron impairment (Table 48A–1F). Upper motor dysfunction leads to

increased tone and reflexes, with upgoing toes and clonus, while hypotonicity, hyporeflexia, fasciculations, and mute toes are hallmarks of lower motor neuron dysfunction.

Fundoscopy

The value of fundoscopy in the evaluation of coma is to assess for intracranial hypertension (IC-HTN) and retinal ischemia. IC-HTN slows axoplasmic flow in the optic nerve producing axonal swelling. When sustained over several hours or longer, this is seen on fundoscopy as papilledema. Optic nerve demyelination or infarction (ie, papillitis), will also be seen as papilledema, as thus should be included in the differential. Dampening or loss of retinal venous pulsations can be seen when ICP exceeds systemic venous pressure. This finding is present in 20% of the population, limiting its specificity for IC-HTN.

Brainstem/Cranial Nerves

The brainstem examination allows for the identification of herniation syndromes, acute treatable lesions of the brainstem (eg, acute basilar thrombosis), and is the crux of brain death examination. The components are pupillary assessment, oculomotor examination, and elicitation of the corneal, gag, and cough reflexes.

Pupillary Evaluation

Components of the pupillary exam include assessment of size and symmetry in ambient light, followed by dim lighting, direct and consensual reactions to

TABLE 48A–1 F Neurologic exam findings in lower versus upper motor neuron lesions.

Finding	Upper Motor Neuron	Lower Motor Neuron
Reflexes	Increased	Decreased
Clonus	+	–
Tone	Increased	Decreased
Fasciculations	–	+
Atrophy	–/late	+

TABLE 48A–1G Physical findings in drug-induced coma.

Drug Class	Pupils	Other changes
Opioids	Miotic	Hypopnea/apneic
Barbiturates and benzodiazepines	Reactive	Hypopnea, mild hypotension

Anticholinesterases (organophosphates)	Miotic	Bradycardia, sweating, salivation, lacrimation, diarrhea, vomiting, urination
Cocaine and amphetamine	Mydriasis	Tachycardia, hypertension, hypotension, arrhythmia
Neuroleptics	Variable	Motor rigidity, hypotension, hyperthermia
Antidepressants	Mydriasis	Rarely seizure

bright light, and the ciliospinal response. Pupillary responses in stuporous and comatose patients are often subtle and difficult to detect with the naked eye. The exam can be aided by an ophthalmoscope or otoscope for magnification, or a pupillometer.

An understanding of pupillary innervation is critical to the interpretation of the exam. Parasympathetic innervation, which control pupillary constriction, begins in the medial midbrain at the Edinger-Westphal nucleus (EWN) and runs superficially on the dorsal aspect of the third cranial nerve (CN3). Light detected by the retina sends a signal through the optic nerve to the EWN, producing pupillary constriction. Lesions that stretch or injury CN3, such as a herniating medial temporal lobe or expanding posterior communicating artery aneurysm, impair parasympathetic innervation and produce a unilateral pupillary dilation.

Sympathetic innervation takes a longer and more complicated course. It begins in the hypothalamus, projecting caudally through the brainstem where it receives inputs from several other pathways, proceeds to the upper thoracic spine where it exits and joins the superior cervical ganglion, then branches to the internal carotid artery and finally courses through the cavernous sinus to the pupil. Assessing for the presence of the ciliospinal reflex challenges the integrity of the sympathetic pathway. This is done by pinching the face or neck and observing for a 1 to 2 mm dilation of the pupils bilaterally. The painful stimulus is received in the lower brainstem, where it triggers autonomic pathways that

produce a sympathetic discharge. The presence of a ciliospinal reflex implies that if a brainstem lesion is present, it is in the rostral pons or higher, and that the lower brainstem is spared.

Pupils are often observed to be small and reactive in diencephalic dysfunction and metabolic coma/encephalopathy. Notable exceptions to the latter are some drug-induced comas (Table 48A–1G). Midbrain dysfunction, whether via a primary lesion or downward or laterally compressive forces, produced 4 mm, mid-position, fixed pupils. If the lesion affects the more dorsal pretectal midbrain (eg, pineal gland mass, enlarged third ventricle, or dorsal midbrain stroke [Parinaud's syndrome]), the pupils tend to be slightly larger (~5 mm) and a downward gaze is observed (sunset eyes). Compressive midbrain lesions that also stretch the CN3 will produce fully dilated (~8 mm) and nonreactive pupils.

Further progressive downward injury or primary pontine injury will produce nonreactive pinpoint (1 mm) pupils. Table 48A–1E summarizes the neurologic exam findings in various brainstem lesions.

Oculomotor Exam

Gaze palsies result from injury to the frontal eye fields (frontal lobes), CN3, sixth cranial nerve (CN6), or the brainstem connections between the CN3 and CN6 nuclei (ie, pontine paramedian reticular formation [PPRF], medial longitudinal fasciculus [MLF]). Symmetric lateral gaze is accomplished by signaling the ipsilateral CN6 via PPRF, and the contralateral

TABLE 48A–1H Full outline of unresponsiveness (FOUR) score.

Score	Eye	Motor	Brainstem	Respiration
4	Open and tracks or blinks to command	Follows command ^a	PR and CR present	Not intubated, normal RP

Total score ranges from 0 to 16.
^aGives thumbs up, makes fist, or shows two fingers.

CN3 through the MLF. Integrity of this system is assessed in conscious patients by having the patient follow the examiner’s finger through all extremes of eye movement. The oculocephalic (doll’s eyes) reflex is used to assess the oculomotor system in stuporous and comatose patients that are unable to follow commands. It is performed with the patient’s neck in 30° of extension and by gently rolling the patient’s head from side to side while observing eye movements. The patient’s eyes should attempt to move in the opposite direction of head. If this maneuver fails to produce a response or if it cannot be done because of concern for a cervical spine injury, then caloric oculovestibular testing (ie, cold calorics) can be performed by injecting 30 to 60 mL of cold saline on the tympanic membrane (TM), then observing for 1 to 2 minutes for tonic eye deviation toward stimulus. Before performing this maneuver, be certain that the TM is intact and unobstructed (eg, cerumen impact or hemorrhagic debris in the external auditory canal).

Corneal Reflex, Gag, and Cough

The corneal reflex (CR) is examined by stimulating the cornea with either saline drops or by gently touching the delicate corneal with a cotton swab and observing for a blink and/or elevation of the eye. The CR evaluates CN3, CN5, CN7, the midbrain, and pons. Contact lens wearers will have a suppressed CR. It should not be performed in conscious patients. The gag reflex, which assesses CN9, CN10,

and CN12, is assessed by stimulating the posterior pharynx with a tongue blade or a similar object and visually observing for elevation of the ipsilateral soft palate and depression of the tongue. A cough is elicited by carefully advancing the endotracheal suction catheter to the greatest possible depth.

Brain Death Declaration

Patients with loss of all cerebral function due to an irreversible cerebral insult can be evaluated for brain death. The examination components include an assessment of motor function, pupil reactivity, caloric oculovestibular testing, corneal, gag, cough, and oculocephalic reflexes, in the absence of any neuromuscular blockers (NMBs), CNS depressants, metabolic derangements, or physiologic abnormalities. If there is no evident neurologic function, apnea testing is performed to pronounce brain death. Apnea is diagnosed if the PaCO₂ rises from a normal level (35–45 mm Hg) to more than 60 mm Hg or by more than 20 mm Hg without evidence of respiratory effort over at least 8 minutes while patient’s endotracheal tube is disconnected from the ventilator. A RR greater than the set rate on the ventilator does not imply the patient is not apneic; cardiac pulsations are capable of triggering tidal volumes. Table 48A–1I summarizes the brain death examination conditions and components.

If select components of the neurologic exam cannot be performed (eg, caloric oculovestibular testing due to traumatic TM perforation) or the

patient’s physiology cannot tolerate at least 8 minutes of apnea, then a confirmatory test can be completed instead. Options include a digital subtraction angiography, CT angiography of the head, cerebral scintigraphy (preferred in most centers), transcranial Dopplers, or electroencephalography (EEG).

The brain death process is prone to institutional idiosyncrasies due to local and state policies. Your institutional policy and state laws should be consulted when pronouncing brain death. Movements in the brain dead have been observed, such as “the undulating toe,” lower extremity reflexes, such as “triple flexion” and the “Lazarus sign” (ie, arms raised, then crossed on the chest). These require interpretation. If there is ambivalence, confirmatory testing should be pursued.

Once brain death is pronounced, an organ donation representative may approach the family of the deceased. The clinician should not engage organ donation discussions with patient’s surrogate/proxy. If the surrogate/proxy inquires about donation, they should be referred to the organ donation representatives. Leading up to and following brain death declaration, the clinician should continue to optimize the deceased’s physiology, as this has been shown to improve the success of transplantation. Physiologic

replacement of hypothalamic hormones can help achieve hemodynamic stability, including vasopressin, levothyroxine, and methylprednisolone. A recent randomized trial found that delayed graft function was decreased in recipients of kidneys from deceased donors that were cooled to 34°C to 35°C.

Pathophysiology and Differential Diagnosis

CNS dysfunction may occur for several reasons. Table 48A–1J breaks them into 7 mechanistic categories that provide a structure for a differential diagnosis. It is not uncommon for multiple etiologies to coexist and synergistically impair CNS function. Asymmetric or lateralizing neurologic findings often suggest a primary CNS disorder, but they can also be seen with systemic illness in patients with a prior CNS insult. Above all, the identification and treatment of etiologies that will lead to irreversible CNS injury with delays in care must be prioritized. This includes failure of systemic substrate delivery, impairment in the local delivery of substrate (eg, AIS or vasospasm), rapidly expanding intracranial masses (eg, ICH), unmitigated deranged physiology (eg, status epilepticus), anatomic neuronal

TABLE 48A–1J Pathophysiologic mechanisms of encephalopathy, stupor, and coma.

Mechanism	Examples
Failure of substrate delivery	Hypoxemia, severe anemia, hypoglycemia, hypotension, cardiogenic shock
Metabolically or pharmacologically induced neuronal dysfunction	Uremia, hyponatremia, liver failure, hypercarbia, drug ingestion, toxidrome, hypothermia
Primary disturbance in neuronal function or physiology	Seizures, convulsive or nonconvulsive status epilepticus
Primary diffuse, bihemispheric cortical pathology	Encephalitis, acute demyelinating Encephalomyelitis, CNS vasculitis
Focal lesion of the ARAS	Acute basilar thrombosis, brainstem intracerebral hemorrhage
Anatomic distortion or compression of the ARAS	Hydrocephalus, SDH with uncal herniation, pineal gland tumor with dorsal midbrain compression
Intracranial hypertension	Acute aSAH, dural sinus thrombosis, meningitis

ARAS, ascending reticular activating system; SDH, subdural hematoma; aSAH, aneurysmal subarachnoid hemorrhage.

distortion (eg, cerebral herniation), and failure of global or focal cerebral perfusion (eg, intracranial hypertension, collapse of perforating vessels causing focal infarction).

Hypotension, hypoxemia, and hypoglycemia warrant immediate exclusion and treatment. Those with evidence of or risk factors for malnutrition should receive thiamine intravenously. wPetCO_2 may fail to detect hypercarbia in hypopneic patients; therefore, a blood gas is warranted. [Table 48A–1K](#) summarizes these as well as other metabolic, environmental, and toxicologic processes that require immediate consideration. [Table 48A–1G](#) outlines findings in some common toxidromes. Other chapters in this text cover toxicologic and environmental emergencies in greater detail.

Delays of as little as 15 minutes in the diagnosis and treatment of acute primary neurologic emergencies have been associated with worse outcomes. Acute disorders and their corresponding diagnostic tests are found in [Table 48A–1L](#). Neuroimaging, cerebrospinal fluid (CSF) analysis, and EEG will capture nearly all of these conditions. [Table 48A–1M](#) lists etiologies of stupor and coma that will require more sophisticated diagnostics, consultative services, and/or unique therapies.

Intracranial Pressure

In adults, the cranial vault is a rigid, noncompliant structure filled with brain tissue, blood, CSF, and

meninges. The brain is divided into supratentorial and infratentorial compartments by a dural fold, the tentorium cerebelli. The brainstem passes through an opening in the tentorium, called the tentorial incisura or notch. Another dural fold, the *falx cerebri*, similarly divides the brain into the left and right hemispheres and importantly contains the superior and inferior sagittal sinuses. Cisterns filled with CSF, cranial nerves, and large intracranial arteries surround the brainstem.

Pressure is a function of the amount of mass occupying a fixed amount of space (eg, the human cranium) and is expressed in force per unit area. Alternatively, it is reported in either centimeters of water ($\text{cm H}_2\text{O}$) or millimeters of mercury (mm Hg). Literally, it is the amount of force applied by a column of either H_2O or Hg, with the height of the column being cm with H_2O or mm with Hg. When pressures vary at different locations (ie, there is a pressure gradient), objects are liable to be moved from their position by these differences in force. In the brain, pressure gradients cause cerebral tissue to herniate, nerves to stretch, and vascular and ventricular structures to be compressed, displacing CSF and blood and eventually disrupting the circulation of CSF and/or flow of blood. Initial elevations in ICP cause CSF to shift from the ventricles to the spinal subarachnoid space. Next, venous outflow is accelerated when ICP exceeds right atrial pressure. With further increases, cerebral tissue is

TABLE 48A–1 K Acute undifferentiated encephalopathy, stupor, and coma: substrate delivery and initial metabolic and environmental considerations.

Condition	Diagnostics and Considerations
Hypoglycemia	FSBG
Hypoxia	Pulse oximetry, arterial blood gas, CO-oximetry
Severe anemia	CBC, inspect conjunctiva, mucus membranes
Hypercarbia	Blood gas (venous or arterial)
Hypotension (absolute or relative)	Palpate pulse, sphygmomanometry, arterial line
Cardiogenic shock	Capillary refill, pulse quality, bedside echocardiography
Severe sepsis or septic shock	Core temperature, physical evidence of infection, WBC, lactate, lipase, U/A
DKA/HONC	BMP, VBG, serum ketones, U/A, serum osm, fruity breath, severe tachypnea without respiratory illness
Myxedema coma/thyrotoxicosis	TSH, free T4, T3; bradycardia, hypothermia or tachycardia, hyperthermia, hypertension
Uremia	BMP
Beriberi/Wernicke’s encephalopathy	Evidence or risk factors for malnourishment, empirically treat
Electrolyte derangement	BMP, iCa, PO4, Mg
Hepatic encephalopathy	NH3, LFTs
Carbon monoxide	CO-oximetry, appropriate environmental setting
Methemoglobinemia	CO-oximetry
Cyanide	Lactate, building fire victim, initiate hydroxocobalamin
Hypo- or hyperthermia	Core temperature (bladder, rectal, and esophageal). If hyperthermia considers sepsis, serotonin syndrome, NMS, MH, heat stroke. If hypothermia, consider myxedema, pituitary apoplexy, Addison’s disease
Intentional ingestion (suicide attempt)	Serum tylenol, salicylates, toxic alcohols, ethanol, serum Osm, Urine drug screen, evidence of prior or recent self-harm
Electrocution/lightning strike	Total CPK, ferning, entry and exit burns, charred clothing

displaced (herniated) and arterial perfusion pressures are exceeded, producing ischemia and infarction. The infarcted tissue then swells, leading to further herniation and compromise of arterial blood flow. Once compensatory mechanisms are exhausted (ie, the displacement of CSF and/or venous blood), larger pressure increases occur with

small increases in volume (ie, compliance worsens). These are the principles of the Monro-Kellie doctrine (Figure 48A–3). When measured via intraparenchymal fiberoptic monitors or intraventricular catheters, ICPs of greater than 20 mm Hg have been associated with worse outcomes. It is important to note that most intracranial disease processes do

TABLE 48A–1L Primary neurologic process and preferred diagnostic tests.

Neurologic Process	First Line Diagnostics
Acute Ischemic stroke	NCHCT (insensitive acutely), CTA head and neck, MRI w/DWI + ADC sequences (difficult to obtain emergently)
Intracerebral hemorrhage	NCHCT
Traumatic brain injury	NCHCT
Extra-axial hemorrhage	NCHCT
Meningitis/encephalitis	LP with CSF analysis
Acute hydrocephalus	NCHCT
Aneurysmal subarachnoid hemorrhage	NCHCT

not lead to global symmetric increases in pressure. Instead, the aforementioned concepts are frequently localized phenomena that may be under-appreciated by monitors placed in nondiseased tissue (Table 48A–1N). Further details on ICP monitoring, indications, waveforms, and their interpretation can be found in Chapter XY.

Cerebral Herniation Syndromes

Cerebral herniation tends to follow one of several anatomic trajectories, which are accompanied by an expected constellation of neurologic changes, termed herniation syndromes (Table 48A-1O and Figure 48A–4). Supratentorial syndromes include

TABLE 48A–1M Less common etiologies of stupor and coma.

Brainstem tumor/malignancies Leptomeningeal carcinomatosis Pituitary apoplexy Paraneoplastic encephalopathies Demyelinating disorders Posthypoxic ischemic encephalopathy Acute disseminated encephalomyelitis Marburg variant of multiple sclerosis Central pontine myelinolysis CNS vasculitis or vasculopathies Chronic meningitis/CNS infections Progressive multifocal leukoencephalopathy Prion disease Several nutritional deficiencies Inherited metabolic disorders
--

subfalcine, diencephalon shift, uncal, and central, while infratentorial syndromes include tonsillar and upward.

Subfalcine herniation and diencephalon shift are the result of lateral pressure gradients across the hemispheres. In subfalcine herniation, the cingulate gyrus is forced against and eventually under the inferior margin of the falx cerebri, where the pericallosal branches of the anterior cerebral artery can be compressed, leading to infarction and impaired motor function in the contralateral leg. They are radiographically quantified by the amount of midline shift (MLS) at the septum pellucidum (subfalcine) or pineal gland (diencephalon shift) on axial sequences. Clinically, the level of arousal is depressed in proportion to the degree of MLS.

Uncal herniation occurs when the medial aspect of the temporal lobe is forced over the tentorial edge into the basal cisterns, eventually compressing and pushing the midbrain laterally. The first manifestation is typically impaired consciousness with ipsilateral pupillary dilation due to stretching of the CN3 as it course through the cisterns, followed by contralateral hemiparesis from compression of the midbrain. Approximately 25% of the time, ipsilateral hemiparesis occurs when the midbrain is forced against the contralateral free edge of the tentorium. Arousal is impaired from stretching of the elements of the ARAS. The posterior cerebral artery territory is subject to compression by the uncus with subsequent infarct of its territory.

FIGURE 48 A–3 Monroe-Kellie hypothesis. An increase in cranial volume will lead to an increase in pressure unless an equal amount of volume in cerebrospinal fluid and/or blood is displaced.

Central transtentorial herniation begins with compression of the diencephalon, followed by the midbrain, then the pons, and finally the medulla. It is often the result of obstructive hydrocephalus or other mass located in the midline. Clinically, a rostrocaudal deterioration of brainstem function can be appreciated. Initially, compression of the diencephalon causes a depression in arousal with small, minimally reactive pupils. Untreated, midbrain compression ensures, where the pupils enlarge to

approximately 4 to 5 mm (mid-position) or dilated and nonreactive, often with flexor posturing. Further progression yields miotic pupils and/or extensor posturing. Finally, once the medulla is compressed, the patient becomes quadriplegic and hypotensive. Neuroendocrine functions can become disturbed at various points along this deterioration as a result of pituitary ischemia or avulsion of the stalk. Additionally, both posterior cerebral arteries are at risk for compression and infarction in this syndrome.

TABLE 48 A–1 N Regional mass lesion and increasing ICP difference with focal hemispheric lesion.

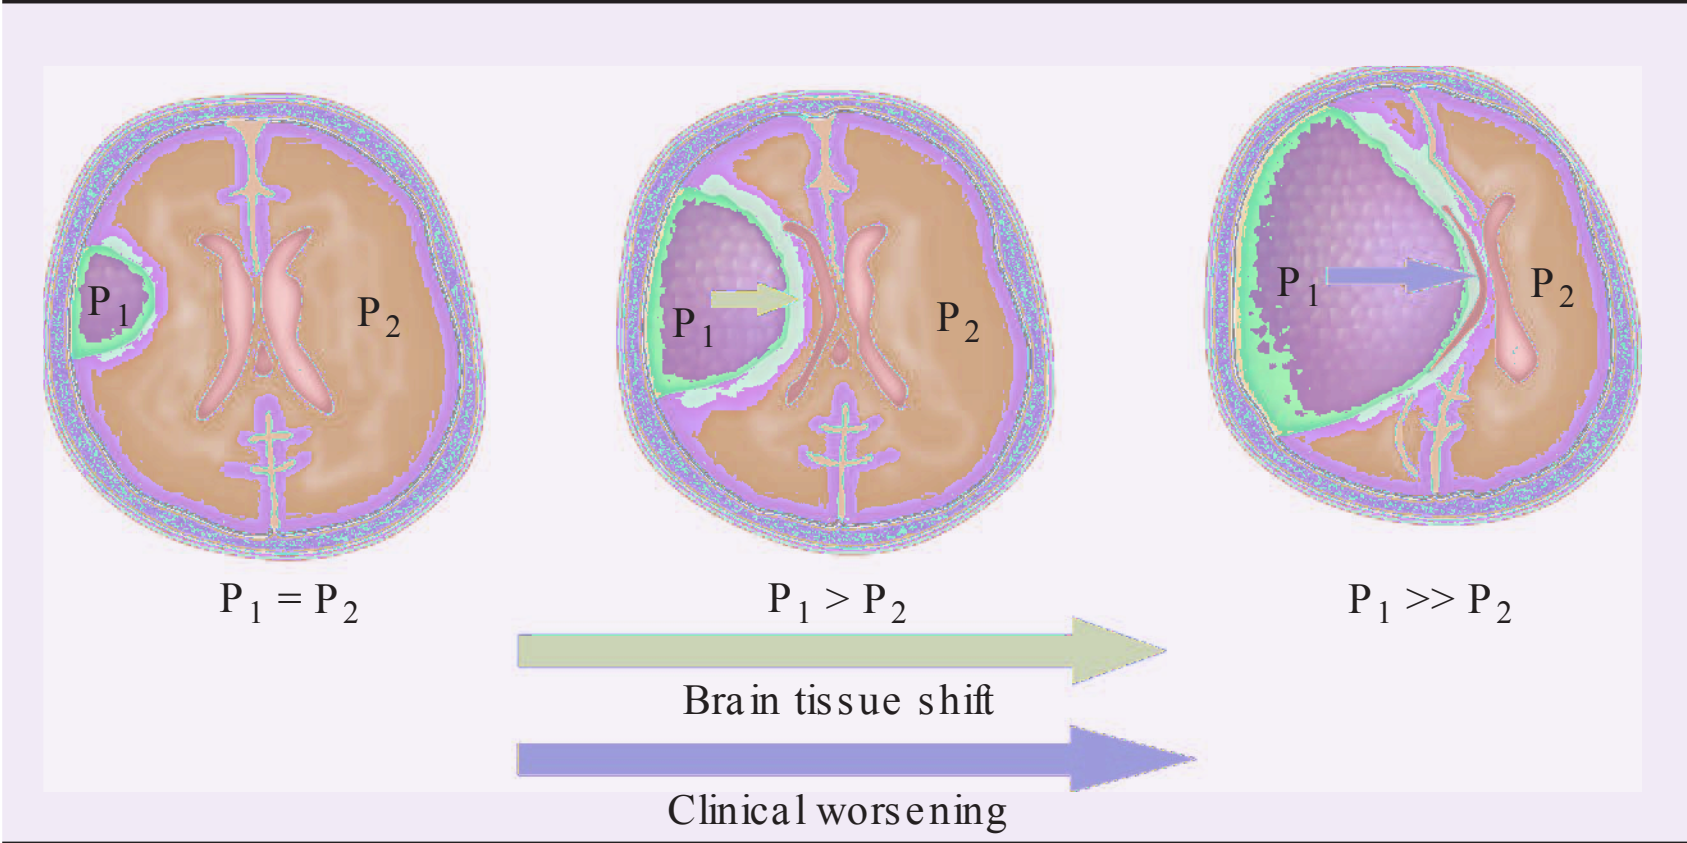

TABLE 48A–1 O Herniation syndromes.

Herniation Syndrome	Level of Arousal	Motor Exam	Pupillary Exam	Other Findings
Subfalcine, early	Drowsy to lethargy	Normal to CLLE paresis, paratonia	Normal

Upward, late	Coma	EP to QP, ± TF of LEs	Mid-position, NR, maybe irregular	No VOR

CL, contralateral; IL, ipsilateral; UE, upper extremity; LE, lower extremity; QP, quadriplegia; NR, nonreactive; VOR, oculoccephalic testing; TF, triple flexion; FP, flexor posturing; EP, extensor posturing; HP, hemiparesis; DC, dysconjugate.
^aDue to the anatomic location of the third cranial nerve (CN3), the first finding in uncal herniation can be a partial to full CN3 palsy.

Tonsillar herniation can result from posterior fossa masses or advanced transtentorial herniation (uncal or central). The cerebellar tonsils are forced through the foramen magnum, compressing the caudal medulla, causing apnea, hypotension (but often initially hypertension), miotic pupils, and quadriplegia. The fourth ventricle is commonly compressed, leading to obstructive hydrocephalus. In this setting, treating the hydrocephalus first with an external ventricular drain can cause the brainstem to herniate upward, causing the brainstem to buckle and bend, compressing its perforating arterial supply, leading to infarction. Therefore, it is often prudent to

prioritize or simultaneously perform a suboccipital decompression while establishing diversion of CSF.

Neurologic Resuscitation: Treatment of Acute Stupor and Coma

The early treatment goals in undifferentiated acute disturbances in anchor on the empiric optimization of cerebral blood flow (CBF) and delivery of critical substrates, such as oxygen and glucose. To do so, the clinician needs to have a firm understanding of the relationships between MAP, ICP, ventilation, oxygenation, CBF as well as the effects of

Herniation syndromes

airway management on ICP. Immediate actions are to correct hypoxia, hypoglycemia, hypotension, hypoperfusion, and hypo, or hypercarbia. Prolonged hyperoxia should be avoided, as this is associated with harm. BP reduction and goals are tailored to the etiology of the neurologic change. Prior to definitive diagnostics, it is likely unclear whether the brain is in a hypoperfused state (eg, critical carotid stenosis) or would benefit from aggressive BP reduction (eg, ICH). In those with a diastolic blood pressure (dBP), more than 120 mm Hg or systolic blood pressure (sBP) more than 230 mm Hg, gentle BP reduction to a sBP less than 220 mm Hg and/or dBP less than 120 mm Hg are reasonable, but it represents a low priority therapeutic target, with more risk than reward in the undifferentiated patient. Mildly hypothermic states may not warrant immediately, rapid correct; if ICP proves to be an issue, as rapid normalization can produce herniation. Suggested initial empiric diagnostic and therapeutic targets are summarized in [Table 48A–1P](#).

The PaCO₂ heavily influences CBF due to its powerful effects on cerebral vessel diameter. About 1 mm Hg increase in the PaCO₂ will increase the CBF by 2% to 4% (and vice versa). Beyond this physiologic relation, hypo- and hypercarbia have been associated with worse outcomes in several

TABLE 48 A–1P Empiric diagnostics and therapeutic targets in the patient with undifferentiated disturbance in consciousness.

neurologic emergencies. Therefore, vigilant ventilator management is crucial. End-tidal capnography (ETCO_2) is a valuable tool to accomplish this, noting that it may prove inaccurate if there is upper airway obstruction, hypopnea, pulmonary disease, hypotension, metabolic acidosis, and/or thoracic trauma. One caveat is the patient with hypocarbia as a compensation for a metabolic acidosis; this patient should have their PaCO_2 forcibly normalized, as it will worsen the underlying acidosis and potentially produce cardiovascular collapse.

Via autoregulatory feedback, systemic hypotension will produce cerebral vasodilation, increasing the cerebral blood volume (CBV) (Figure 48A–5). A minimal mean arterial blood pressure (MAP) target of more than 65 mm Hg may be inadequate for those with flow limiting cervical or cerebral vessel stenosis and many not produce the desired cerebral perfusion pressure (CPP) of more than 60 mm Hg in those with IC-HTN ($\text{CPP} = \text{MAP} - \text{ICP}$); therefore, an initial target MAP of more than 80 mm Hg is often selected. Ensuring euvolemia through clinical intravascular volume assessment and provision of isotonic crystalloids initially pursues MAP targets. Albumin and synthetic colloids have not found a place in the neurologic resuscitation. In fact, a subgroup analysis of the SAFE trial found albumin to be associated with increased mortality in TBI

patients, when compared to crystalloids. Bedside echocardiography is a valuable tool to screen for acute cardiac dysfunction and neurogenic stunned myocardium.

As discussed earlier, ICP is a product of the amount of mass in the intracranial vault. Actions that increase CBV can increase ICP. Hypermetabolic states, such as agitation, seizures, or hyperthermia will increase CBF. Cerebral venous drainage can be impaired when the patient's head is falling to one side or if their cervical collar is tight fitting, causing ICP elevations.

Acute intracranial hemorrhage should remain high on the differential. Inquiries regarding anticoagulant use and serologic assessment of the patient's coagulation status must occur. If intracranial hemorrhage is identified, rapid, immediate correction of any coagulopathy is mandatory and must be conducted with the highest sense of urgency, regardless of any perceived transient stability.

Airway Considerations

Hypoxia, hypercarbia, hypertension, IC-HTN, and hypotension are all known complications of endotracheal intubation (ETI). As described earlier, many acute neurologic conditions are worsened by these physiologic perturbations and must be avoided.

FIGURE 48A–5 Autoregulatory curve.

Hypoxia can be avoided with optimal preoxygenation and utilizing techniques, strategies, and equipment that optimize the probability of first pass success. Similarly, hypercarbia will be minimized with short paralysis to intubation times. The PaCO_2 rises by 6 to 7 mm Hg in the first minute of apnea, followed by a 3 to 4 mm Hg rise for every minute thereafter, with greater jumps in those increased metabolism (eg, hyperthermia) and likely with depolarizing NMBs, such as succinylcholine. Hypotension can be avoided via intravascular volume loading with isotonic crystalloids, selection of induction agents with hemodynamic stability (eg, etomidate and ketamine, KET), and using lower doses of induction agents in comatose patients.

Laryngoscopy and endotracheal suctioning are known to increase in ICP via several hypothesized pathways. Weak evidence suggests that administering 1.5 mg/kg of lidocaine IV (up to 150 mg) 3 minutes prior to intubation may mitigate this increase. If provided, note that systemic BP decreases can be seen and the fasciculations normally seen after succinylcholine administration will be blunted or absent. Alternatively, fentanyl (1-3 mcg/kg) IV can be provided to blunt the sympathetic response to laryngoscopy that is blamed for some of the ICP rise.

KET has been reported to dramatically increase ICP and has been contraindicated into those with IC-HTN. More recently, several small, randomized trials have not observed this increased when KET is used in combination with propofol (PRO), benzodiazepines, or barbiturates, although none of these studies used KET for ETI. The overall safety of bolus KET in patients with IC-HTN is still not entirely clear, but its hemodynamic stability makes it an appealing option for those with hypotension or assessed to be high risk for hypotension during intubation.

Extraglottic devices (EGDs) in the acute management of CA have been associated with inferior outcomes, possibly due to compression of the carotid arteries, reducing CBF and exacerbating brain injury. Randomized evidence is lacking to definitely inform the EGD versus ETI decision, but these observations are worth considering with ETI is an option.

Despite some of the speculative physiologic limitations, succinylcholine is the preferred paralytic

in these patients, assuming the absence of other contraindications to its use, as its short duration action allows for immediate recovering of the neurologic exam, which is absolutely needed for decisions on further diagnostics and therapeutics. The recent approval of sugammadex (a reversal agent for rocuronium) in the United States does trump this concern, making rocuronium the preferred NMB where sugammadex is available.

SEIZURES AND STATUS EPILEPTICUS

Seizures are a heterogeneous clinical event with scores of etiologies, but a unifying pathophysiologic origin. Seizures that last for more than 5 minutes or sequential seizures without intervening resumption of baseline neurologic function are termed status epilepticus (SE). A comprehensive discussion on seizures in critical illness is beyond the scope of this text and should be sought in other resources. This section will focus on the identification and management of SE.

Definitions and Presentation

Generalized tonic-clonic seizures (GTCs), which consist of generalized convulsions in association with a depressed level of arousal, are the most commonly recognized type of seizures. A patient with GTCs meeting SE criteria is in generalized convulsive status epilepticus (GCSE). If GCSE persists despite first and second line antiepileptic drug (AED) therapy (to be discussed further later), it is termed refractory status epilepticus (RSE).

Clinical events not uncommonly confused for GTCs are myoclonus, posturing, and psychogenic seizures. It is reasonable to initially treat myoclonus and psychogenic seizures as GTCs, as it is better to err on the side of treatment, since delayed AED administration is associated with an increased likelihood of intubation and being refractory to AEDs. Psychogenic seizures may particularly be difficult to distinguish from a GTC. Confusing the issue further is the high rate of psychogenic seizures in patients with epilepsy. Extensor posturing movements due to acute brain stem injury have been confused with GCSE, as the patient will violently and intermittently

extensor posture in response to inconspicuous stimuli, such as a ventilator delivered breath.

Focal seizures (formerly known as “partial” seizures) are a heterogeneous clinical event, with symptoms consistent with area(s) of the brain that are involved. Repetitive, involuntary, and stereotyped movements are the most readily identified clinical demonstration. If a focal seizure persists despite treatment, it is called *epilepsia partialis continua*, which has a very low mortality rate and therefore does not require aggressive treatment. When focal seizures occur in concert with a disturbance in consciousness, they are termed “complex.” If this persists, the patient is in nonconvulsive status epilepticus (NCSE). When there is a motor component to the clinical presentation of NCSE, it may also be called “subtle status epilepticus,” as it may represent inadequately treated GCSE. A nonconvulsive seizure (NCSz) is appreciated electrographically in patients with either vague symptoms or a depressed level of consciousness. Table 48A–1Q lists signs and symptoms seen with NCSz.

TABLE 48A–1Q Symptoms and signs of nonconvulsive seizures.

Negative	Positive
Amnesia	Agitation/aggression
Anorexia	Automatisms
Aphasia/mutism	Blinking
Catatonia	Crying
Coma	Delirium
Confusion	Delusions
Lethargy	Echolalia
Staring	Facial twitching
	Laughter
	Nausea/vomiting
	Nystagmus/eye deviation
	Perseveration
	Psychosis
	Tremulousness

Etiologic Considerations

Distinguishing between provoked and unprovoked seizures is an important therapeutics step, as the former require resolution of the underlying cause, while treatment of the later is largely dependent on the administration of AEDs, and in very advanced or challenging cases, the consideration of surgical options. The most common cause of SE is AED discontinuation; therefore, AED levels should be obtained immediately. Hypoglycemia, infectious (particularly CNS, but also systemic), metabolic, toxicologic, or environmental etiologies also require immediately consideration. Early neuroimaging (eg, non-contrast head CT (NCHCT)) is warranted to evaluate for a primary neurologic etiologies, such as ICH, SAH, PRES, abscess, tumor, or malignancy. Many medications, particularly when used in combination (ie, polypharmacy) can reduce the seizure threshold. Serotonin syndrome and neuroleptic malignant syndrome should be considered, as well as ethanol or benzodiazepines withdrawal. Those with a primary neurologic insult, who then suffer from a metabolic or systemic illness, are prone to experiencing provoked seizures (eg, patient with prior ischemic stroke now with sepsis).

SE patients often present with a fever, but this should not delay the attainment of CSF and provision of corticosteroids and meningitic-coverage antimicrobials. Encephalitis, whether it is infectious, inflammatory, autoimmune, or paraneoplastic require early consideration, as the former many benefit from specific antimicrobials, and the later three many require immunomodulatory therapies, such as high-dose corticosteroids, Intravenous Immunoglobulin (IVIG), plasmapheresis, and/or chemotherapeutic agents, such as cyclophosphamide or rituximab. CNS vasculitis, leptomeningeal carcinomatosis, and, rarely, demyelinating disorders, may warrant consideration.

Treatment

The initial approach to the seizing patient includes the principles outlined previously in this Chapter, under “Neurologic Resuscitation,” in addition to the cessation of seizure activity, whether it is clinical or electrographic.

Benzodiazepines (BZP) are the first line treatment for SE. When intravenous (IV) access is immediately available, lorazepam (LZP) 4 mg IV is the

preferred agent, which may be repeated once, with a success rate of approximately 60%. If an IV is not established, midazolam (MDZ) 10 mg IM has been shown to be noninferior to LZP. Other alternatives include diazepam (DZP) 20 mg per rectum, DZP 10 mg IV, buccal MDZ, or intranasal MDZ.

All patients in SE should be given a second AED. Commonly selected agents include phenytoin (PHT), fosphenytoin (fPHT), valproate (VPA), levetiracetam (LEV), and phenobarbital. If noncompliance with an already prescribed AED is known, it is prudent to reintroduce their home AED. If seizure activity has appeared to clinically resolve and twenty minutes have passed without improvement in their level of consciousness (LOC), continuous video electroencephalogram (ccEEG) should be initiated to exclude NCSE/NCSz.

PHT, while effective, has several drawbacks. If infused too rapidly it can cause heart block, cardiac arrhythmias, hypotension, and cutaneous reactions, including Stevens-Johnson syndrome. fPHT, the

prodrug of PHT, is less liable to produce hemodynamic instability during its infusion. PHT is highly protein bound (with free drug providing the clinical activity) displacing other protein bound medications and it induces cytochrome p450 enzymes CYP3A and CYP2C, leading to a variety of drug interactions, particularly in the critically ill patient. [Table 48A–1R](#) provides further information on dosing and serum levels.

Limited evidence suggests VPA is likely to be as efficacious as, if not superior to, PHT as a second line agent for SE. Limitations include its potential hepatotoxicity, pancreatitis, CYP2C9 inhibition, and antiplatelet effects, making it unattractive in intracranial hemorrhages. Total and free levels can be monitored. It uncommonly causes hyperammonemic encephalopathy (independent of any hepatic toxicity), which can be treated with L-carnitine, although its efficacy in this regard is questionable. LEV is an attractive option due to its lack of

TABLE 48A–1R Second line antiepileptic drug dosing and serum levels.

AED	Loading Dose (IV)	Postload Level Timing	Maintenance Dose	Trough Level	Level Correction ^a	Toxicities and Interactions
PHT	20 mg/kg	1 hour	5-7 mg/kg/d Q8H, adjust based on trough levels	Total: 15-25 mg/L Free: 1.5-2.5 mg/L	PHT/ ((Adj x Alb) +0.1) ^b	Cardiac arrhythmias, hypotension with infusion; purple glove syndrome, SJS, CYP450 inducer
fPHT	20 PE/kg	2 hours	5-7 PE/kg/day Q8H adjust based on trough levels	Same as PHT	Same as PHT	Same as PHT, but safer infusion
VPA	40 mg/kg up to 3 gm	4-6 hours	30-60 mg/kg/day Q12H	Total: 80-120 ug/mL Free: 7-23 ug/ mL	None clearly agreed on	Hyperammonemia, hepatotoxicity, pancreatitis, anti-platelet, inhibits
LEV	30-60 mg/kg up to 4.5 g	n/a	2-6 g/d Q12H	Not usually obtained ^c	n/a	Minimal
PHB	20 mg/kg	n/a	1-4 mg/kg/d PO/ IVQ12H	30-50 mg/L	n/a	Hypotension, respiratory depression, over sedation, CYP450 inducer

AED, antiepileptic drug; PHT, phenytoin; fPHT, fosphenytoin; VPA, valproic acid; LEV, levetiracetam; PHB, phenobarbital; Adj, adjustment; Alb, albumin; SJS, Steven’s Johnson syndrome; Q8H, every 8 hours; Q12H, every 12 hours.

^aCorrected for protein binding.

^bAdj = 0.2, unless creatinine clearance < 20 = 0.1.

^cTypical therapeutic level 25 to 60 mcg/mL in SE/RSE.

TABLE 48A–1 S Continuous infusion anesthetics for RSE and SRSE

Anesthetic	Loading Dose	Maintenance Infusion Rate
MDZ	0.2 mg/kg IV, repeat Q5 min until Szs stop (max 2 mg/kg)	Start at 0.2 mg/kg/h and increase by 0.2 with every bolus, up to 2.7 mg/kg/h
PTB	5mg/kg IV, repeat Q5 min until Szs stop or BS achieved (max 15 mg/kg)	Start at 1.0 mg/kg/h and increase by 0.5-1.0 mg/kg, max 10 mg/kg/h
PRO	2 mg/kg IV, repeat Q5 min until Szs stop or BS achieved (max 10 mg/kg)	Start 1 mg/kg/h, max 10 mg/kg/h ^a
KET	0.5-2.0 mg/kg, repeat Q5 min until seizures stop (max 4.5 mg/kg)	Start 1.2 mg/kg/h and increase by 0.6 mg/kg/h, up to 6 mg/kg/h

MDZ, midazolam; PTB, pentobarbital; PRO, propofol; KET, ketamine; Szs, seizures; BS, burst suppression.
^aIf on PRO for more than 48 hours, max rate is 5 mg/kg/h to reduce risk of propofol-related infusion syndrome (PRIS).

life-threatening adverse reactions. Limited available evidence suggests that is has some ef cacy in SE, but how that compares with VPA or PHT is unclear.

If seizures persist despite administration of first and second line AEDs, the patient is considered to be in RSE, and a continuous infusion of an anesthetic (cIV) should be initiated and placed on cvEEG. Options include midazolam (cIV-MDZ), PRO, and pentobarbital (PTB). [Table 48A–1S](#) outlines dosing of these agents. All of these agents are liable to cause hypotension, so a vasopressor should be prepared and euvolemia ensured. The target for their therapy has not yet been agreed upon, as some centers will increase the dose to achieve burst suppression and others will simply abolish clinical and electrographic seizure activity. The literature is not

strong enough to definitely recommend one agent or strategy over another.

In parallel to the cIV, all current AED dosing should be optimized and a third AED can be considered, with lacosamide (LCS) and topiramate (TOP) being the most common third line agents. LCS is a new AED whose primary reported side effect is PR-prolongation. TOP is only given enterally and causes a metabolic acidosis by inhibiting carbonic anhydrase. See [Table 48A–1T](#) for a list of other candidate AEDs and therapies for RSE.

Patients that recrudescence into SE after having been adequately treated with cIV are in malignant or super RSE. When this occurs, either the same or an alternative cIV is reinitiated and the goal (burst or seizure suppression) is lengthened by another

TABLE 48A–1 T Fourth line therapies for RSE and SRSE

Aeds and Other Medications		Immunomodulatory	Other Interventions
Lacosamide	Pregabalin Gabapentin	High-dose Corticosteroids ^a	Mild hypothermia (33°C)
Topiramate	Inh anesthetics	IVIg ^b	Ketogenic diet
Perampanel	Etomidate	Plasmapheresis (PE) ^c	ECT
Carbamazepine	IVmagnesium	Cyclophosphamide ^d	Neurosurgical resection
Oxcarbazepine	IVpyridoxine	Rituximab ^d	VNS
Zonisamide	Lidocaine	ACTH	DBS
Clobazam	Verapamil		TMS
Lamotrigine			

ECT, electroconvulsive therapy; AEDs, antiepileptic drugs; VNS, vagal nerve stimulation; TMS, transcranial magnetic stimulation; DBS, deep brain stimulation; ACTH, adrenocorticotrophic hormone; Inh, inhaled.

^aCommon dose is 1 g methylprednisolone IVQ24 for 3 to 5 doses.

^bIntravenous immunoglobulin, dosing is 0.4 g/kg/d for 5 days.

^cNo agreed upon regimen; often PE on days 1, 2, then every other day for total of 5 to 7.

^dThese agents are selected when an autoimmune or paraneoplastic process have been diagnosed as the etiology of the RSE/SRSE.

24 hours or longer. Small case series have suggested using a continuous infusion of KET in combination with cIV-MDZ or PTB may provide an incremental improvement in efficacy.

As more experience with cvEEG grows, further insight into the significance of different patterns has been to develop. Periodic epileptiform discharges of varying arrangements are often seen in the comatose patient, and particularly after SE. Certain characteristics of these patterns may raise concern for persistent epileptic activity, especially if the patient remains comatose. In this instance, some centers advocate for attempting a cIV or a BZP trial. The latter involves giving small doses of MDZ in rapid succession and observing the patient for a clinical improvement in association with an improvement in the pattern on the EEG. If the EEG improves, but the patient does not, the result is equivocal.

NEUROMUSCULAR DISORDERS

Neuromuscular disorders are a cohort of diseases (NMDz) that result in skeletal muscle weakness, but

differ in their pathophysiology and anatomic localization. The spinal anterior motor neurons, nerve roots, peripheral nerves, neuromuscular junction, and muscles are all potential sites of the different maladies (Table 48A–1U). Intensive care admission is required for those with respiratory failure, significant bulbar dysfunction requiring frequent respiratory care, unstable cardiac arrhythmias, or rapidly progressive symptoms.

More common NMDzs are Guillain-Barré syndrome (GBS), myasthenia gravis (MG), amyotrophic lateral sclerosis, and Duchenne muscular dystrophy (DMD); whereas, Lambert-Eaton myasthenic syndrome (LEMS), botulism, tetanus, porphyria, and diphtheria are less frequent. Neurotoxins can also cause neuromuscular weakness (eg, organophosphates). Chronic NMDz may lead to restrictive pulmonary disease from kyphoscoliosis.

Respiratory failure is due to bulbar muscle weakness resulting in aspiration and compromised upper airway patency and respiratory muscle weakness resulting in atelectasis causing hypoxemia, hypoventilation causing hypercarbia, and a weak cough that impairs alveolar recruitment

TABLE 48A–1U Neuromuscular disease anatomic location of pathology.

Disease	Spinal Cord	Anterior Horn Cells	Peripheral Nerve	Neuromuscular Junction	Muscle

FIGURE 48A–6 Effects of decreasing vital capacities secondary to neuromuscular diseases.

and airway clearance. Respiratory function can be tracked clinically by assessing forced vital capacity (FVC) (ie, the largest volume of air that a patient can exhale), which is a composite measure of inspiratory and expiratory respiratory muscle strength (Figure 48A–6). FVC of less than 20 mL/kg warrant ICU monitoring, while those of less than 10 to 15 mL/kg typically require ETI. Beware of dogmatic statements that mandate intubation for FVC values only; ETI is still a clinical assessment. Noninvasive positive pressure ventilation (NIPPV) and/or high-flow nasal cannula can be considered for the management of mild to moderate respiratory symptoms. FVC values do not provide insight into the quality of secretion clearance or upper airway obstruction, which are more subjective in assessment and must be considered in ETI decisions. Other measures of respiratory function include the negative inspiratory force (also called the maximal inspiratory pressure) and the maximal expiratory pressure or force, which have not been shown to provide any incremental value over FVC. Cough peak flow can be measured by standard peak flow meter and values of less than 270 L/min in an adult suggests inappropriate

clearance of secretions, while results of less than 160 L/min identify profound weakness.

Cardiac complications of NMDz include arrhythmias, autonomic dysfunction (AD), and myopathy. AD is seen in about one quarter of GBS patients and is often provoked by endotracheal suctioning, ETI, or NIPPV. The AD maybe paradoxical and is characterized by severe hypertension, labile BP, postural hypotension, facial flushing, bradycardia, tachycardia, and possible asystole. Patients with SMA may suffer from cardiomyopathy and bradyarrhythmias. AD is much less common in MG patients. Patients with DMD are at increased risk for CA and rhabdomyolysis. Anesthesia-related sudden death and congestive heart failure have well been reported. Patients with myotonic dystrophy may present with cardiac conduction abnormalities such as first degree and paroxysmal complete heart blocks.

The use of NMBs in NMDzs warrants some caution. Nondepolarizing NMBs may lead to prolonged diaphragmatic paralysis with extended need for ventilatory support and smaller doses are suggested. Hyperkalemia is more likely with depolarizing NMBs (eg, succinylcholine), and therefore

is best avoided. Additionally, muscular dystrophy patients are at risk for rhabdomyolysis and malignant hyperthermia-like reactions. Frequently encountered gastrointestinal problems included dysphagia, delayed gastric emptying, gastrointestinal dysmotility which are all associated with nutritional impairment.

Critical Care of Cerebrovascular Disease

48B

Christopher Zammit, MD; Ko Eun Choi, MD and Axel Rosengart, MD, PhD, MPH

KEY POINTS

- 1 Stroke is the leading cause of disability and fourth cause of death in the United States. Of the 800,000 annual strokes in the United States, 85% are acute ischemic strokes (AIS).
- 2 Intensive care issues pertinent to the care of AIS include the recognition and diagnosis of stroke, the provision of fibrinolytics and/or endovascular management, as well the medical management in the 24 hours posttreatment, and management of cerebellar or large hemispheric infarcts (LHIs).
- 3 Clinical symptoms of stroke are highly heterogeneous and variable and are objectively scored using the National Institutes of Health Stroke Scale (NIHSS).
- 4 Intravenous recombinant tissue plasminogen activator (IV-rtPA) should be administered as soon as possible to all patients with AIS who meet inclusion/exclusion criteria.
- 5 Endovascular treatment (EVT) is recommended in AIS patients with an internal carotid artery (ICA) or M1 occlusion who are more than 17 years of age, receiving IV-rtPA and have a prestroke modified Rankin Score (mRS) of 0 to 1, NIHSS greater than 5, and Alberta stroke program early computed tomography score (ASPECTS) greater than 5, and who can have EVT initiated (ie, groin puncture) within 6 hours of their last known well time.
- 6 During and after the administration of reperfusion therapy (IV-rtPA or endovascular), blood pressure (BP) parameters must be vigilantly maintained ($< 180/105$ mm Hg). All antiplatelet and anticoagulant medications are held for at least the first 24 hours. Aspirin should be provided 24 hours after IV-rtPA or EVT if the patient is neurologically stable and neuroimaging does not demonstrate hemorrhagic conversion of the infarct.
- 7 The management of LHI includes therapies aimed to minimize the development of cerebral edema and identifying candidates for decompressive hemicraniectomy (DC).
- 8 Surgical options in the management of intracerebral hemorrhage (ICH) include craniotomy with or without clot evacuation and, in the setting of obstructive hydrocephalus due to intraventricular hemorrhage, the placement of an intraventricular catheter.
- 9 Treatment goals for patients with subarachnoid hemorrhage in the first 6 hours include BP control, cardiopulmonary stability, correction of symptomatic hydrocephalus, treatment of intracranial hypertension, reversal of herniation syndromes, and consideration of antifibrinolytics.

ACUTE ISCHEMIC STROKE

Stroke is the leading cause of disability and fourth greatest cause of death in the United States. Of the 800,000 annual strokes in the United States, 85% are acute ischemic strokes (AIS). The remaining 15% are intracerebral hemorrhage (ICH) or subarachnoid hemorrhage (SAH). Intensive care issues pertinent to the care of AIS include the recognition and diagnosis of stroke, the provision of fibrinolytics and/or endovascular management, as well the medical management in the 24 hours posttreatment, management of cerebellar or large hemispheric infarcts (LHIs), and considerations in the management of a critical stenosis of a cervical arterial vessel.

History and Physical Examination

AIS is the result of a sudden loss of blood flow within a vascular region of the brain, retina, or spinal cord due to arterial vessel occlusion. The flow is most often compromised by the development of an atherosclerotic clot (ie, thrombosis) or sudden occlusion by a clot from a distant source (ie, embolism). The contemporary definition includes imaging findings of an acute infarction, even if clinical symptoms are not observed. Clinical symptoms of stroke are highly heterogeneous and variable (Table 48B–1) and are objectively scored using the National Institutes of Health Stroke Scale (NIHSS) (Table 48B–2). Presentations associated with a delay in stroke diagnosis included mild symptoms (NIHSS < 4), severe symptoms (NIHSS > 25), strokes affecting multiple vascular territories, isolated aphasia,

posterior circulation symptoms, and young age. Symptoms typically begin suddenly, but a stuttering presentation can be seen in the setting of a partially occluded large vessel. The patient's last known well time (LKWT, ie, when they did not have any stroke symptoms) must be aggressively, thoroughly, and creatively sought (eg, using last social media interaction).

The physical examination is focused on cataloging a very accurate NIHSS, exploring for etiologies of stroke mimics, and findings suggestive of contraindications to intravenous (IV) thrombolysis (eg, scar from recent surgery).

Diagnostics

The ideal diagnostic approach utilizes lean processing, with a prioritization of diagnostics that are critical for the decision to offer thrombolysis with IV recombinant tissue plasminogen activator (IV-rtPA) (see treatment, later). A list of comprehensive diagnostics is found in Table 48B–3. Critical immediate diagnostics are a blood glucose and noncontrast head computed tomography (NCHCT) to rule out hypoglycemia and an intracranial hemorrhage, respectively. The remaining diagnostics should be immediately obtained, but stroke specialists will not uncommonly make decisions to offer IV-rtPA based on patient-related factors, rather than waiting for the results. This is to hasten the provision of thrombolysis, as a 15-minute delay in treatment is associated with worsened outcomes, even if within 3 hours of symptom onset and within an hour of hospital presentation.

The timing of CT angiography (CTA) of the head and neck, CT perfusion, and/or magnetic resonance imaging (MRI) is dependent on local protocols and patient specific conditions. The acquisition of these images should never delay the administration of thrombolysis. A diagnosis of AIS is most commonly confirmed using MRI through interpretation of the diffusion-weighted imaging (DWI) and apparent diffusion coefficient (ADC) sequences. An acute stroke (< 7 days) has occurred when a specific region of the brain is bright (hyperintense) on DWI and dark on ADC. Magnetic resonance angiography (MRA) is also able to characterize the cerebral and cervical vasculatures.

TABLE 48B–1 Common signs and symptoms of acute ischemic stroke.

- Hemiparesis, monoparesis, or (rarely) quadriparesis (in brainstem stroke)
- Hemisensory deficits
- Monocular or binocular visual loss
- Visual field deficits
- Diplopia
- Dysarthria
- Facial asymmetry
- Ataxia
- Vertigo (rarely in isolation)
- Aphasia
- Sudden decrease in the level of consciousness

TABLE 48B–2 National institutes of health stroke scale (NIHSS).

Item	Category	Description	Score Range
1a	Level of consciousness (LOC)	Alert, drowsy, stuporous, coma	0-3
1b	LOC questions (month, age)	Answers both, one, or none correctly	0-2
1c	LOC commands (open and close eyes, grip and release hand)	Obeys both, one, or none	0-2
2	Best gaze	Normal, partial palsy, forced deviation	0-2
3	Best visual (visual fields)	Normal, partial hemianopia, complete hemianopia, bilateral hemianopia	0-3
4	Facial palsy	Normal, minor, partial, complete	0-3
5a	Motor arm, left	No drift, drift, some effort against gravity, no effort against gravity, no movement	0-4
5b	Motor arm, right	No drift, drift, some effort against gravity, no effort against gravity, no movement	0-4
6a	Motor leg, left	No drift, drift, some effort against gravity, no effort against gravity, no movement	0-4
6b	Motor leg, right	No drift, drift, some effort against gravity, no effort against gravity, no movement	0-4
7	Limb ataxia	None, present in one limb, present in both	0-2
8	Sensory	Normal, mild to moderate loss, severe to complete loss	0-2
9	Best language	No aphasia, mild to moderate aphasia, severe aphasia, mute with global aphasia	0-3
10	Dysarthria	Normal, mild to moderate dysarthria, severe dysarthria	0-2
11	Extinction and inattention	No neglect, partial, complete	0-2
Total		n/a	0-42

Data from National Institute of Health (NIH).

Treatment

Acute treatment of AIS consists of restoring blood flow to the compromised neuronal tissue. The first step is to determine eligibility for thrombolysis with IV-rtPA, which should be administered as soon as possible to all patients that meet inclusion/exclusion criteria (Table 48B–4) at a dose of 0.9 mg/kg, maximum dose 90 mg, with 10% bolused over 1 minute, and the remainder dripped over 1 hour. If possible, consent should be obtained, although if the patient is unable to consent and a legal representative is not available, IV-rtPA should be administered, as the benefits outweigh the risks of treatment and

the degree of benefit is time-dependent. If a stroke mimic (ie, neurologic change concerned for AIS) is suspected, but cannot be definitely determined, and no contraindications exist, IV-rtPA administration should not be delayed.

AIS secondary to large vessel occlusions (LVOs), particularly those with large clots (> 8 mm), respond poorly to IV-rtPA alone. Recent randomized controlled trials (RCTs) have concluded that endovascular treatment (EVT) of AIS improves outcomes in those with anterior circulation LVOs (ie, internal carotid artery [ICA] terminus and middle cerebral artery [MCA] M1). Identification and selection of candidates for this therapy can involve clinical

TABLE 48B–3 Acute ischemic stroke diagnostics.

On Presentation	During Admission
<ul style="list-style-type: none">• Finger stick blood glucose• Complete blood count• Basic metabolic panel• PT/INR/aPTT• Pregnancy test• Troponin• Electrocardiogram• Chest X-ray• Noncontrast head CT• CT angiography head and neck^a• CT perfusion head^a	<ul style="list-style-type: none">• Hgb a1c• Lipids• Thyroid studies• Transthoracic echocardiography (TTE) with bubble study• Cervical and intracranial vessel imaging (MRA, CTA, DSA, or Carotid Dopplers^b)• Hypercoagulability panel^c• Cardiac MRI^c• Transesophageal echocardiography^c• IEDopplers/CTpulmonary Angiography^d• Rheumatologic work up^e• CSF studies^e

MRA, magnetic resonance angiography; CTA, computed tomography angiography; DSA, digital subtraction angiography; CSF, cerebrospinal fluid.

Bold and italics: Most critical diagnostics for IVrtPA decision making. Other studies are required in the appropriate clinical context or when possible contraindication to IVrtPA is suspected based on history, medical record review, and physical examination.

^aConsult your institutional/regional protocols or stroke team for the role and timing of CT angiography and perfusion studies in AIS. These are critical diagnostics routinely utilized in acute decision making in AIS.

^bCTA or MRA are preferred over carotid Dopplers, when possible.

^cOften performed in those less than 50 years with AIS of unknown etiology.

^dConsider in those with a positive bubble study on TTE and unknown AIS etiology.

^ePerformed in those with AIS presumed or suspected to be due to primary or secondary central nervous system vasculitis.

assessment, CTA, or MRA. The administration of IV-rtPA should never be delayed for the acquisition of angiography. Based on these new data, American Heart Association/American Stroke Association (AHA/ASA) AIS guidelines now make the class 1 recommendation that EVT should be provided to AIS patients with an ICA or M1 occlusion who are more than 17 years of age, receiving IV-rtPA and have a prestroke modified Rankin Score (mRS) of 0 to 1 (see [Table 48B–5](#)), NIHSS greater than 5 ([Table 48B–2](#)), and Alberta stroke program early CT score (ASPECTS) greater than 5 (see [Table 48B–6](#)), and who can have EVT initiated (ie, groin puncture) within 6 hours of their LKWT. Patients should never be observed for a response to IV-rtPA who meet the indications for EVT. As with IV-rtPA, time to

endovascular recanalization has been shown to be a predictor of outcomes.

Of note, the first 3 endovascular trials did not find a benefit, which has been attributed to the poor recanalization rates with the early generation devices. The 5 most recent RCTs, all of which were positive, used newer generation stent retrievers that achieve a much higher rate of vessel recanalization. Although the strongest recommendations were made for those with a mRS of 0 to 1, NIHSS of greater than 5, and ASPECTS of greater than 5, those that fail to meet these criteria should not be interpreted as having an absolute contraindication to EVT. Rather, a class IIb recommendation was issued that it may be reasonable to acutely revascularize some patients with a M1 or ICA occlusion within 6 hours of LKWT, who do not meet all of the ASPECTS, NIHSS, and mRS criteria. More distal MCA (M2, M3), anterior cerebral artery (ACA), basilar artery, and posterior cerebral artery (PCA) occlusions can also be considered for EVT, but the degree of benefit is less certain, as they were either less prevalent or not included in the recent RCTs. Lastly, patients with contraindications to IV-rtPA, but within the 6-hour time window, can be considered for acute EVT (eg, international normalized ratio [INR] > 1.7).

During and after the administration of reperfusion therapy (IV-rtPA or endovascular) the patient requires frequent reassessment, with careful attention to their neurologic status and blood pressure (BP). BP parameters must be vigilantly maintained (< 180/105). All antiplatelet (AP) and anticoagulant (AC) medications are held for at least the first 24 hours. Aspirin, which has been shown to reduce stroke reoccurrence and mortality, should be provided 24 hours after IV-rtPA or EVT if the patient is neurologically stable and neuroimaging does not demonstrate hemorrhagic conversion of the infarct. In some circumstances, BP targets may be more strict after EVT with full revascularization (thrombolysis in cerebral infarction 3 or 2b flow).

BP targets in patients not receiving IV-rtPA are less clear. Current guidelines support gentle BP reduction if the systolic BP (SBP) greater than 220 mm Hg or the diastolic BP is greater than 120 mm Hg. If performed, a modest goal should be set, so as to avoid expanding the infarct by hypoperfusing penumbral tissue, particularly in those with untreated LVOs.

TABLE 48B–4 Inclusion/exclusion criteria for intravenous recombinant tissue plasminogen activator in acute ischemic stroke.

Inclusion Criteria
<ul style="list-style-type: none">• Diagnosis of ischemic stroke causing measurable neurologic deficit• Neurologic signs not clearing spontaneously to baseline• Neurologic signs not minor and isolated^a• Symptom onset less than 4.5 hours from initiation of IVrtPA (see below additional exclusion criteria for the 3.0-4.5 hour window)
Exclusion Criteria
<p>History and physical</p> <ul style="list-style-type: none">• Symptoms suggest subarachnoid hemorrhage• Significant head trauma or prior stroke in the previous 3 months• Arterial puncture at noncompressible site in previous 7 days• History of previous intracranial hemorrhage• Intracranial neoplasm, AVM, or aneurysm• Recent intracranial or intraspinal surgery• Elevated blood pressure (systolic >185 mm Hg or diastolic >110 mm Hg)• Active internal bleeding• Stroke suspected to resulting from a septic embolus (eg, infective endocarditis^a) <p>Laboratory investigations</p> <ul style="list-style-type: none">• Platelet count less than 100,000/μL• Heparin received within 48 hours with aPTT above the upper limit of normal• Current use of Vitamin KAntagonist with INR>1.7 or PT>15 s• Current use of direct thrombin inhibitors or direct factor Xa inhibitors with elevated sensitive laboratory tests (eg, aPTT, INR, platelet count, ECT, TT, or appropriate factor Xa activity assays)• Blood glucose concentration less than 50 mg/dL (2.7 mmol/L) <p>Imaging findings</p> <ul style="list-style-type: none">• Head CT demonstrates multilobar infarction (hypodensity >1/3 cerebral hemisphere)
Relative Exclusion Criteria
<ul style="list-style-type: none">• Minor or rapidly improving stroke symptoms• Pregnancy• Seizure at onset with postictal residual neurological impairments• Major surgery or serious trauma within previous 14 days• Gastrointestinal or urinary tract hemorrhage within previous 21 days• Acute myocardial infarction within previous 3 months
Exclusion Criteria for the 3 to 4.5 hour Time Window
<ul style="list-style-type: none">• More than 80 years of age• Use of oral anticoagulants, regardless of the INR• Baseline NIHSS score of more than 25• History of stroke and diabetes

^aThe threshold for treatment is not based on the score on the NIHSS. Rather it is a subjective determination of the functional impact of the deficit on the patient’s outcome.
Data from Demaerschalk BM, Kleindorfer DO, Adeoye OM, et al: Scientific Rationale for the Inclusion and Exclusion Criteria for Intravenous Alteplase in Acute Ischemic Stroke, Stroke 2016 Feb;47(2):581-641.

Large Hemispheric Infarction

AIS secondary to the occlusion of a cervical or large proximal intracranial vessel, such as the carotid terminus (ICA-t) or MCA, is termed LHI. Although LHIs only account for 10% of all AIS, their mortality

rate is 15% to 80% and the majority of survivors have significant disability. Clinical manifestations include hemiparesis, homonymous hemianopsia, ipsilateral gaze deviation, aphasia (usually with left LHIs), and agnosia and left-sided neglect (with right LHIs).

TABLE 48B–5 Modified rankin scale.

Score	Clinical Symptoms
0	No symptoms at all
1	No significant disability despite symptoms; able to carry out all usual duties and activities
2	Slight disability; unable to carry out all previous activities, but able to look after own affairs without assistance
3	Moderate disability; requiring some help, but able to walk without assistance
4	Moderately severe disability; unable to walk without assistance and unable to attend to own bodily needs without assistance
5	Severe disability; bedridden, incontinent, and requiring constant nursing care and attention
6	Dead

The large area of infarcted brain tissue produces substantial clinical defects at ictus. Over the following 24 to 96 hours (and less commonly up to 10 days) cytotoxic edema (CE) develops, causing the tissue to enlarge, which then compresses, distorts, and herniates neighboring uninfarcted tissues. Unaffected cerebral vessels can be pinched or kinked by the herniating infarcted brain, expanding the territory of infarction.

The first clinical sign of cerebral edema is a decline in the level of arousal. This is followed by ipsilateral or contralateral leg weakness (due to compression of the anterior cerebral artery in the setting of subfalcine herniation). Alternatively or later, findings of uncal herniation (see Chapter 48A—Principles of Neurosciences Critical Care) are seen, during which time the PCA may be compressed expanding the area of infarction. The lateral forces may also compress the third ventricle, producing an obstructive hydrocephalus and its associated symptoms.

The management of LHI includes therapies aimed to minimize the development of CE and identifying candidates for decompressive hemicraniectomy (DC). Strategies that mitigate CE include keeping the head of bed elevated to 30° and the neck in a neutral position, avoiding hypervolemia, and maintaining normothermia, normonatremia,

TABLE 48B–6 Alberta stroke program early CT score (ASPECTS).

Region	Anatomic Location	Head CT Level
C	Caudate head	
LN	Lentiform nuclear or putamen	
IC	Posterior limb of internal capsule	
I	Insular cortex	Third ventricle
M1	Frontal operculum (anterior MCA territory)	
M2	Anterior temporal lobe (lateral to insula)	
M3	Posterior temporal lobe	
M4	Anterior MCA, superior to M1	
M5	Lateral MCA, superior to M2	Lateral ventricles, superior to third ventricle
M6	Posterior MCA, superior to M3	

This score is for anterior circulation ischemic strokes and is used to quantify the amount of territory with ischemic changes on a noncontrast Head CT (NCHCT). Starting from a score of 10 (signifying a NCHCT without ischemic changes) one point is deducted for each of the above areas with ischemic changes (ie, hypodense). Scores of more than 6 are associated with better outcomes. Most recent endovascular treatment trials required a score of more than 5, but there is some evidence that even those with a score of more than 3 may derive benefit from revascularization.

normoglycemia, and normocarbia. The infusion of dextrose containing and hypoosmotic solutions must not occur.

Empiric administration of hyperosmotic solutions is not an uncommon practice, but evidence is lacking to support its efficacy. Aggressively maintaining the serum blood glucose below 125 mg/dL may lead to an increase in infarct size, so a goal of 140 to 180 mg/dL is recommended. Seizure prophylaxis is not indicated, but continuous video electroencephalogram (cvEEG) monitoring can be considered, particularly in patients with fluctuations in mental status. Corticosteroids do not have a proven role in the management of LHI. Dual AP therapy and therapeutic anticoagulation should be held, but subcutaneous heparin or low-molecular-weight heparin

should be used for venous thromboembolism (VTE) prophylaxis.

Unfortunately, the available evidence is not able to fully predict which patient is going to have cerebral edema. Intracranial pressure (ICP) monitoring is of limited utility and is not typically performed. Instead the neurologic examination is performed at frequent, regular intervals. Older patients have some degree of cerebral atrophy; therefore they are less likely to deteriorate even if cerebral edema occurs, while the opposite holds true for the younger patient. Risk factors for cerebral edema and subsequent neurologic deterioration include female gender, nausea and vomiting on presentation, congestive heart failure, history of hypertension, leukocytosis, and initial NIHSS greater than 20 in dominant LHI or greater than 15 in nondominant LHI. Neuroimaging findings suggesting increased risk are summarized in [Table 48B–7](#).

In the event that hemispheric swelling occurs causing symptomatic neurologic deterioration, the initial response is to provide therapies that reduce

cerebral edema, such as bolus hyperosmolar therapy (eg, 30 mL of 23.4% hypertonic saline or 1-1.5 mg/kg of 20% mannitol). See [Chapter _____](#) for further guidance on the management of cytotoxic cerebral edema/intracranial hypertension. Ultimately, 70% to 80% of patients will die with maximal medical therapy in the absence of early surgical intervention (ie, DC).

Five randomized control trials have explored the efficacy of early DC in LHI. Overall results demonstrate a reduction in mortality (from ~70% to ~20%) and an improvement in functional outcomes in those 18 to 60 years of age. A recent trial demonstrated a similar reduction in mortality in older patients (61-82 years of age), although functional outcomes were not improved. When a DC is performed it should create a bony window of greater than or equal to 12 cm in the anterior-posterior dimension, with a medial border 1 cm lateral to the superior sagittal sinus and inferior border at the floor of the middle cranial fossa. The dura is then opened with cruciate incision (ie, durotomy). Although the timing

TABLE 48B–7 Neuroimaging findings associated with an increased risk of neurologic deterioration in large hemispheric infarction.

Imaging	Timing	Finding
MRI DWI sequence	6 hours after onset	Infarct > 80 mL
MRI DWI sequence	Within 14 hours of onset	Infarct > 145 mL
NCHCT	Within 6 hours of onset	Frank hypodensity > 1/3 of MCA territory
NCHCT	Admission	Dense MCA
NCHCT	Within 48 hours of onset	MLS > or = 5 mm
NCHCT or MRI	Any point	Involvement of multiple vascular territories
NCHCT or MRI	Any point	Infarct of 50% of MCA territory
NCHCT or MRI	Any point	MCA infarct involves the basal ganglia
CTA head, MRA head, catheter angiography	Any point	Occlusion at the carotid terminus
CTA head, MRA head, catheter angiography	Any point	Incomplete circle of Willis
CTA head or catheter angiography	Any point	Marginal leptomeningeal collaterals

MRI DWI, magnetic resonance imaging diffuse weighted imaging; NCHCT, noncontrast head CT; MCA, middle cerebral artery; MLS, mid-line shift; CTA, CT angiography; MRA, magnetic resonance angiography.

of DC was not uniform among the published data, a consistent benefit was seen if it was performed within 48 hours of stroke onset in those experiencing neurologic deterioration. It is uniformly felt that once deterioration occurs, DC should be performed promptly, as unreversed herniation will produce irreversible brainstem injury. Although the evidence for its efficacy is not clear more than 48 hours after stroke onset, it is similarly felt that if deterioration occurs, benefits are likely to be seen.

When considering DC, patients and families must be aware that the procedure is not restorative. That is, it is a lifesaving procedure that may help reduce the degree of loss in functionality in the young patient (< 60 years of age), while strictly striving to save the life of the older patient, who will most likely be left moderately to severely disabled at 12 months (ie, mRS of 4 or 5, see Table 48B–5.) It is best to inform the patient and family of their possible candidacy for the procedure on admission to the ICU. That way if deterioration does occur, they will not be forced to make a hasty decision under duress. Furthermore, neurosurgery should be engaged on admission to avoid unnecessary procedural delays in the event of neurologic deterioration.

Cerebellar Infarctions

Similar to LHI, cerebellar strokes are subject to swelling and mass effect leading to herniation. Although they are smaller infarcts, their infratentorial location and juxtaposition to the fourth ventricle lends less room for their growth. Small increases in volume can compress the fourth ventricle, producing obstructive hydrocephalus. Further swelling will directly compress the brainstem.

As with LHI, similar measures to reduce the likelihood of swelling apply. If neurologic deterioration occurs, ICP lowering therapies can temporarily reverse the mass effect of the swelling, but ultimately surgical intervention is required. Obstructive hydrocephalus from fourth ventricular obstruction is often addressed with the placement of an external ventricular drain (EVD), but this will cause the swollen cerebellum to herniate upward, compressing and kinking the brainstem, producing local ischemia and potentially infarction of the midbrain and pons. Therefore, a suboccipital craniectomy (SOC) should be performed immediately after or

simultaneously with EVD placement, which will allow for the swollen cerebellum to temporarily herniate extracranially. In contrast to LHI, nearly 3/4 of patients with large cerebellar infarcts will have very good outcomes.

INTRACEREBRAL HEMORRHAGE

ICH, also referred to as “hemorrhagic stroke,” constitutes approximately 15% of all strokes and has an incidence of approximately 25 cases per 100,000 person-years. When compared with AIS of similar presenting severity, the mortality and long-term morbidity of ICH is greater. Management of ICH includes measures to prevent further hematoma expansion, mitigate and treat cerebral edema, prevent further neurologic deterioration, and provide excellent supportive care. Although ICH carries a high morbidity and mortality, decisions on the withdrawal of life sustaining therapy (WLST) and early do-not-resuscitate (DNR) have been found to contribute greatly to outcomes. Prognostication is difficult and ambivalent cases with supportive and willing surrogate decision makers should be allowed time to declare their outcomes, in lieu of the early implementation of WLST.

History and Physical Examination

Those presenting with a headache, unexplained nausea and vomiting, or neurologic change may be harboring an ICH. Clinical features commonly seen in, but not specific to ICH, include nausea, vomiting, impaired level of consciousness, severe hypertension, and headache. As with any neurologic emergency, the LKWT must be expeditious ascertained. Patients presenting within 6 hours of symptom onset are much more likely to experience further enlargement of the hematoma. Hematoma volume is predictive of poor outcomes, therefore those presenting quickly after onset may respond favorably to treatments targeting hemostasis. A history of AC or AP use must be obtained.

Diagnostics

Any patient suspected of having an ICH should immediately receive a NCHCT. MRI can also detect

an ICH, particularly when T2*, gradient-recalled echo (GRE), or susceptibility weighted images (SWI) are obtained, but a NCHCT is typically much quicker to obtain. Simultaneous information should be obtained about their hemostatic capacity by obtaining a complete blood count, basic metabolic panel, prothrombin time (PT), INR, and activated partial thromboplastin time (aPTT). Some centers routinely obtain viscoelastic tests, such as thromboelastography, and platelet function assays, but the value of these diagnostics and subsequent therapies targeting their “correction” is as yet unclear.

A critical component of ICH care is determining the etiology of the ICH. Subcortical and pontine ICHs commonly result from hypertension-induced lipohyalinosis of the small perforating arteries in the pons, thalamus, and basal ganglia. Cerebral amyloid angiopathy (CAA) is more common in those more than 70 years of age and involves the cortical regions (lobar ICH). ICHs due to ruptured vascular malformations (arteriovenous malformation [AVM], cavernous, aneurysms, dural arteriovenous fistula [dAVf]) must be promptly identified promptly to allow for prompt surgical interventions that will mitigate rebleeding. Other etiologies are listed in Table 48B–8. CT or MRA is highly sensitive for underlying vascular malformations. Younger patients, those without a history of hypertension or coagulopathy, and females are at greater risk for vascular malformations. The secondary ICH (sICH) score maybe helpful in deciding who should

undergo angiography to rule out an underlying vascular malformation (see Table 48B–9).

CTA may also identify a “spot sign” or evidence of contract extravasation into the hematoma, implying that the hemorrhage is ongoing and the hematoma is enlarging. The clinical utility of this information is as yet unclear. Ongoing trials are exploring the value of administering a prohemostatic agent (either activated factor VIIa [aFVIIa] in STOP-IT and SPOTLIGHT or tranexamic acid [TXA] in the SPOT-AUST) in those with a “spot sign.” Other features on the NCHCT suggestive of hematoma expansion include a heterogeneous appearance of the ICH, larger volumes, and those with ventricular extension.

The volume of ICH can be estimated on NCHCT by applying the $(A \times B \times C)/2$ method, where A represents the maximal diameter on an axial image, B is the diameter perpendicular to A, and C is the height of the ICH, as determined by the number of axial slices the ICH is seen on times the width of the slices. Applying this method on serial images provides a quasiobjective was of assessing for hematoma growth. The severity of the ICH is often quantified by determining the ICH score (see Table 48B–10). This score should not be used to assign outcomes, as its correlation with outcomes worsens when excluding those that have undergone WLST.

Treatment

An immediate treatment goal is to stop further hemorrhaging from occurring, as hematoma size is predictive of poor outcome. In parallel, those with acute neurologic deterioration due to cerebral herniation or mass effect may require craniectomy and/or clot evacuation, while those with symptomatic hydrocephalus due to intraventricular hemorrhage (IVH) may undergo ventricular catheterization.

BP control and reduction is a must to mitigate hematoma expansion. Two large randomized trials have been completed in this realm. Second Intensive Blood Pressure Reduction in Acute Cerebral Hemorrhage Trial (INTERACT-2) randomized ICH patients presenting within 6 hours of onset and a SBP of 150 to 220 mm Hg to a target SBP of less than 140 mm Hg or less than 180 mm Hg (without a prescribed approach). No difference in mortality or adverse effects were seen, but an ordinal analysis

^aNCHCT probability determination:

- High-probability NCHCT either:
 1. Enlarged vessels or calcifications along the margins of the ICH
 2. Hyperattenuation within a dural venous sinus or cortical vein along the presumed venous drainage path of the ICH
- Low-probability NCHCT has both of the following:
 1. No high-probability features
 2. ICH is located in the basal ganglia, thalamus, or brain stem
- Indeterminate NCHCT: does not meet high- or low-probability criteria.

^bAdmission INR more than 3, aPTT more than 80 seconds, platelet less than 50,000, or daily antiplatelet therapy.

found a statistically significant reduction in the mRS (Table 48B–5) in the group targeted to a SBP of less than 140 mm Hg. Based on these data, the subsequent AHA/ASA ICH guidelines published in 2015 were updated to state “for ICH patients presenting with SBP between 150 and 220 mm Hg and without

contraindication to acute BP treatment, acute lowering of SBP to 140 mm Hg is safe (class I; level of evidence A) and can be effective for improving functional outcome (class IIa; level of evidence B).” The most recent RCT of SBP control in ICH, Antihypertensive Treatment of Acute Cerebral Hemorrhage

^aEstimated, insufficient number of cases when described.

(ATACH-2), failed to find any difference in functional outcomes or hematoma growth, but there were more renal adverse events in the intensive control, compared to the conventional control arm (SBP < 140 mm Hg vs < 180 mm Hg, 9% vs 4%, number needed to harm of 20). These conflicting findings may be explained by how the patients in the each arm of ATACH-2 and INTERACT-2 were actually treated, as the conventional treatment arm in ATACH-2 had SBPs lower than the intensive arm in INTERACT-2. In the absence of updated guidelines, the best recommendation based on available data is to lower the SBP to 140 to 150 mm Hg in those presenting with a SBP of 180 to 240 mm Hg. If the SBP is greater than 240 mm Hg, a 25% reduction is a reasonable goal, followed by reassessment for tolerance of a lower SBP. Additionally, a post-hoc analysis of the INTERACT-2 trial found that increasing degrees of BP variability were associated with worse outcomes, suggesting that continuous SBP management is preferred to reactionary maneuvers by using a continuous infusion of an antihypertensive, such as nicardipine, labetalol, or clevidipine.

Acute ICH complicated by ACs or coagulopathy must be provided reversal or prohemostatic therapy immediately and without delay. The time to “reversal” is predictive of outcome, with those achieving their target BP and antithrombotic reversal within 4 hours of onset having the best outcomes. [Table 48B–11](#) provides a summary of ACs and suggested reversal strategies. The impact of APs on outcomes and how they should be managed in ICH is less clear. A recently completed RCT of platelet transfusion for reversal of AP activity in nonvascular supratentorial ICH patients presenting within 6 hours of onset, a history of AP use (aspirin, P2Y₁₂ inhibitor, or adenosine reuptake inhibitor), and not requiring an intraventricular catheter (IVC) or surgery found that not only was platelet transfusion ineffective in reducing hematoma expansion, but it was also observed to worsen outcomes and increase the risk of neurologic deterioration. Therefore, platelet transfusion should not be performed in this subcategory of ICH. [Table 48B–12](#) provides a recommended approach to ICH complicated by AP agents.

After the initial several hours, secondary intracranial and systemic effects are the next layer of

complications that are to be managed. Perihematomal edema develops early, and commonly peaks in the following 4 to 7 days, but atypically courses are seen and can last for upward of a month. Management includes the maintenance of normoglycemia, normothermia, normonatremia, and avoidance of elevated central venous pressures. Fever is associated with worsened outcomes, but temperature control has not been proven to improve outcomes, and maybe associated with longer hospital stays and increased tracheostomy.

Seizures, both convulsive and nonconvulsive, are common in ICH, particularly in those with larger more symptomatic and cortical hemorrhages. Prophylaxis with phenytoin has been associated with, but not causational of, worse outcomes. Guidelines recommend against seizure prophylaxis with antiepileptic drugs, but it is not unreasonable to do so in those at higher risk. A low threshold should be kept for evaluation for nonconvulsive seizures with continuous electroencephalography, particularly in those whose neurologic examination is worse than expected.

Up to one quarter of intubated ICH patients will develop acute respiratory distress syndrome (ARDS), therefore lung protective ventilation should be provided after intubation, as long as normocarbia and ICP can be maintained. Hyperoxia is associated with worsened outcomes in ICH, among other acute brain injuries, therefore normoxia should be targeted at all times, sans the peri-intubation period to prevent hypoxia during airway establishment.

The timing of VTE prophylaxis is not clearly guided by available evidence. Best practice at this time is to initiate pharmacologic VTE prophylaxis with unfractionated or low-molecular-weight heparin 24 hours after demonstrated ICH stability (ie, no further hematoma expansion), assuming there is not underlying coagulopathy. Sequential compression devices should be placed immediately. In the case of a newly diagnosed VTE during the course of care, there is a lack of evidence to advise on when it is safe to initiate therapeutic anticoagulation. A common practice is to wait at least 14, if not 30 days after an ICH. Depending on the etiology of the ICH, the patient may never be a candidate for therapeutic anticoagulation (eg, unsecured vascular etiology or CAA).

TABLE 48B–11 Suggested anticoagulant reversal strategies.

Category	Specific Medications	“Reversal” ^a	Notes
Vitamin K antagonists	Warfarin	Vitamin K 10 mg IV AND 3F- or 4F-PCC ^{b,c}	If PCC unavailable or CI to PCC, then 15-20 mL/kg of FFP
Xa inhibitors (Xa-Is)	Rivaroxaban, Apixaban, Edoxaban	aPCC (FEIBA) or 4F-PCC, 50 units/kg If < 2 hours from last drug ingestion, 50 g of activated charcoal oral	Pre- and post-4F-PCC PT should be obtained. Studies of 4F-PCC administration for Xa-Is demonstrate complete normalization of the PT
Direct thrombin inhibitors (DTI)	Oral competitive inhibitor—Dabigatran IV, reversible inhibitors—Argatroban, Bivalirudin SC, irreversible inhibitor ^{d,*} —Desirudin	For dabigatran ONLY— Idarucizumab 5 g IV ^e If < 2 hours from last drug ingestion, 50 gm of activated charcoal oral Other DTIs ^f	Pre- and post-PTT should be obtained for dabigatran, as with Xa-Is
Unfractionated heparin (UFH)	Heparin (IV and SC)	Protamine 1 mg IV for every 100 units of heparin administered in the previous 2-3 hours	Protamine dosing must be precise, as excess protamine becomes an anticoagulant itself
Low molecular weight heparin (LMWH)	Enoxaparin, Dalteparin, Nadroparin, Tinzaparin, Danaparoid	Enoxaparin w/in 8 hours: Protamine 1 mg IV per 1 mg Enoxaparin w/in 8-12 hours: Protamine 0.5 mg IV per 1 mg Dalteparin, Nadroparin, and Tinzaparin: w/in 3-5 half-lives of LMWH— Protamine 1 mg IV per 100 units If protamine contraindicated: rFVIIa 90 mcg/kg IV	Protamine dosing must be precise, as excess protamine becomes an anticoagulant itself
Penta saccharides	Fondaparinux	aPCC (FEIBA) 20 units/kg IV or rFVIIa 90 mcg/kg IV	
Thrombolytics	Alteplase, Reteplase, Tenecteplase	If thrombolytic still active, based on half-life of drug, then 1-2 g TXA or 4-5 g EACA IV Check fibrinogen, if low, administer cryoprecipitate	Alteplase is notable for metabolizing fibrinogen in addition to fibrin. AIS patients who receive IV rtPA and have the greatest drop in fibrinogen are at the greatest risk of hemorrhagic complication

IV, intravenous; SC, subcutaneous; 3F-PCC, 3 factor prothrombin complex concentrates; 4F-PCC, 4 factor prothrombin complex concentrates; aPCC, activated prothrombin complex concentrate; FEIBA, factor eight inhibitor bypassing activity; PT, prothrombin time; PTT, partial thromboplastin time; TXA, tranexamic acid; EACA, epsilon aminocaproic acid; AIS, acute ischemic stroke; rtPA, recombinant tissue plasminogen activator, that is, alteplase.

^aIf emergent neurosurgical intervention is required, consider 20 to 40 mcg/kg of recombinant activated factor VII (rFVIIa) just prior to surgery to complement the administration of the above suggested agents for reversal of VKA, Xa Inhibitors, LMWH, nondabigatran DTIs, and Penta saccharides. Of note: rFVIIa is not to be administered if the patient has received aPCC/FEIBA, as these products already contain FVIIa.

^bIn all cases of PCC use, 4F-PCCs are preferred to 3F-PCCs.

^cThe dose of 4F-PCCs for VKA is dependent on INR: 25 unit/kg if INR 2 to 4, 35 unit/kg if INR 4 to 6, and 50 unit/kg if INR more than 6. A postreversal INR should be obtained. If INR is more than 1.3, more PCC or FFP should be administered. Of note: the manufacturer of K-Centra does not recommend repeat dosing.

^dLepirudin is another irreversible DTI. The manufacturer discontinued its production in 2012 for business reasons.

^eIf idarucizumab unavailable, then emergent hemodialysis to hasten drug elimination AND one of the following: FEIBA 50 unit/kg or 50 unit/kg 4F-PCC and 40-80 mcg/kg rFVIIa. If patient supratherapeutic on dabigatran due to overdose or impaired clearance, then redosing of idarucizumab may be required and should be guided by complete correction of the PTT, assuming no other condition (eg, lupus anticoagulant) or anticoagulant (eg, heparin) is present.

^fThe half-life of argatroban (~45 minutes), bivalirudin (~25 minutes), and desirudin (~2 hours) are quite short. Stopping their infusion/administration while administering a short burst of a prothrombotic regimen (eg, FEIBA 50 unit/kg or 50 unit/kg 4F-PCC and 40 mcg/kg rFVIIa) is a reasonable approach, but there is a severe paucity of evidence to guide this recommendation.

TABLE 48B–12 Suggested antiplatelet reversal strategies.

Category	Specific Medications	“Reversal”	Undergoing Neurosurgical Procedure ^a
Salicylates	Aspirin	DDAVP 0.4 mcg/kg IV	Platelet transfusion ^{b,c}
COX-1 and 2 inhibitors	Ibuprofen, Naproxen	DDAVP 0.4 mcg/kg IV	Nothing further
ADP/P2Y ₁₂ inhibitors	Clopidogrel, Prasugrel, Ticlopidine, Ticagrelor ^d	DDAVP 0.4 mcg/kg IV	Platelet transfusion ^{b,c}
Adenosine reuptake inhibitors	Dipyridamole	DDAVP 0.4 mcg/kg IV	Platelet transfusion ^{b,c}
PDE III inhibitors	Cilostazol, Anagrelide	DDAVP 0.4 mcg/kg IV	Platelet transfusion ^{b,c}
GIIb/IIIa antagonists	Abciximab ^e , Eptifibatide, Tirofiban	Hold agent ^f	10 units cryoprecipitate ^g , platelet transfusion ^{b,c}

^aIn cases of significant clinical coagulopathy due to antiplatelet agents or congenital disorders of platelet function or the need to perform neurosurgical procedure in the setting of significant antiplatelet activity, activated recombinant factor VII (rFVIIa), 20 to 80 mcg/kg IV has been reported to have been used. However, it should be considered as a desperation measure and is not recommended for widespread use.

^bTransfuse one single-donor apheresis unit (which is the same as 6 pooled units or one random donor unit per 10 kg of body weight).

^cWhen possible, obtain platelet function assays before and after transfusion. Correction of the platelet function assay is seen in a minority of cases of attempted reversal with transfusion.

^dTicagrelor is a unique member of this category, as it is not a thienopyridine, but it is a P2Y₁₂ inhibitor. Additionally, ticagrelor is the only reversible inhibitor of P2Y₁₂ receptor.

^eIn contrast to eptifibatide and tirofiban, abciximab is an irreversible inhibitor of the G IIb/IIIa receptor. Despite its plasma half-life of ~30 minutes, its receptor-binding half-life is 24 to 48 hours.

^fThe short half-lives of these agents leaves a short window of action for their “reversal.” An exception is abciximab, as per the comments under **

^gGIIb/IIIa platelet receptors allow for platelet-fibrinogen crosslinking. Given the larger quantity of fibrinogen in cryoprecipitate, its transfusion has been reported as a possible measure in hemorrhage complicated by GIIb/IIIa inhibitors.

Surgical options in the management of ICH include craniotomy with or without clot evacuation and, in the setting of obstructive hydrocephalus due to IVH, the placement of an IVC. Two randomized trials (Surgical Trial in Lobar Intracerebral Hemorrhage [STICH] and STICH-2) explored the value of craniotomy for supratentorial ICHs and failed to find a benefit, possibly due to the increased cerebral injury caused by the open craniotomy approach. As such, at present, craniotomy with surgical evacuation is largely considered in those with a deteriorating neurologic examination, symptomatic herniation syndromes, or refractory intracranial hypertension not amendable to medical therapy and diversion of cerebrospinal fluid (CSF) (when IVH complicates the ICH). The failure of open craniotomy led to an interest in minimally invasive stereotactic approaches to aspirate the hematoma. An approach currently under investigation is to stereotactically place a catheter into the hemorrhage, aspirate hematoma, and then leave the catheter in place to instill rtPA every 8 hours for 9 total doses

(Minimally Invasive Surgery Plus rt-PA for Intracerebral Hemorrhage Evacuation [MISTIE III]).

ICH complicated by IVH causes obstructive hydrocephalus, which maybe aided by enhanced clearance of the ventricular clot with intraventricular rtPA. Clot Lysis: Evaluating Accelerated Resolution of Intraventricular Hemorrhage Phase III (CLEAR-III), a randomized trial of intraventricular rtPA in IVH, failed meet its primary outcome of increasing the proportion of patients with a good outcome (mRS 0-3), but there was a 10% reduction in mortality and a subgroup benefit in those with a large clots or if the catheter was inserted directly into the clot.

SUBARACHNOID HEMORRHAGE

SAH can occur spontaneously, which is often the result of a vascular malformation, such as an arterial aneurysm (aSAH), or from traumatic injury to bridging veins. The incidence of spontaneous SAH, which this section will focus on, is poorly quantified,

TABLE 48B–13 Etiologies of spontaneous SAH.

Type	Proportion (%)
Aneurysm	85
Perimesencephalic	10
Nonaneurysmal other: tumor, dural sinus thrombosis, cortical vein thrombosis, arterial dissection, RCVS, vascular lesion, ^a vasculitis, sickle cell disease, mycotic aneurysm, coagulopathy, sympathomimetic drugs	5

RCVS, reversible cerebral vasoconstriction syndrome.
^aArteriovenous malformation, dural arteriovenous fistula, amyloid angiopathy.

but is estimated to occur in 20 out of every 100,000 adults in the United States. A specific subtype of nonaneurysmal SAH is perimesencephalic SAH (PMSAH), which is thought to be due to a spontaneous venous rupture in the basilar cisterns, producing a radiographic pattern of SAH similar to that seen with aSAH, but it has a much more benign course. [Table 48B–13](#) outlines etiologies of spontaneous SAH.

Risk factors for aSAH include hypertension, smoking, alcohol abuse, use of sympathomimetic drugs, such as cocaine, female sex, family history, collagen vascular diseases, such as type IV Ehlers-Danlos syndrome, and polycystic kidney disease. Cerebral arterial aneurysms are present in 3.6% to 6% of the population and more common in the anterior circulation. Rupture risk increases with aneurysm size and posterior circulation aneurysms.

When an aneurysm ruptures, the pressure in the subarachnoid space rapidly increases and approximates the arterial pressure. This can lead to a temporary decrease or cessation in blood flow to the brain, resulting clinically in syncope. During this period of reduced cerebral blood flow, a clot is able to tenuously form in the aneurysm, stopping further hemorrhaging. This sudden increase in ICP, combined with a brief period of cerebral ischemia can lead to the development of cerebral edema in the first several hours after the aneurysm rupture. Additionally, subarachnoid blood can obstruct the flow and absorption of CSF through the foramen of

Luschka and Magendie and arachnoid granulations respectively, producing an obstructive and/ or communicating hydrocephalus. The tenuous clot in the recently ruptured aneurysm is a high risk for dislodgement, making early surgical obliteration of the aneurysm a priority. Beginning at about day 4 after the aneurysm bleed, the risk for cerebral vasospasm (VSP) resulting in delayed cerebral ischemia (DCI) begins. This typically lasts for 14 days, with the peak period being 7 to 10 days postbleed, but can be seen up to 28 days from ictus.

Outcomes after aSAH are highly associated with the severity of presenting symptoms, quantity of SAH, comorbidities, and age. Overall mortality rate ranges from 30% to 40%, with nearly half of survivors experiencing some type of permanent disability. More subtle deficits in memory, executive function, and language ability, as well as psychiatric symptoms, such as anxiety or depression are common. Despite the high morbidity and mortality, even patients with severe presentations can experience outcomes that allow them to return to independent living or a high quality of life.

History and Physical Examination

The most common presenting symptom of aSAH is headache. Less common presentations are syncope or new onset lethargy or confusion. Deciding which headaches are concerning for aSAH can be challenging, both for health care providers and patients themselves. Classically, the patient will describe the worst headache of their life that came on very suddenly (ie, “thunderclap”). A careful neurologic examination should be performed with particular attention to the cranial nerve examination and performance of an assessment of concentration (eg, reciting months of the year backward). Unfortunately, in the presence of a normal neurologic examination there are not any highly specific historical features of aSAH. Given the extremely high morbidity and mortality of a missed aSAH, we must be persuaded to seek out highly sensitive tools at the expense of specificity.

A sentinel headache, or milder headache or headache without neurologic change, can occur a few weeks prior in up to 40% those who experience an aSAH. It represents an initial hemorrhage from the aneurysm of less severity.

TABLE 48B–14 Clinical grading scales for aneurysmal subarachnoid hemorrhage.

Grade ^a	Hunt and Hess (H/H)	World Federation of Neurological Surgeons (WFNS)
1	Asymptomatic or minimal headache	GCS 15, no motor deficit
2	Moderate to severe headache; may have one isolated cranial nerve deficit	GCS 13-14, no motor deficit
3	Drowsy, confused, or mild focal deficit	GCS 13-14, with motor deficit
4	Stupor, moderate to severe hemiparesis	GCS 7-12
5	Deep coma, decerebrate rigidity	GCS 3-6

GCS, Glasgow Coma Scale.
^aScore to be assessed after patient is resuscitated.

There are 2 widely used systems that score the severity of the aSAH and are based on clinical symptoms. Hunt and Hess (H/H) and World Federation of Neurosurgeons (WFNS) are outlined in Table 48B–14.

Diagnostics

The initial diagnostic test is a NCHCT. If performed without 6 hours of symptom onset, it is a modern day CT scanner, and the patient is not anemic or coagulopathic, the sensitivity approaches 100%. There are reports of reduced sensitivity in this time frame on modern scanners when the head CT is read by nonneuroradiologists in the community setting. After this time frame, a lumbar puncture (LP) may need to be performed to full exclude the possibility of SAH, depending on the pretest probability/clinical suspicion, as the SAH will begin to degrade and may no longer be hyperdense on a NCHCT. Of note, the LP should be performed at least 12 hours after symptom onset, as the intracerebral subarachnoid blood may not have adequately circulated into the lumbar cistern, from which the CSF will be collected. An aSAH is excluded by the absence of red blood cells and xanthochromia in the CSF. An MRI of the head can also be performed, with particular attention to the GRE, T2*, or SWI images, but LP remains the gold standard when performed more than 12 hours after symptom onset.

Once SAH is diagnosed, an etiology must be pursued, which begins with vascular imaging. A CTA of the head is most common performed, but if

contraindications exist to its performance, an MRA can be performed, although it has a lower sensitivity for aneurysms than CTA. If the CTA is nondiagnostic, a digital subtraction angiogram (DSA) should be performed.

The risk of VSP, DCI, and delayed neurologic deterioration (DND) are proportional to the amount of SAH. Two scoring systems are in use to help stratify this risk, based on the initial head CT. The original system was the Fischer Scale, which was modified in 2001 by Claassen et al and then revalidated by Frontera in 2006. Table 48B–15 summarizes each of these scales and their associated risk of DND.

Treatment

Early (the first 6 hours) treatment goals include BP control, cardiopulmonary stability, correction of symptomatic hydrocephalus, treatment of intracranial hypertension, reversal of herniation syndromes, and consideration of antifibrinolytics. Aneurysmal rebleeding is a catastrophic event. It is associated with a more than 50% mortality rate and none of the survivors recover to a mRS of 0 to 2 (good outcome). It occurs in 8% to 23% of aSAH, with 83% of the rebleeds occurring in the first 6 hours. The risk can be mitigated with rapid, smooth, consistent BP control, minimization of patient agitation, and the rapid correction of any coagulopathy. Commonly selected short acting continuous infusion antihypertensives include nicardipine, clevidipine, labetalol, and esmolol. Robust vasodilators, such as

TABLE 48B–15 Fischer scale and modified Fischer scale for risk of delayed neurologic deterioration in aneurysmal subarachnoid hemorrhage.

Fischer			Modified Fischer		
Grade	Description	DND Rate (%)	Grade	Description	DND Rate (%)
–			0	No SAH or IVH	0
1	No blood or focal thin	0-21	1	Thin SAH, no b/l IVH*	12-24
2	Diffuse, thin SAH < 1 mm thick	20-25	2	Thin SAH, b/l IVH	21-33
3	SAH > 1 mm thick	28-37	3	Thick SAH**, no b/l IVH*	19-33
4	ICH or IVH with SAH	19-31	4	Thick SAH**, b/l IVH*	40

SAH, subarachnoid hemorrhage; ICH, intracerebral hemorrhage; IVH, intraventricular hemorrhage; DND, delayed neurologic deterioration; b/l, bilateral.

*For the modified Fischer Scale, a score of 2 or 4 requires that there is blood layering in both of the lateral ventricles.

**Thick SAH = SAH completely fills at least one cistern of fissure.

nitroglycerin, hydralazine, and sodium nitropruside are typically avoided, as they may cause significant increases in cerebral blood volume and blood flow dynamics. Antifibrinolytics such as TXA or epsilon-aminocaproic acid (EACA) appear to reduce the risk of rebleeding, but have not been definitively shown to improve functional outcomes. If administered, they should be discontinued 4 hours prior to DSA to minimize the risk of iatrogenic ischemic strokes during the procedure from catheter thrombi. If the patient has a depressed level of consciousness or demonstrated intracranial hypertension, a mean arterial pressure of 80 mm Hg (assuming no intracranial monitoring) or cerebral perfusion pressure of 60 mm Hg should be maintained, while controlling the SBP. An epidemiologic BP target has not been clearly established, but many centers use a target SBP of less than 140 mm Hg. The value of seizure prophylaxis is unclear. Similar observations about phenytoin have been made in aSAH. Many centers will provide 7 days of prophylactic levetiracetam in poor grade aSAH and those undergoing open surgical clipping, but the value of this approach is unclear. Any patient with poor neurologic examination or one that is worse than expected for the severity of the hemorrhage should undergo cvEEG monitoring.

Neurogenic stunned myocardium and/or neurogenic pulmonary edema are not uncommon after

aSAH, particularly in those with poor grade (ie, high H/H or WFNS scores) aSAHs. Cardiac complications include dramatic (self-limited) reduction in ejection fraction (Takotsubo cardiomyopathy), electrocardiographic changes (ST/T wave, QT prolongation, U waves) and supraventricular and ventricular arrhythmias. In fact, some aSAH will present in cardiac arrest. Ventilatory support with positive pressure along with optimization of serum potassium (> 4.0) and magnesium (> 2.0) are cornerstones in the management of these cases. If an airway needs to be obtained, be sure to minimize patient agitation, physiologic fluctuations, and BP spikes during the procedure to minimize the risk of causing a rebleed.

Early decisions should be made regarding whether to place an IVC to treat a hydrocephalus, particularly if the patient is going to DSA for diagnostics and possible aneurysmal intervention, where they will be laying flat for a prolonged period of time and difficult to monitor. Cerebral edema may require treatment with hyperosmolar agents, such as mannitol or hypertonic saline.

Early surgical or EVT of the aneurysm is recommended as it improves outcome, most commonly with 24 hours or, as identified in a meta-analysis, within 72 hours. The European International Subarachnoid Aneurysm Trial (ISAT; 2002) randomized good neurologic grades (WFNS I-III) aSAH

to surgical clipping ($n = 1070$) or coiling ($n = 1073$) with death and dependency at 1 year as the primary outcome measure. The authors reported better outcome for coiling group (23.5%) compared to surgical clipping group (30.9%); however, the rebleeding rate at 1 year was 2.6% in the coiling versus 1% in the clipping group. However, at 5-year follow-up a reduced death rate for coiling (11%) compared to clipping (14%) was observed while the percentage of independent survivors did not differ making the overall death rate in the coiled group 3% at 5 years. Bias in recruitment strategy, aneurysm location, aneurysm size, selection of good grades, treatment time window, operator experience, age exclusion, presurgical evaluations, choice of techniques and questionnaire follow up are cited in order to understand the limitation of this landmark study. A follow up trial (ISAT II) is underway. Currently, most investigators identify equipoise with respect to longer term outcomes and treatment approach and identify that certain patients are not suitable for either surgical or EVT. For example, coiling is the less preferred option in patients with aneurysms of large size, with large mass effect, wide neck (neck-to-dome ratio > 0.5), fusiform appearance, and at arterial bifurcations. In contrast, posterior circulation aneurysms, especially basilar tip aneurysms, locations within or between the cavernous sinuses, or those that can more readily be accessed by an endovascular approach. Age is a relevant factor in the decision making as younger patients have better long-term protection from recurrent SAH with clipping while coiling is preferred in elderly with multiple comorbidities.

As with all critical brain injuries, normoglycemia, normothermia, normonatremia, and normovolemia must be maintained. Fluid and electrolyte abnormalities are common in aSAH patients. Cerebral salt wasting syndrome and syndrome of inappropriate secretion of antidiuretic hormone (SIADH) are common, and may even coexist in the same patient. Fluid balance must be vigilantly maintained, as negative fluid balances in aSAH are associated with worsened outcomes.

As stated aforementioned, VSP occurs commonly during period following rupture of aSAH, with a peak incidence on postbleed days 7 to 10 (with the day of the bleed being day 0). Those with

a normal neurologic examination should have serial assessments vigilantly performed. If the neurologic examination is impaired, serial angiographic assessments with transcranial Dopplers (TCDs), CTAs, CT perfusion studies, and/or DSAs. TCDs noninvasively assess for the velocity of blood flow through the large cerebral arteries (MCA, ACA, Basilar), with increase in velocity indicative of VSP. MCA velocities of greater than 200 cm/s or a ratio between the MCA and the extracranial ICA of greater than 6 (Lindgaard ratio [LR]) are suggestive of severe VSP. TCDs also provide a pulsatility index (PI), which is a marker of distal arteriolar resistance, as would be seen in small vessel VSP.

Examination changes related to VSP should be treated immediately by ensure euvolemia and raising the BP, often pharmacologically. If the neurologic change does not resolved, then more aggressive should be expeditiously performed, such as DSA where intra-arterial verapamil or milrinone can be administered or angioplasty can be performed. Medical measures that have been demonstrated to have some effect with the treatment of VSP include IV milrinone, intrathecal nicardipine, IV magnesium, high-dose statins, and endothelin-receptor antagonists. Unfortunately RCTs exploring the value of the later 3 classes failed to meet their primary functional outcomes, despite evidence suggesting that they are effective at treating angiographic VSP.

Most recently, DCI is being better understood as an arteriolar VSP that results in microvascular thrombosis and perfusion mismatch and neurovascular uncoupling, complicated by spreading depolarizations, which begin at the time of the aneurysm rupture and ultimately lead to cortical infarctions. Nimodipine is a stalwart in the management of aSAH. It should be started on day of arrival and continued for 21 days. It has been shown to improve functional outcomes, but interestingly, it failed to produce a statistically significant reduction in VSP. Reasons for this discrepancy are related to other suspected benefits of calcium channel blockade, including the prevention of small vessel VSP, stabilization of the neurovascular unit, prevention of intracellular calcium influx as part of apoptosis, and mild profibrinolysis that mitigates microvascular thrombosis.

Delirium in the Intensive Care Unit

S. Jean Hsieh, MD

KEY POINTS

- 1 ICU delirium is a common form of acute “brain failure” that is associated with significant morbidity and mortality. Delirium has a dose response relationship with poor outcomes: the longer the delirium duration, the poorer the outcome.
- 2 Delirium can be missed in up to 75% of patients if a screening tool is not used, likely because of the high prevalence of hypoactive delirium.
- 3 Early diagnosis of delirium is imperative for effective delivery of delirium reduction strategies. Therefore, delirium assessments should be part of the ICU admission physical exam and should be incorporated into the daily work-flow.
- 4 ICU-acquired risk factors for delirium (eg, oversedation, immobilization, uncontrolled pain) are potentially modifiable and closely interrelated. Implementation of nonpharmacologic multicomponent strategies to prevent and reduce delirium on an ICU-wide scale (eg, targeted light/no sedation, early rehabilitation) can shorten the duration of ICU delirium and improve clinical outcomes.
- 5 Pharmacologic prevention and treatment of delirium (eg, dexmedetomidine over benzodiazepines for sedation) can be considered for individual patients, although the efficacy of these strategies is still unclear.

INTRODUCTION

Delirium is the most common form of acute brain injury in critically ill patients and is associated with potentially long-lasting serious consequences. This chapter reviews the essentials of diagnosis, risk factors, prevention, and treatment of ICU delirium.

GENERAL CONSIDERATIONS

Delirium is a disturbance of consciousness and cognition that develops acutely (ie, hours to days), fluctuates over time, and is generally reversible.¹ It is characterized

by an acute change or fluctuation in baseline mental status, inattention, and either disorganized thinking or an altered level of consciousness. ICU delirium is the most common form of acute brain dysfunction in critically ill patients, with estimates of incidences ranging from 20% to 50% in nonventilated patients and 60% to 80% in ventilated ICU patients, depending on the diagnostic criteria used and the patient characteristics.²⁻⁶ It is important to recognize that delirium is not a normal part of critical illness, but rather represents an acute organ failure that is associated with profound short- and long-term consequences.

Pathophysiology

While the pathophysiology of delirium is still poorly understood, it is thought to be a disease-driven process caused by the complex interaction of various factors including (1) the underlying disease itself, (2) predisposing risk factors unique to each patient, and (3) environmental and treatment-related factors.

Neurotransmitter Imbalance

Delirium is hypothesized to be caused by imbalances in neurotransmitters due to factors such as systemic inflammation, metabolic derangements, acute stress responses, and exposure to psychoactive medications.⁷ The 2 main neurotransmitters implicated in these derangements are dopamine and acetylcholine, and they work in opposition by increasing and decreasing neuronal excitability, respectively. Other neurotransmitters that have been implicated in the pathogenesis of delirium include γ -aminobutyric acid (GABA), serotonin, glutamate, and endorphins. At this time, data supporting these hypotheses are limited and thus pharmacologic treatment of ICU delirium is largely empirical.

Neuroinflammation

Inflammatory cytokines and endotoxins are postulated to contribute to the development of ICU delirium in several ways.⁸ Infiltration of leukocytes and cytokines into the central nervous system may lead to neuronal apoptosis, and may interfere with neurotransmitter synthesis and neurotransmission, increase vascular permeability, and reduce cerebral microvascular blood flow through the formation of microaggregates of fibrin, platelets, erythrocytes, and neutrophils. Microglial activation and oxidative injury can also occur.

Alterations of Brain Structure

Preliminary studies using magnetic resonance imaging have shown an association between the duration of ICU delirium and both cerebral white-matter disruption and cerebral atrophy. Because of the lack of imaging before critical illness, these findings suggest that either the presence of these abnormalities makes patients more vulnerable to developing ICU delirium or that ICU delirium leads to abnormalities in brain structure.^{9,10}

Risk Factors

Despite our relatively poor understanding of the overall pathophysiology of delirium, clinical studies have shown delirium to be a disease-driven process caused by a complex interaction of factors including: (1) baseline risk factors unique to each patient; (2) the patient's acute illness and illness-related factors; and (3) ICU-environment and treatment-related factors ([Figure 49–1](#)). These risk factors can be further classified as nonmodifiable (ie, predisposing factors that are out of the control of the admitting clinician) and modifiable (ie, factors that the clinician may be able to treat). Although over 100 risk factors have been identified in the literature,¹¹ few have consistently remained associated with delirium across different studies after adjusting for confounding variables. This is likely due to the different underlying pathophysiology of delirium across study populations.^{2,3,6,12–14} This chapter will review risk factors that have been most consistently identified in the literature.

Patient-Level Predisposing Risk Factors

Studies have consistently identified pre-existing cognitive impairment, alcohol use, and history of hypertension as risk factors that significantly increase the risk of delirium in ICU patients ([Figure 49–2](#)).^{2,5,13,15} Although advanced age has been identified as one of most significant risk factors outside of the ICU, this association has remained inconsistent across ICU studies.^{16,17} Physiologic dependence from chronic exposure to alcohol, opiates, and benzodiazepines can lead to withdrawal in the setting of abrupt discontinuation of alcohol use. Of the predisposing patient-level risk factors, withdrawal from these substances is the only modifiable factor, and thus should be carefully considered when encountering a delirious patient.

Illness-Related Risk Factors

High severity of illness at ICU admission and medication-induced coma (as opposed to coma due to a primary neurologic condition) have been consistently identified as independent risk factors for development of delirium in ICU patients.^{5,13,16–19} Respiratory failure requiring mechanical ventilation has been identified as a risk factor for delirium, although the results have been inconsistent across studies.^{2,5,14,16,20}

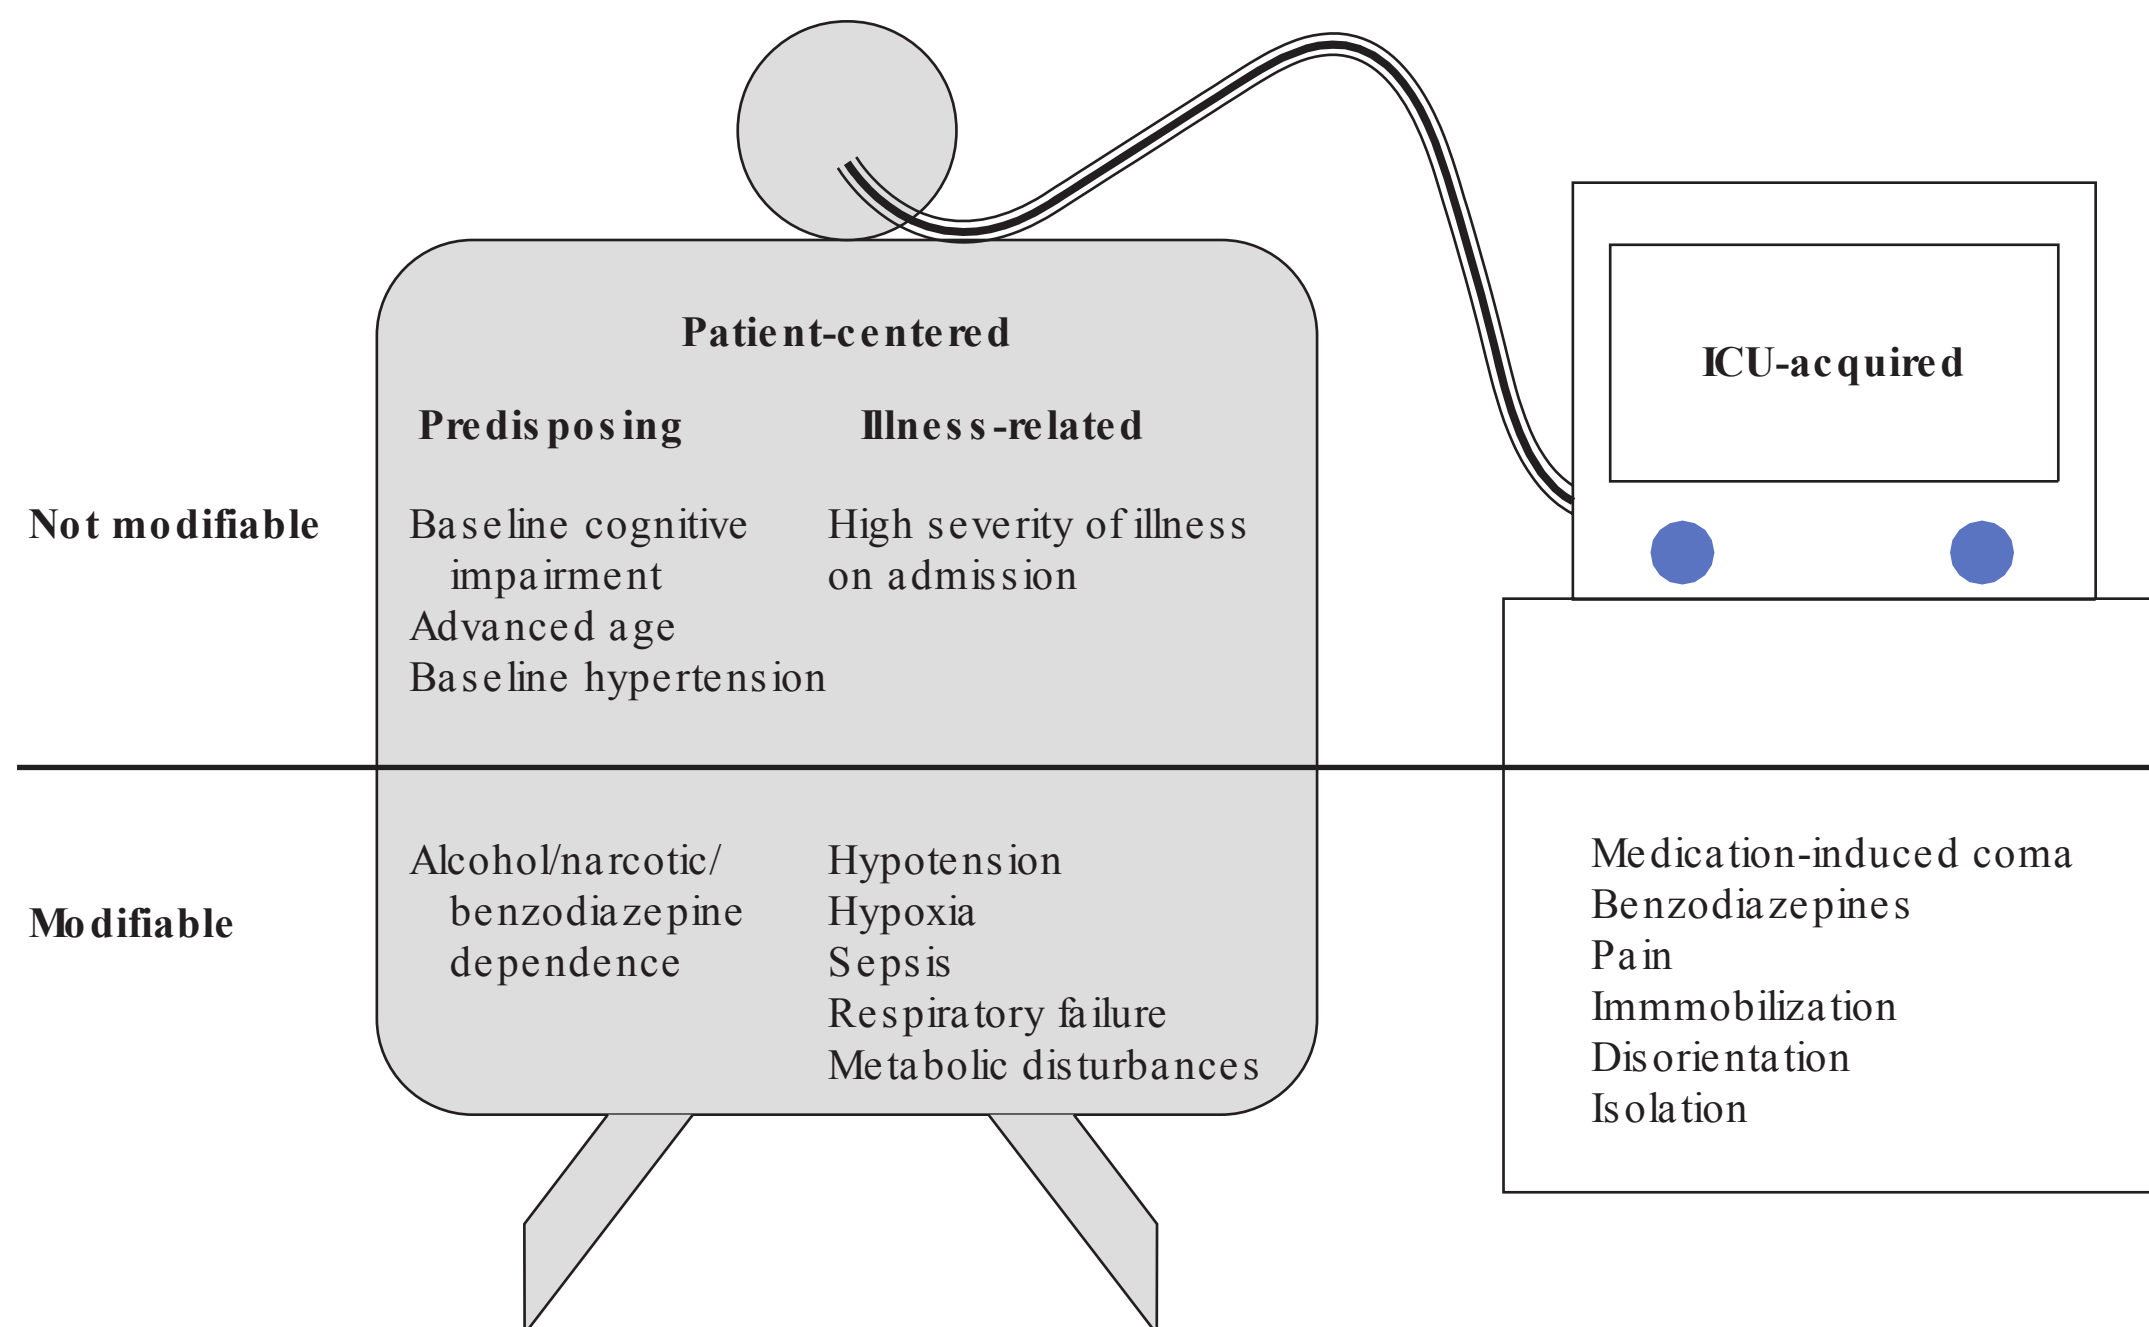

FIGURE 49–1 Risk factors for ICU delirium.

(Data from Devlin JW, Marquis F, Riker RR, et al: Combined didactic and scenario-based education improves the ability of intensive care unit staff to recognize delirium at the bedside, *Crit Care*. 2008;12(1):R19 (bottom).)

Potential reasons for the discrepant findings include exclusion of nonmechanically ventilated patients from observational studies^{12,19,21} and lack of measurement of mechanical ventilation as a risk factor in ICU delirium studies.^{13,15}

ICU Treatment-Related Risk Factors

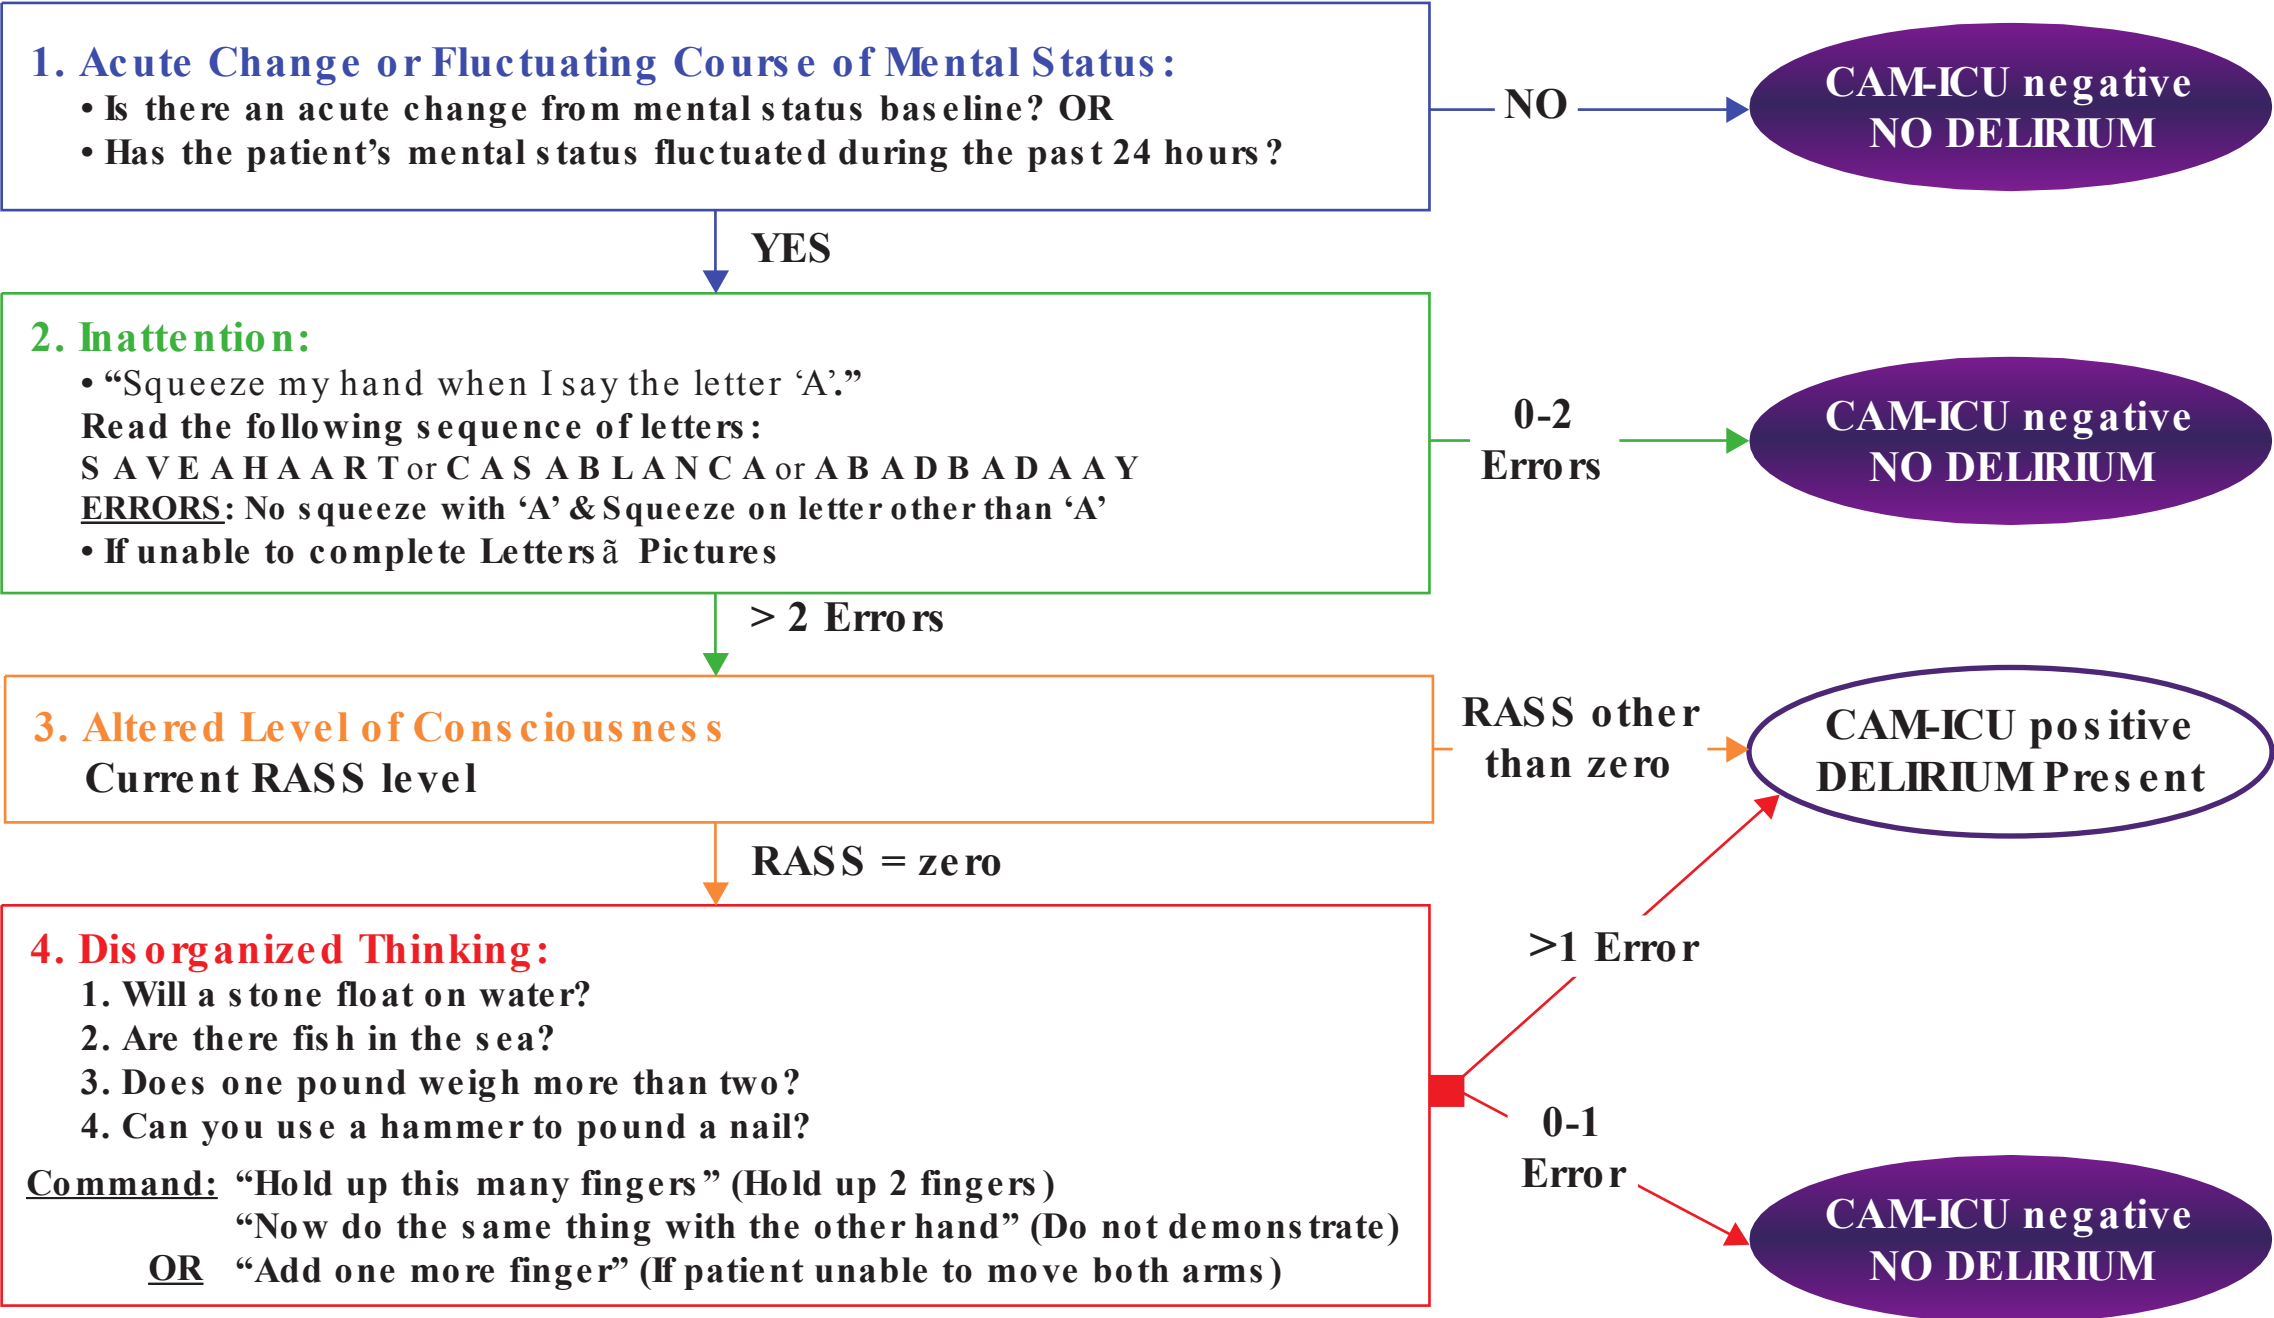

An appreciation of the impact of ICU-level risk factors on the development and persistence of delirium is particularly important because (1) these factors are all modifiable, (2) reduction of these risk factors is associated with reduced incidence and duration of ICU delirium and improvements in clinical outcomes, and (3) these factors are closely interrelated.

Sedative Use—Most mechanically ventilated patients receive sedatives in the ICU. Both sedative choice and sedative-induced coma are independently associated with an increased risk of delirium.¹³ Benzodiazepines are most consistently associated with delirium across different ICU populations and have demonstrated a dose-dependent relationship, although a few studies have found no significant

relationship.^{12,16,17,22–24} Most studies on opiates and propofol report an increased risk of delirium, particularly when used in combination with other sedatives or when associated with coma.^{2,13,14,16,25} In contrast, recent studies suggest that use of dexmedetomidine and/or avoidance of benzodiazepines may be associated with both a lower risk of developing delirium and a shorter duration of delirium.^{26,27} Preliminary data in cardiac surgery patients suggests that dexmedetomidine may also be associated with a lower incidence of delirium compared to propofol and shorter duration of delirium compared to morphine.^{28,29}

Immobility—A number of observational studies suggest that neuromuscular function and ICU delirium are closely interconnected.³⁰ For instance, observational and clinical trial data suggest that immobility is an independent risk factor for delirium in ICU and non-ICU hospitalized patients.^{5,22,30–33} Studies show that ICU's that institute early mobilization programs have a lower prevalence and shorter duration of ICU delirium.^{33,34}

Confusion Assessment Method for the ICU (CAM-ICU) Flowsheet

Intensive Care Delirium Screening Checklist (ICDSC) ^{ab}
1. Anything other than normal wakefulness
2. Inattention
3. Disorientation
4. Hallucinations or delusions
5. Psychomotor agitation or retardation
6. Inappropriate speech or mood
7. Sleep/wake cycle disturbance
8. Symptom fluctuation

^aEach positive component is scored 1 point
^bA total score ≥ 4 is positive for delirium; scores 1-3 is termed "subsyndromal" delirium

Clinical Features

ICU delirium is characterized by the following 4 DSM-V criteria: (1) inattention (the most common feature), (2) an acute change or fluctuation in baseline mental status, and either (3) disorganized thinking or (4) an altered level of consciousness.¹ Notably, while delusions and hallucinations can be present in delirious patients, these symptoms are not defining features of delirium. Patients with delirium can

present in 3 different ways: calm or somnolent (ie, hypoactive), agitated (ie, hyperactive), or alternating between the 2 states (ie, mixed).²⁴ While hyperactive delirium can be more easily identified without a screening tool, only 2% of patients have purely hyperactive delirium. In contrast, hypoactive and mixed forms are much more common in critically ill patients,³⁵ and are associated with worse clinical outcomes.³⁵

Diagnosis

ICU delirium is a clinical diagnosis; no diagnostic lab, imaging, or electroencephalographic test can accurately diagnose delirium. However, without the use of a delirium assessment tool, over 3/4 of delirium can be missed in routine practice because patients more often present with hypoactive rather than hyperactive delirium.³⁶ This highlights the importance of integrating a structured tool into clinical practice to rapidly and accurately detect delirium, rather than relying on clinical impressions. Indeed, delirium assessment in the ICU is now considered to be a requisite part of high-quality ICU care.

All patients should be screened for delirium as soon as they are admitted to the ICU and then at least once per nursing shift. Because delirium can only be assessed in patients who are arousable to voice, level of consciousness needs to be determined first. Therefore, delirium screening is a 2-step process.

Step 1: Determine Level of Consciousness—The level of consciousness needs to be determined using a sedation-agitation scale. The 2013 American College of Critical Care Medicine (ACCM) clinical practice guidelines recommended the Richmond agitation-sedation scale (RASS)³⁷ and Riker sedation-agitation scale (SAS)³⁸ as the 2 most valid and reliable sedation assessment tools (Table 49–1 and 1B).

Step 2: Screen for Delirium—If the patient is not comatose (ie, RASS –3 or more or SAS 3 or more), delirium can be assessed using a screening tool. Many tools for delirium screening have been published. This chapter will review the 2 most well-studied and commonly used ICU delirium screening tools, that were also recommended by the recently updated ACCM clinical practice guidelines: the Confusion Assessment Method-ICU (CAM-ICU) and Intensive Care Delirium Screening Checklist (ISDSC) (Figure 49–1).^{24,40} Both tools have (1) high sensitivity, specificity (ranging from 74% to 96%) and (2) excellent clinical feasibility in both nonventilated and ventilated critically ill patients in mixed ICUs.⁴¹

Confusion Assessment Method-ICU (CAM-ICU)

The CAM-ICU provides a dichotomous assessment (ie, delirious vs not delirious) at a single time point and can be performed in less than 1 minute. Advantages of the CAM-ICU are its discrete defined measures that

TABLE 49–1 A

Richmond Agitation-Sedation Scale (RASS) ⁸⁸	
+4: Combative	Overtly combative, violent, immediate danger to self
+3: Very agitated	Pulls or removes tubes or catheters; aggressive
+2: Agitated	Frequent nonpurposeful movement, fights ventilator
+1: Restless	Anxious but movements not aggressive or vigorous
0: Alert and calm	Alert and calm
–1: Drowsy	Not fully alert but has sustained awakening to voice (eye opening or eye contact >10 s)
–2: Light sedation	Briefly awakens with eye contact to voice (< 10 s)
–3: Moderate sedation	Movement or eye opening to voice but no eye contact
–4: Deep sedation	No response to voice but movement or eye opening to physical stimulation
–5: Unarousable	No response to voice or physical stimulation

Adapted with permission from Sessler CN, Gosnell MS, Grap MJ, et al: The Richmond Agitation-Sedation Scale: validity and reliability in adult intensive care unit patients, *Am J Respir Crit Care Med* 2002 Nov 15;166(10):1338-1344.

are obtained from physical assessment of the patient. A disadvantage is that, given delirium's fluctuating course, the periodic nature of the CAM-ICU may miss an episode of delirium. Therefore, it should be performed on a regular basis (eg, every 4 to 12 hours) and with changes in the patient's mental status.

ICDSC

The ICDSC is an 8-item checklist of symptoms observed over an 8-hour to 24-hour period in which a score of 4 or more is positive for delirium and scores of 1 to 3 are defined as “subsyndromal” delirium. Advantages of the ISDSC are its ability to detect “subsyndromal delirium” and a longer assessment period which decreases the chance of missing signs of delirium. A disadvantage is that the ISDSC relies on more subjective observations in the setting of mechanically ventilated patients (eg, hallucinations, inappropriate speech) and thus can be more dependent on the clinical experience of the practitioner.

TABLE 49–1 B

Riker Sedation-Agitation Scale (SAS) ⁸⁹	
7: Dangerous agitation	Pulling at endotracheal tube, trying to remove catheters, climbing over bed rail, striking at staff, thrashing from side to side
6: Very agitated	Requiring restraint and frequent verbal reminding of limits, biting endotracheal tube
5: Agitated	Anxious or physically agitated, calming at verbal instruction
4: Calm and cooperative	Calm, easily arousable, follows commands
3: Sedated	Difficult to arouse but awakens to verbal stimuli or gentle shaking; follows simple commands but drifts off again
2: Very sedated	Arouses to physical stimuli but does not communicate or follow commands, may move spontaneously
1: Cannot be aroused	Minimal or no response to noxious stimuli, does not communicate or follow commands

Adapted with permission from Riker RR, Picard JT, Fraser GL: Prospective evaluation of the Sedation-Agitation Scale for adult critically ill patients, *Crit Care Med* 1999 Jul;27(7):1325-1329.

Differential Diagnosis

Pain

Untreated pain can be both a risk factor for ICU delirium and a cause of agitation that is not due to delirium. While the standard for pain assessment is self-report, patients in the ICU often are unable to communicate due to respiratory failure or decreased level of consciousness. Because increased vital signs such as tachycardia or hypertension do not always correlate with pain, it is important to use a structured tool for pain monitoring in patients who are unable to communicate, such as Behavioral Pain Scale (BPS)⁴² or the Critical-Care Pain Observation Tool (CPOT).^{24,43}

Dementia

While dementia is a risk factor for delirium, it can also be confused with delirium because of changes in cognition. However, its course progresses over a much longer period of time (months to years) in contrast to hours to days in delirium, and the symptoms fluctuate much less. In addition, attention remains relatively intact whereas inattention is the most common feature of delirium.

Underlying Psychosis

Agitation due to underlying psychosis or mania, and inattention due to underlying depression can masquerade as delirium. However, the symptoms associated with psychosis, mania and depression can persist for longer periods of time and fluctuate less, and the sensorium is usually clear.

Prevention

Data on effective pharmacologic prevention strategies are limited. A few preliminary studies in patients undergoing elective surgery suggest that low-dose haloperidol and low-dose risperidone reduced the incidence of postoperative delirium.^{23,44} Because these studies involved patients with a low severity of illness, it is unclear if these findings can be extrapolated to the general ICU population. Dexmedetomidine may be associated with less incident postoperative delirium in cardiac surgery patients, compared to propofol or midazolam.²⁸ However, these findings need to be confirmed before broad treatment recommendations can be made.

Several reasons might explain why studies on successful delirium prevention strategies are limited to date. First, up to 70% patients are admitted to the ICU with delirium already present.¹⁶ Second, prevention studies require a larger sample size to detect differences in incident delirium (which is a binary outcome) compared to duration of delirium (which is a continuous outcome). Finally, most pharmacologic delirium prevention studies did not include concurrent non-pharmacologic delirium prevention strategies such as sedation titration and early mobilization. Because delirium is multifactorial in origin, addressing only a few of the many factors contributing to its development may limit the efficacy of a prevention strategy.

In contrast, preliminary studies suggest that nonpharmacologic strategies targeting multiple risk factors for delirium may be more effective. These strategies include early rehabilitation, sleep-promotion, and structured reorientation. Because these prevention strategies overlap with treatment strategies, they will be discussed in greater detail in the following ICU-level treatment strategies section.

Treatment

Several high-quality intervention studies to halt and limit the duration of delirium in its earliest stages

have successfully reduced the duration of delirium and improved other clinical outcomes. This suggests that despite the occurrence of delirium, strategies to reduce the delirium duration may be the first area of focus for ICU teams. In order to maximize the therapeutic potential, a combination of strategies should be used: (1) multicomponent nonpharmacologic interventions that are useful for all ICU patients should be implemented at an ICU level (ICU-level strategies) and (2) pharmacologic interventions that may be useful for specific patients and should be titrated to each individual (patient-level strategies) (Figure 49–3). Each of these strategies will be discussed in the following sections.

ICU-Level Strategies

Given the multifactorial nature of delirium and the interdependency of ICU-treatment-related

risk factors, it is not surprising that multicomponent ICU-level strategies have had better success with reducing the duration of delirium compared to pharmacologic strategies that address only a few ICU-level risk factors (Figure 49–4).

Pain Management

Nearly 50% of critically ill patients experience significant pain during their ICU stay.⁴² Studies suggest that pain may be a risk factor for delirium.^{12,13} Several possible reasons to explain this relationship are: (1) the deleterious cognitive effects of pain itself, (2) agitation due to untreated pain leading to inappropriate sedative administration, and (3) pain medication doses in excess of what is required for pain control. Indeed a study showed that patients who are regularly assessed for pain received less sedation compared to those who did not receive regular pain

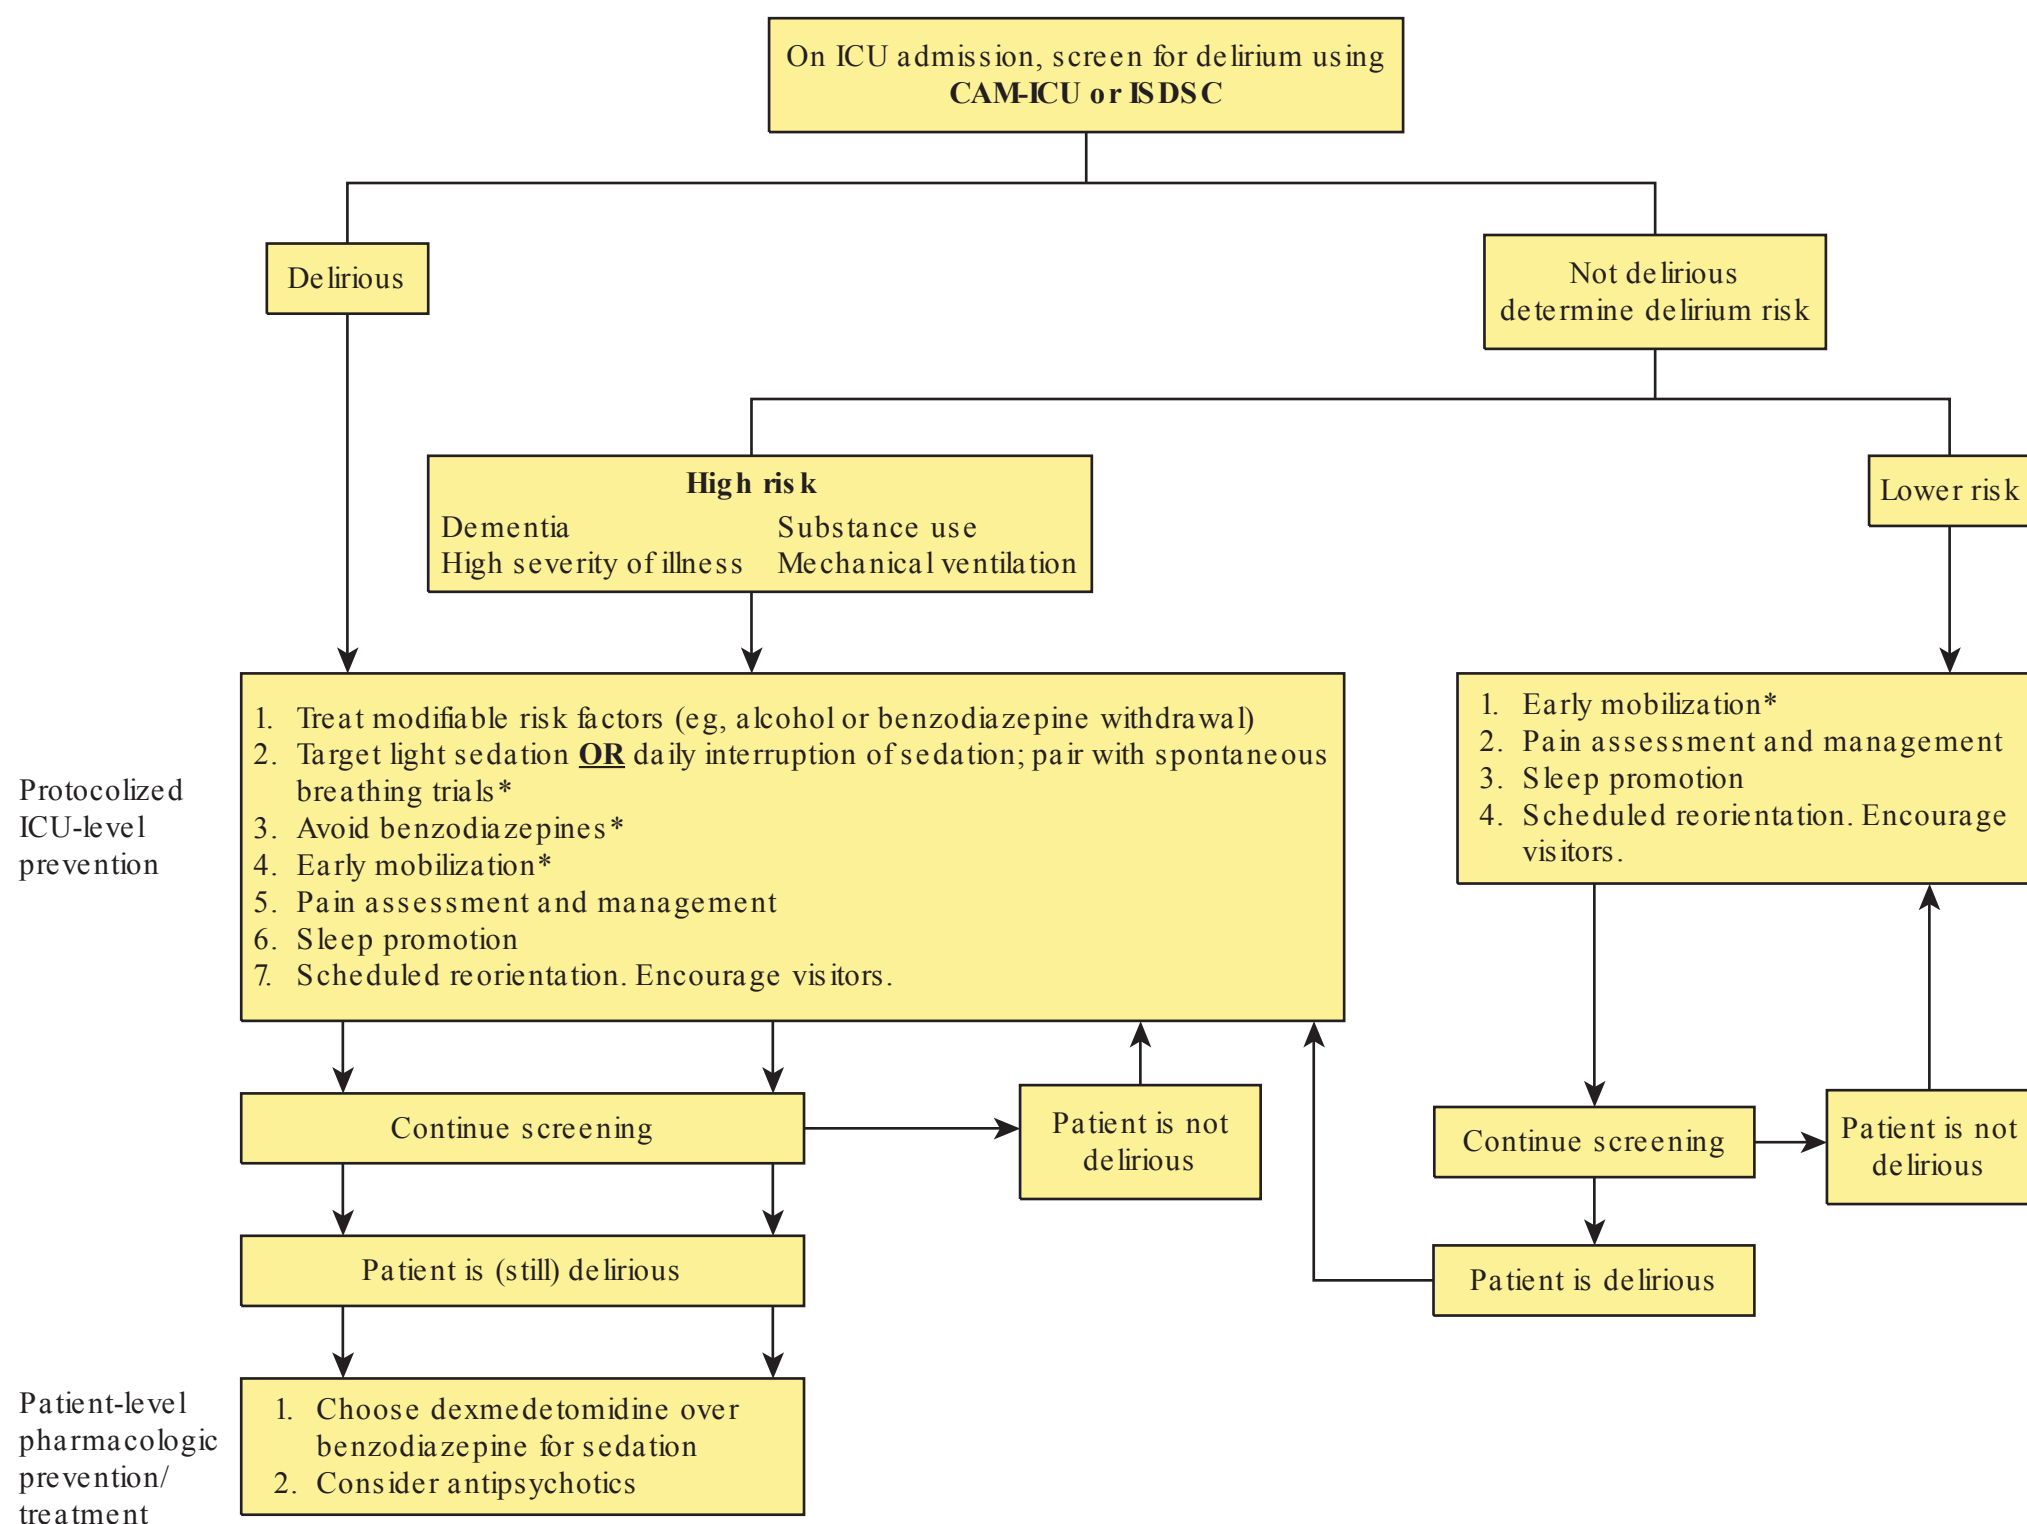

FIGURE 49–3 A clinically useful approach to ICU delirium prevention and treatment. This proposed approach incorporates patient-level delirium prevention and reduction assembled from multiple evidence-based sources, but has not yet been tested in a critically ill population. (Reproduced with permission from Hsieh SJ, Ely EW, Gong MN: Can intensive care unit delirium be prevented and reduced? Lessons learned and future directions, *Ann Am Thorac Soc* 2013 Dec; 10(6):648-656.)

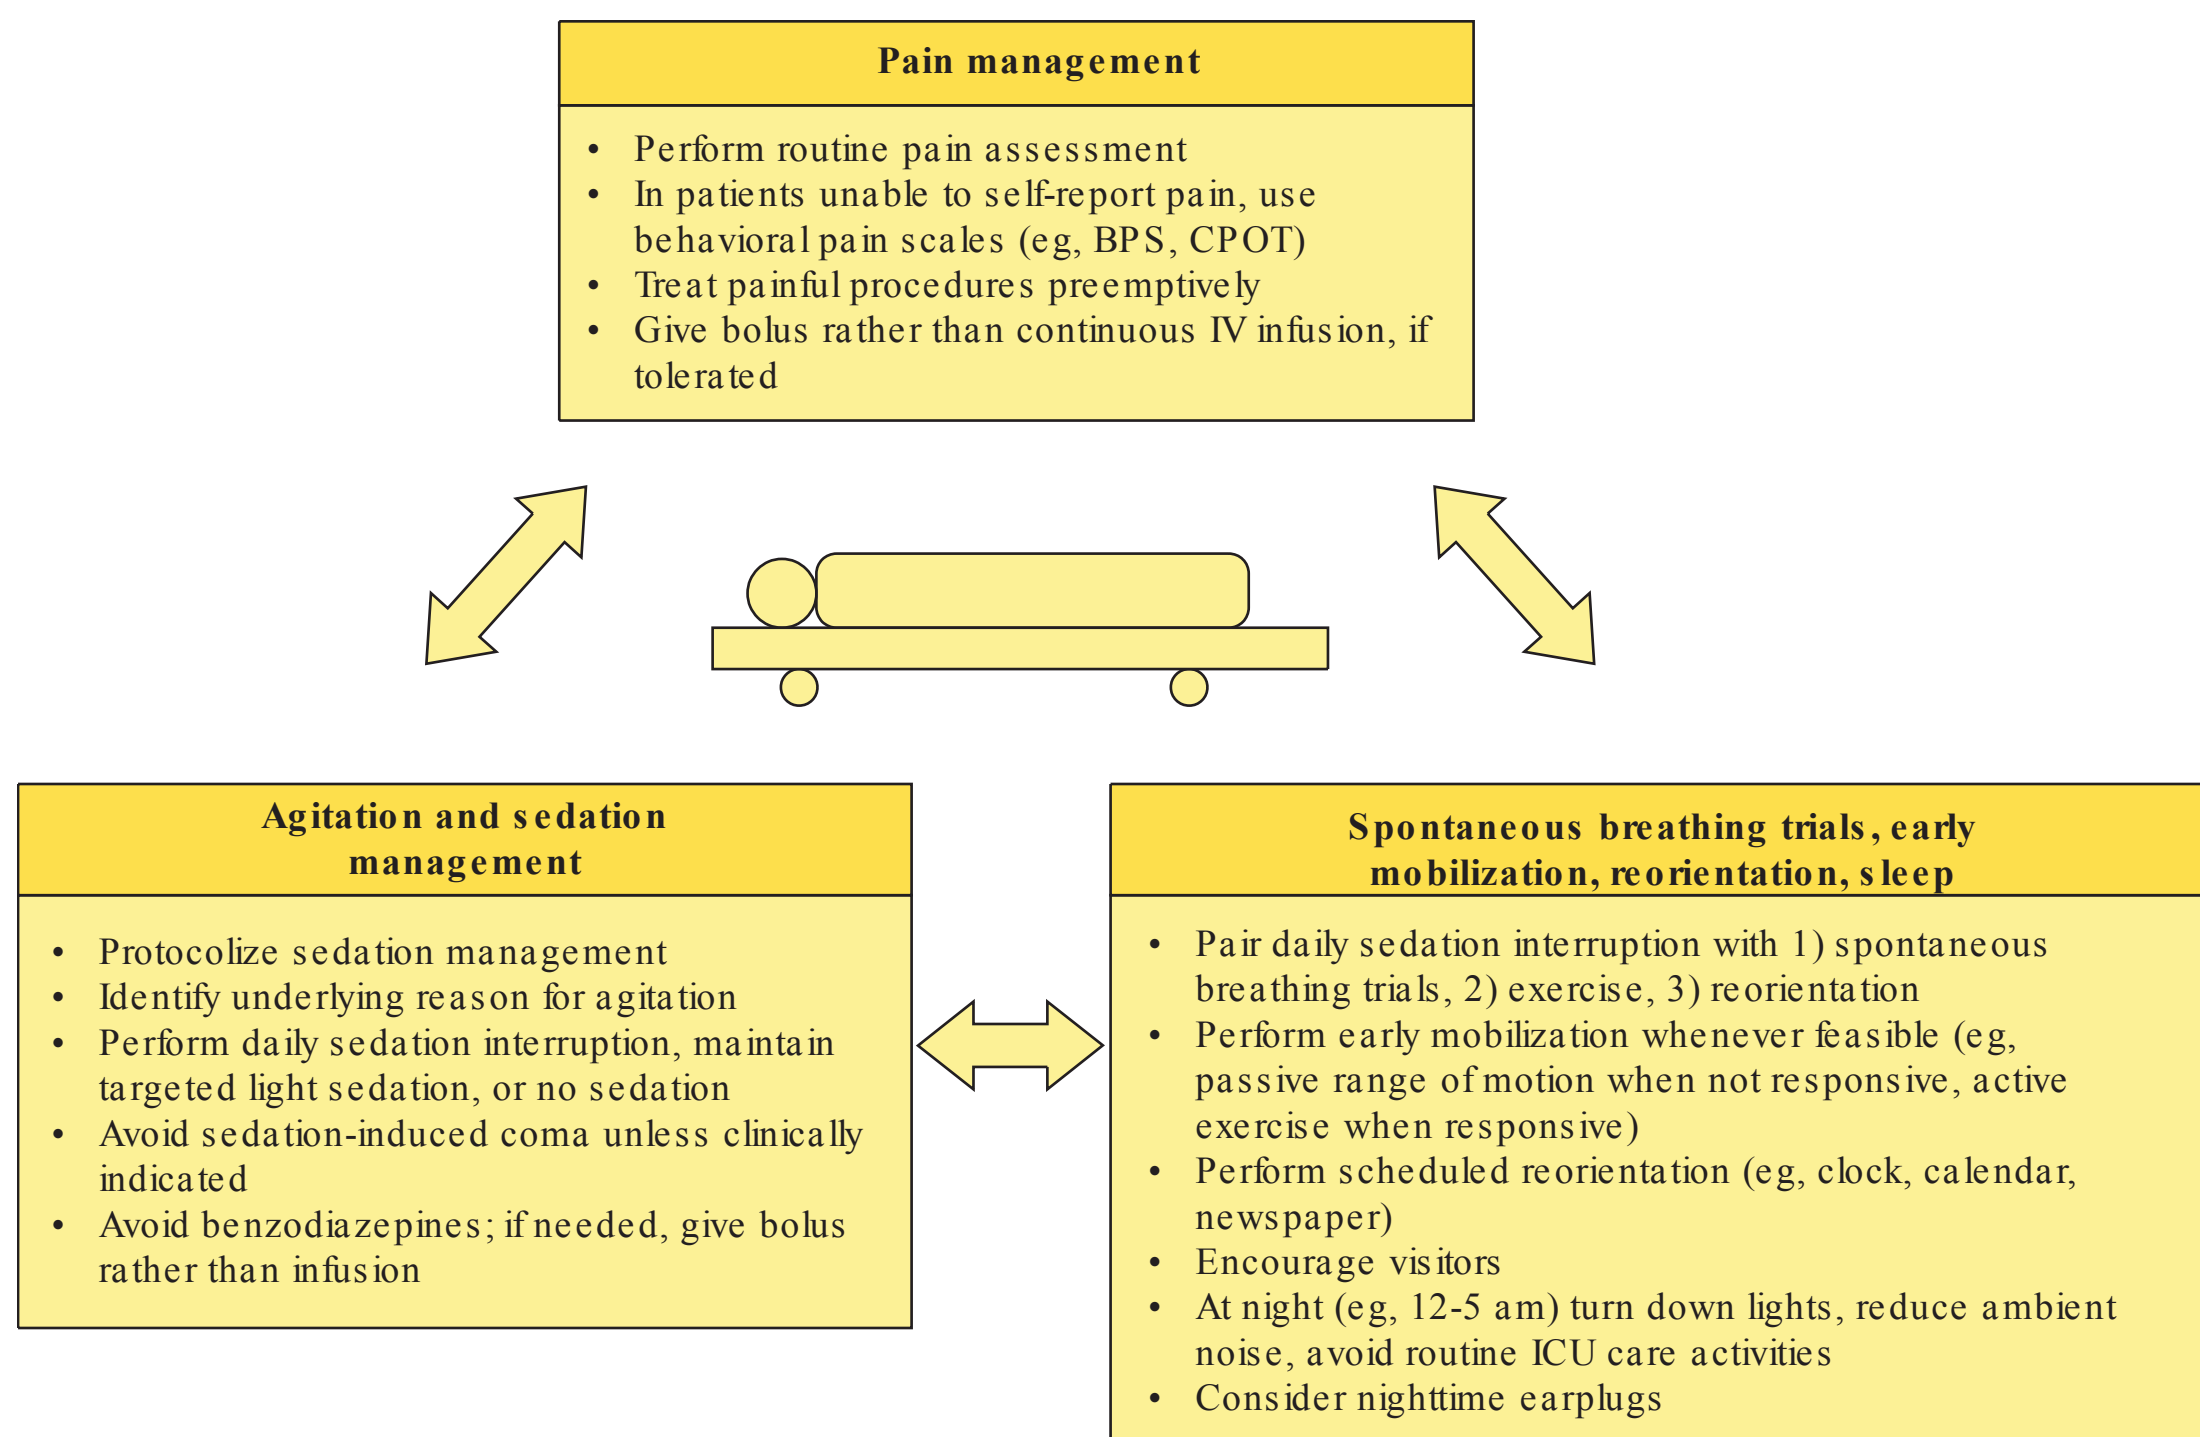

FIGURE 49–4 ICU-level delirium prevention and reduction strategies are interconnected. (Reproduced with permission from Hsieh SJ, Ely EW, Gong MN: Can intensive care unit delirium be prevented and reduced? Lessons learned and future directions, *Ann Am Thorac Soc* 2013 Dec;10(6):648-656.)

assessments.⁴⁵ Therefore, the goal of pain management through routine pain monitoring should be satisfactory pain control without oversedation, and pre-emptive treatment of pain before painful procedures are initiated.

Agitation Management

Agitation is common in critically ill patients. Determining the underlying cause(s) of agitation is essential for determining the appropriate treatment for agitation. Common causes for agitation include untreated pain, anxiety, withdrawal from alcohol or chronic opiates or sedatives, factors associated with the acute illness (eg, hypoxia and hypotension), and delirium. Treatment of agitation that does not address the underlying cause can incite or prolong delirium (eg, a patient with agitation due to uncontrolled pain is given benzodiazepines). Conversely, successful treatment or responsiveness to the underlying cause can potentially reduce sedation use and even improve clinical outcomes.

Sedation Management

Medication-induced coma is a risk factor for ICU delirium. In addition, the prolonged immobility that mechanically ventilated patients experience during deep sedation can lead to complications such as muscle atrophy and weakness, ventilator dependency, pressure sores, and venous thromboembolic disease.⁴⁶⁻⁴⁸ Rather than routinely providing deep sedation to mechanically ventilated patients without a specific indication, the overall goal of sedation should be to achieve a level of wakefulness so patients can actively participate in rehabilitation and cognitive stimulation during their critical illness. Three different approaches that have demonstrated good outcomes are targeted: (1) daily interruption of sedation, (2) light sedation, and (3) no sedation. Strategies to decrease sedation have led to decreased delirium duration, reduced time on the mechanical ventilator, decreased ICU length of stay, and decreased mortality, and have been demonstrated

to be safe, feasible for incorporation into daily care, and acceptable to ICU staff.⁴⁹⁻⁵⁴ At least one, if not all, of these approaches should be adopted for a “less is more” culture of sedation use.^{24,55} Routine monitoring of quality and depth of sedation is needed to guide these strategies. The Richmond agitation-sedation scale (RASS)³⁷ and sedation-agitation scale (SAS)³⁸ were identified by the ACCM Clinical Practice Guidelines as the 2 most valid, reliable, and feasible sedation assessment tools for goal-directed sedation delivery.²⁴

Early Rehabilitation

Multiple studies have consistently identified immobility as a risk factor for delirium.^{5,31} Furthermore, ICU delirium is associated with functional disability after hospital discharge.^{56,57} Early delivery of physical and occupational therapy to mechanically ventilated ICU patients (eg, passive range of motion in unresponsive patients, active exercises in interactive patients) has been associated with reduced delirium prevalence and duration, and is safe and well-tolerated.^{33,58} In addition, early rehabilitation is associated with less time on mechanical ventilation, improved return to functional status, and may lead to cost savings.⁵⁹ Of note, studies demonstrating the benefits of early mobilization also targeted other ICU delirium risk factors such as sedation reduction coordinated with mechanical ventilator weaning.

Sleep Promotion

Critically ill patients frequently experience poor sleep quality in the ICU.⁶⁰⁻⁶² Sleep deprivation has been postulated to be a risk factor for ICU delirium because both sleep-deprived and delirious patients share common clinical and physiologic derangements.⁶³ Preliminary studies suggest that a combination of nonpharmacologic sleep promoting interventions (eg, earplugs and reducing nighttime procedures and noise, daytime mobilization), and decreased use of sedatives known to alter sleep or precipitate delirium (ie, benzodiazepines, opiates, diphenhydramine, trazodone), can improve self-reported sleep quality and may even reduce incident delirium and delirium duration.⁶⁴⁻⁶⁷ Although more work is needed in general ICU populations, given the relative ease of implementation, minimal risk, and potential benefit of

these interventions, it would be reasonable to implement these practices into usual care.

Reorientation

Pre-existing cognitive, visual, and hearing impairment are risk factors for delirium, likely because of the disorientation that patients with these impairments experience.^{5,15} Reorientation strategies, such as reading newspapers, listening to music, wearing visual and hearing aids, and performing cognitively stimulating activities, have effectively prevented delirium in older non-ICU patients; preliminary studies in ICU patients also suggest a benefit.^{68,69}

Patient-Level Pharmacologic Treatment

Data on pharmacologic treatment of ICU delirium is mixed. Current evidence suggests a potential benefit from dexmedetomidine and antipsychotics, but other agents such as cholinesterase inhibitors and melatonin have not been found to be helpful in preventing delirium and may even be harmful in the case of cholinesterase inhibitors.⁷⁰⁻⁷² The limited success of these therapies in clinical trials may in part be due to the lack of concurrent nonpharmacologic multicomponent delirium prevention strategies such as early rehabilitation and reduced sedation practices.

Sedation With Dexmedetomidine

Dexmedetomidine is a selective α_2 -adrenoreceptor agonist that has sedative, analgesic and anxiolytic properties. Studies suggest that it is associated with less delirium and may promote better sleep/wake cycle regulation when compared to medications that work through the GABA receptor pathway such as benzodiazepines.⁷³ Several large, well-designed randomized controlled trials comparing dexmedetomidine vs benzodiazepines for sedation in mechanically ventilated medical and surgical ICU patients have shown that dexmedetomidine was associated with a 30% lower prevalence of delirium²⁶ and more days alive without delirium and coma (7 vs 3 days).²⁷ In addition, patients receiving dexmedetomidine spent less time on mechanical ventilation (3.7 vs 5.6 days),²⁶ and dexmedetomidine was not associated with increased cost.²⁷ While evidence comparing dexmedetomidine to other sedatives such as opiates or propofol in the

general medical and surgical ICU patient population are more limited,⁷⁴ these data are encouraging, particularly since the benefit was observed even in the setting of good sedation practices (eg, daily sedation vacation, targeted light-moderate sedation level, delirium monitoring).

While data are currently insufficient to support the widespread use of dexmedetomidine for sedation in all ICU patients, the 2013 ACCM guidelines recommend that dexmedetomidine could be considered for use as a sedative in patients with delirium and in patients who are at high risk for delirium.²⁴

Antipsychotics

Antipsychotics (eg, haloperidol, risperidone, quetiapine) are hypothesized to treat delirium by blocking dopamine-mediated neuronal excitability and thus stabilizing cerebral function.⁷⁵ Although they were formerly recommended by major guidelines for treatment of ICU delirium (and are still widely used for that indication),^{76,77} no large-scale prospective RCTs have tested the impact of antipsychotics on delirium duration, and the 2013 ACCM guidelines no longer recommend for, or against, their use. A small trial in ICU patients with delirium who were already receiving haloperidol found that delirium resolved faster in patients who received haloperidol plus quetiapine, compared to patients who only received haloperidol.⁷⁸ Clinical trials are currently underway to determine if antipsychotics are an effective treatment for ICU delirium.

Prognosis

Delirium is a strong predictor of ICU length of stay, even after adjusting for factors such as severity of illness and age,⁷⁹ and is independently associated with poor short-term consequences including increased duration of mechanical ventilation, increased hospital length of stay, and institutional placement.^{4,80-83} While even 1 day of delirium is associated with poor clinical outcomes, it is also important to recognize that a “dose-dependent” relationship exists between the duration of delirium and poor clinical outcomes. For each day a patient is delirious, the risk of 6-months and 1-year mortality increases by 10%.^{4,82} In addition, a longer duration of delirium is an independent predictor of cognitive impairment in both older and younger mechanically ventilated patients.^{83,84} A recent study found that up to 34%

of patients had persistent deficits in global cognition and executive function that were similar to mild Alzheimer’s disease and moderate traumatic brain injury 1 year after critical illness.⁸⁵ Increased delirium duration is also associated with disability in activities of daily living and worse motor-sensory function in the year following critical illness.⁸⁶ These adverse consequences can profoundly impact a patient’s ability live independently after hospital discharge and can decrease their health-related quality of life. It can also be highly distressing for family members and caregivers and increase their caregiver burden.⁸⁷ With an annual cost of \$4 to \$16 billion in the United States alone,⁸¹ ICU delirium is now recognized as a major public health problem.

Current Controversies and Unresolved Issues

Over the last 10 years, significant advances have been made in understanding risk factors for ICU delirium and have resulted in effective ICU-level strategies that have reduced the adverse impact of delirium. Nonetheless, many questions remain. First, animal models and trials on pathway modulation are needed to elucidate the pathophysiology of delirium. Second, the optimal pharmacologic therapy to prevent and reduce ICU delirium is still unknown, and the optimal protocols for different patient populations still need to be determined. Third, it is unclear if the improved short-term clinical outcomes that are associated with delirium reduction (eg, decreased time on mechanical ventilation, decreased ICU length of stay) translate into improved long-term cognitive, functional, and psychological outcomes. Fourth, more work is needed to elucidate the clinical implications of delirium severity and its subtypes (eg, subsyndromal delirium; hypoactive vs hyperactive delirium). Finally, more studies on cognitive and physical rehabilitation are needed to determine the optimal prescription, timing, and duration for different ICU patient populations.

Traumatic Brain and Spinal Cord Injury

Vikram Dhawan, MD and Jamie S. Ullman, MD, FACS, FAANS

KEY POINTS

- 1 Traumatic brain injury is primary and secondary. Primary injury is due to the direct impact of the trauma, while secondary is due to hypoxia leading to a cascade of events set off by ischemia/reperfusion. The focus of management is prevention and treatment of secondary injury.
- 2 Severity of brain injury is assessed both clinically and radiologically. A Glasgow Coma Scale (normal range 3-15) of 13 to 15 is considered mild brain injury, 9 to 12 moderate, and 3 to 8 severe brain injury. The Marshall score using head computed tomography (CT) is also used to predict severity.
- 3 The CT scan is the fastest and most widely used initial imaging modality available for skull and brain parenchymal lesions. CT angiography and perfusion studies further help to characterize vascular/perfusion deficits.
- 4 Preventing and treating hypoxia and hypotension to prevent hypoxia and adequate perfusion is of utmost importance.
- 5 Patients with risk factors for spinal cord injury should be handled with care in the field and their spine stabilized with rigid cervical collars on a board with straps.

TRAUMATIC BRAIN INJURY

Introduction

Traumatic brain injury (TBI) is the leading cause of death in the early decades of life. The estimated number of deaths is 50,000 with 40% of survivors with disability after the injury.¹ The estimated incidence is 17.5 to 24.6 deaths per 100,000 population.^{2,3} Men are more likely to suffer TBI compared to women and the majority of injuries are due to falls.

Injury Types

In TBI injuries are classified as primary and secondary. Primary injury ([Table 50–1](#)) happens at the time of impact and secondary injury occurs later due to

oxygen deprivation to the brain and the cascade of events set off by ischemia and reperfusion leading to further injury. The target of management focuses more on prevention and treatment of secondary brain injury.

In primary injury, depending upon the mechanism of trauma, fractures of the skull can be open or closed, depressed or nondepressed, and linear or comminuted. Most of these fractures are evident on clinical exam but radiography is required for accurate diagnosis. Both plain skull X-ray and computed tomography (CT) scan can be used for skull fractures, although plain radiologic films are better for linear calvarial fractures tangential to the axial plane. Multislice CT, alternatively, can delineate skull fractures

TABLE 50–1 Primary brain injury.

Diffuse axonal injury

better than plain CT scans. Fractures can result in neurologic deficits related to underlying brain injury, cerebral spinal fluid (CSF) leak (suggesting dural laceration) such as otorrhea or rhinorrhea, pituitary gland shearing injuries, and cranial nerve (CN) injuries. Depending on the fracture location, different CNs can be involved. Temporal bone fractures cause facial or acoustic nerve injuries, anterior fossa basal skull fracture can cause olfactory and optic nerve injuries, and clival fractures can cause abducens nerve injuries. Postauricular ecchymosis (Battle’s sign) and periorbital ecchymosis (raccoon’s eye) may be seen in basal skull fractures.

Most skull fractures are managed conservatively and prophylactic antibiotic use is controversial. Operative or endovascular treatment is indicated in traumatic aneurysms, carotid-cavernous fistula, CSF fistula, abscess management and for CN decompression.

Depending on the type of injury, different types of hemorrhage can occur in TBI as follows:

1. Epidural: Bleeding between dura and skull, usually from disrupted meningeal artery laceration. The mean age of patients with epidural hemorrhage (EDH) is between 20 and 30 years. About 70% to 90% of EDH is associated with skull fracture and in 36% of cases there was found to be a bleeding artery. Diffuse bone bleeding and venous bleeding (middle meningeal vein, diploic veins and dural venous sinuses) also cause EDH. The most common location is temporal because the bone is relatively thin and more vulnerable to fracture. It appears as a lentiform shape on

CT scan and usually stops at the suture lines where the dura is adherent (Figure 50–1).

2. Subdural: Occurs between the dura and the arachnoid space and is caused by disruption of bridging veins due to acceleration, deceleration, and rotational shearing forces. Frontal and parietal convexities are common places for subdural hemorrhage (SDH). The skull suture lines do not limit the bleeding, so on CT scan it can appear as crescent shape, conforming to the brain surface and traversing suture lines. Acute SDH appears hyperdense on CT scan but can have low-attenuation areas representing hyperacute or active hemorrhage. The incidence of SDH after TBI is approximately 11% with most due to motor vehicle accidents (MVAs) in young people and falls in the elderly. Up to 80% of patients with acute SDH may present with a Glasgow Coma Scale (GCS) less than 8 and pupillary abnormalities are seen in 50% of these patients (Figure 50–2).
3. Subarachnoid: Occurs in the space surrounding the brain and blood vessels.

FIGURE 50–1 Epidural hematoma. Patient with significant head injury resulting in a comminuted right temporal bone fracture and underlying large epidural hematoma with pneumocephalus causing midline shift. This hematoma required surgical evacuation.

FIGURE 50–2 Subdural hematoma. Patient who fell and sustained an occipital laceration with staples noted in the soft tissues. He has a left frontoparietal subdural hematoma which is less than 1 cm in thickness causing only minimal midline shift. This patient underwent observation in the hospital.

FIGURE 50–3 Subarachnoid hemorrhage. Patient fell after syncope, hit the back of his head, and sustained smaller bilateral subdural hematomas and diffuse subarachnoid blood in both sylvian fissures. There is also subdural hemorrhage along the midline falx cerebri.

Trauma is the most common reason and occurs due to crushed or ruptured small vessels. Bleeding is common on the cortical surface but occasionally in the basal cisterns. Complications of SAH include hydrocephalus, seizures, and cerebral vasospasm, the latter an independent predictor of mortality in severe TBI ([Figure 50–3](#)).⁴

4. Intraparenchymal or intracerebral: Bleeding occurs in the parenchyma of the brain. This can vary from contusions to large hematomas in superficial or deep brain areas. Coup injuries are contusions present at the site of impact. For example, an occipital impact may cause frontal contusions. The coup/contrecoup phenomenon can also be seen with subdural hematomas, indicating acceleration–deceleration forces. The inferior

frontal and temporal areas are most vulnerable to contusion formation due to ridging of the orbital roof and floor of the temporal fossa.⁴

Primary injury causes direct trauma to tissue leading to symptoms. Primary injury to the brain can be due to acceleration, deceleration, or rotational forces. Linear forces cause more superficial grey-matter injuries, while rotational forces cause deeper white-matter injuries leading to diffuse axonal injuries.

Secondary injury occurs due to deprivation of oxygen to the brain, which in turn sets off a cascade of biochemical/molecular events leading to further damage to brain. There are complex cellular and molecular changes including glutamate excitotoxic effects, oxidative stress, metabolic derangements, and inflammatory changes that play a major role in its pathogenesis.⁵ Progressive neuronal necrosis and apoptosis may result.

At the beginning of the injury, huge depolarization of neurons and glial cells lead to influx of calcium into the brain cells. This increases oxygen-free

radical reactions producing nitric oxide and excitatory amino acids such as glutamate. Glutamate is believed to promote cell death and dysfunction. Mitochondrial influx of calcium causes swelling and loss of ATP generation. As cellular membranes depend on ATP for their integrity, the inability to produce ATP leads to cell wall disruption and cell death.

Apart from the direct compromise of the cranium and outer layers of brain in TBI, disruption of blood brain barrier (BBB) contributes to loss of cerebral autoregulation. Cerebral autoregulation is the maintenance of cerebral blood flow (CBF) over a wide range of blood pressures of which cerebral perfusion pressure (CPP) is an important component. CPP is defined as the difference between mean arterial pressure (MAP) and intracranial pressure (ICP). In TBI, loss of autoregulation results in the inability to maintain adequate cerebral perfusion at CPP below 50. Loss of the BBB causes vasogenic edema from leaking, dilated blood vessels. In the brain, the edema resulting from cellular swelling is called cytotoxic edema.

According to the Monroe–Kellie principle, the cranium has fixed space and is occupied predominantly by brain tissue, CSF, and blood. Any increase in the volume in the cranium will lead to an increase in ICP, unless it is offset by a decrease in the volume of any one of the contents of the cranium. Therefore, intracranial hemorrhage and brain swelling, which increase intracranial mass, cause ICP increase and further brain damage.

In conclusion, production of oxygen-free radicals and calcium ion influx leads to widespread neuronal injury due to oxidation and enhanced enzymatic activity. Shearing of axons causes neurofilament disruption and increases permeability to calcium ions. Calpains are enzymes, which target the cytoskeleton of axons. Apoptosis ensues during TBI and there is proliferation of glial cells and astrocytes.⁶

Diffuse axonal injury is an acceleration–deceleration and rotational injury leading to shearing and disruption of the white-matter axonal transport system pathways. Both functional and anatomic injury can lead to unconsciousness in a patient not explained by other primary injuries ([Figures 50–4a](#) and [50–4b](#)).

Injury Severity

The severity of injury determines the outcome of patients with TBI. The GCS ([Table 50–2](#)) is the most common tool used to grade severity of TBI at the time of initial injury. It uses 3 parameters—eye opening, motor response, and verbal response—for injury assessment.

A GCS score of 13 to 15 is considered mild TBI, 9 to 12 is moderate TBI, and 3 to 8 is severe TBI (patient in coma). About 70% to 90% of TBI cases are in the mild category. The GCS scoring system is limited when patients are intubated, aphasic, or aphonic as the verbal and eye variables are hard to measure. Other scales have been developed to account for respiratory or pupillary abnormalities.⁷ These scales are not as widely used as the GCS.

Neuroimaging can also be used to predict injury severity. Presence of midline shifts, Intracerebral hemorrhage (ICH), SAH, and extra-axial hematomas on CT scan are poor prognostic markers. CT scan grading systems have been used for grading injury on initial presentation. The Marshall ([Table 50–3](#)) score is an example.^{8,9}

Imaging

Imaging can provide important information regarding severity of injury. The goal of initial imaging is to rapidly diagnose life-threatening injuries in TBI and to treat them in a timely manner.

CT scan is a widely used modality and often the first one to be used in TBI, as it is fast and sensitive. Newer multi-row-detector CT is even faster and can scan a head within seconds. CT scan provides either 2D or 3D reformatted images. CT scans are useful for diagnosing and differentiating different types of brain hemorrhage, hydrocephalus, and mass effect.

In SDH, as mentioned earlier, the bleed can spread beyond skull suture lines and on CT scan blood can appear as crescent-shaped hyperdense in acute stage. Epidural hematomas appear as a lens-shaped hyperdensity not extending beyond suture margins. Subarachnoid hemorrhage usually conforms to the sulcal space of the brain and CT angiography helps in determining aneurysm or vascular malformation as the cause of the bleed.

If hemorrhagic, contusions can be seen on CT scan and if these small hemorrhages coalesce,

(a)

(b)

FIGURE 50–4 Diffuse axonal injury. Patient with a significant diffuse injury after TBI resulting in (A) small right temporal and medial frontal intraparenchymal hemorrhages and (B) compressed/effaced perimesencephalic cisterns resulting in severe diffuse brain swelling. There is also bilateral frontal subarachnoid blood.

they can appear as a hematoma. Small hemorrhages (also called Duret hemorrhages) can be seen in the central pons as a consequence of severe uncal herniation and brainstem compression.

CT angiography is useful for assessing vascular injuries such as aneurysm, pseudoaneurysm, dissection, or thrombus, especially in the face of basilar skull fracture or those crossing a venous sinus. CT perfusion scanning evaluates time to peak (contrast) density, mean transit time, cerebral blood volume, and CBF. Normal CBF is 50 mL/100 g/min (of brain tissue). This modality helps in differentiating between ischemia and infarction, CBF measure 10 to 22 mL/100 g/min and less than 10 mL/100 g/min, respectively.

Magnetic resonance imaging (MRI) evaluates the movement of protons in the tissue when a magnetic field is applied. MR is sensitive in detecting subacute hemorrhage and depending on the appearance of blood on T1 and T2 weighted images, it can

detect the timeline of the bleed. Gradient Recalled Echo is a modality of MR that provides information about blood or its degradation products, which appears as a low-intensity signal.

MR angiography is an alternative to CT angiography for characterizing major arterial or venous vascular injuries and can be done with or without contrast. Catheter angiography is the gold standard for diagnosing and treating vascular injuries. Due to long acquisition times, MR imaging may be problematic in critically ill, intubated trauma patients.¹⁰

Management

Prehospital Management

Management of TBI starts with basic resuscitation efforts. Supplemental oxygen to correct hypoxemia is essential. Hypoxemia should be avoided as it leads to an increase in severe disability and mortality.¹¹

TABLE 50–2 Glasgow coma scale (GCS).

Class	Def nition	Mortality
Diffuse injury type 1	No visible intracranial abnormality	10%
Diffuse injury type 2	0-5 mm midline shift/ cisterns present/and or lesion density present	14%
Diffuse injury type 3	0-5 mm midline shift/ cisterns compressed or absent/no lesion density > 25 cm ³	34%
Diffuse injury type 4	Midline shift > 5 mm/no lesion density > 25 cm ³	56%

If needed, the airway should be secured in the field. Volume resuscitation should begin prior to reaching the hospital. Hypertonic solutions such as hypertonic saline (HS) solutions are anti-inflammatory and immunomodulatory.¹² They can be used in case of suspected high ICP.

There is no role for prophylactic hyperventilation that should only be used as a brief temporizing measure when there are visible signs of herniation such as dilated and unreactive pupils, asymmetric pupils, extensor posturing, or no response or decline of 2 or more points from the baseline GCS.

Hospital Management

General Principles—Care should be taken to avoid hypoxemia and hypotension at all costs in TBI patients. Patients with oxygen saturations less than 60% have a 50% incidence of mortality or severe disability. Correction of hypotension improves outcomes. Although a systolic blood pressure value cutoff of 90 is normally targeted, the best systolic blood pressure for optimal outcomes is unknown.

Patients with concussion should be managed based on the severity of the concussion. Patients with mild TBI may be discharged home after a brief observation without any follow-up CT scan or imaging. The only exception is EDH as these patients may have a lucid interval and then rapidly progress to coma and death. Normally, analgesics (avoiding opioids) for headache and meclizine or vestibular exercises for dizziness are sufficient, along with appropriate rest. Some may have a seizure that may be mistaken for a more severe brain injury.

For severe TBI, management is based mainly on treatment of ICP/CPP derangements. Both mannitol and HS can be used to lower ICP. If patients have signs of high ICP such as transtentorial herniation or deteriorating mental status, ICP monitoring is advised for goal directed ICP treatment. Mannitol expands plasma volume and improves blood viscosity and improves oxygen delivery often reducing ICP within a few minutes. The osmotic effect starts within a few minutes and may last for a few hours as a gradient is established between plasma and cells. Mannitol can be given as an intravenous infusion or as a bolus in dosages of 0.25 g/kg to 1 g/kg. HS acts by mobilization of water from the brain across the BBB due to its high osmolality. It also improves plasma

volume and hence blood flow. As with mannitol, it can also be given as intravenous infusion or bolus. HS comes in different concentrations ranging from 1.5% to 23.4%. As of this writing, there has been no consensus on the dosing and method of administration. Serum osmolality and serum sodium (Na) levels should be periodically checked, with a goal of not exceeding 320 mOsm/kg and Na of 155, respectively; there is potential for acute kidney injury if these levels are exceeded.

Hyperventilation reduces CO_2 and causes cerebral vasoconstriction, decreasing ICP. Hyperventilation is to be avoided in patients with TBI in the first hours (24-48 hours) as the CBF is decreased. It should only be used as a short-term temporizing measure to delay impending herniation.¹³

Currently, the indications for measuring ICP are GCS less than 8, an abnormal CT scan showing evidence of mass effect in the presence of SDH, EDH, or brain swelling. If the CT scan is normal but injury is severe then monitoring is indicated in patients who have 2 or more of the following:

1. Age above 40 years of age
2. Systolic blood pressure below 90
3. Unilateral or bilateral posturing

Measurement of ICP is useful for prognosis and helpful in guiding therapy. Patients in whom ICP responds to treatment do better than patients who fail to respond, while ICP elevations have been associated with poorer outcomes. The currently proposed threshold to initiate treatment for ICP is 20 to 25 mm Hg.

The devices to monitor ICP range from invasive to less invasive. The gold standard and most accurate ICP monitor is an external ventricular drain (EVD) attached to an external strain gauge pressure transducer. Although being most invasive, EVD confers the benefit of CSF drainage to manage ICP. The risk of hemorrhage is about 0.5% and infection is about 8% with these catheters. Internal transducer devices consisting of a fiber-optic cable or strain-gauge wire can be placed in the brain parenchyma. They are largely accurate but unable to be calibrated once inserted in the parenchyma and are subject to varying degrees of drift after several days of monitoring. Parenchymal devices are also helpful in cases where

intraventricular drain insertion is unsuccessful or when the ventricles are collapsed around the catheter. Subdural, subarachnoid, or epidural space transducers are fluid-coupled systems placed through a hollow bolt in the cranium but are less accurate and are now rarely used.

CPP, the difference between MAP and ICP, is a primary determinant of CBF (along with cerebrovascular resistance). Patients with TBI should be targeted for CPP between 60 and 70 mm Hg. CPP less than 50 mm Hg should be avoided and aggressively treated as patient outcomes are poor. In the same manner, higher CPP should be avoided, as there is an increased risk of acute lung injury, which is thought to be due to increased fluid and inotrope usage.

Besides monitoring and treating ICP/CPP, there are other parameters that can be monitored. These include brain tissue oxygen tension (PtiO_2), jugular venous oximetry, near infrared spectroscopy, cerebral microdialysis, CBF assessment, and continuous electroencephalography. Among these parameters, PiO_2 is the most commonly used due to wider commercial availability. TBI patients with optimal ICP/CPP may still have cerebral hypoxia in pericontusional areas according to PtiO_2 measurements. Patients who have PtiO_2 less than 15 for increased duration have been shown to have poor outcomes and increased mortality. Use of PtiO_2 along with use of ICP-based treatment/CPP-based treatment may improve outcomes as compared to only ICP-based management/CPP-based management.¹⁴

TBI patients may need sedation or analgesia or both for comfort and pain relief. Analgesics such as morphine, fentanyl, or sufentanil provide pain relief, but have minimal effect on ICP. Sedative agents commonly used include propofol and midazolam. The long-term use of propofol or midazolam does not result in significant differences in ICP, CPP, or MAP. In general, sedation decreases ICP in patients with TBI. Propofol infusion may have some side effects such as hypertriglyceridemia (if patients are on TPN, the lipid should be reduced) and the propofol infusion syndrome (rare but usually fatal), especially if used in doses of more than 4 mg/kg/h for more than 48 hours. Barbiturates such as pentobarbital can be used in patients with elevated ICP. For pentobarbital, the following dosing regimen can

TABLE 50–4 Analgesic and sedative dosing.

Morphine sulfate	4 mg/kg infusion with titration
Fentanyl	2-5 mcg/kg/h infusion
Sufentanil	0.05-2 mcg/kg infusion
Midazolam	2-4 mg/h
Propofol	20-75 mcg/kg/min infusion

be used: loading dose 10 mg/kg over 30 min; 5 mg/kg/h for 3 doses; and maintenance of 1 mg/kg/h (see [Table 50–4](#)).

Other medications that are used include ketamine and etomidate. The use of any specific analgesics or sedatives, however, has not shown to improve outcome after TBI.¹⁵

Use of prophylactic hypothermia in patients with TBI has not shown statistically significant mortality benefit,¹³ although hypothermia can be used for the management of high ICP.

Patients with TBI and spinal cord injury are at high risk of venous thromboembolism (VTE). The risk ranges from 5% to 6% in patients with spinal cord injury and 3% to 5% in TBI.¹⁶ Currently, the recommendations are to add mechanical thromboprophylaxis to pharmacologic thromboprophylaxis in patients with TBI. When the decision to employ pharmacologic thromboprophylaxis is made after TBI or spinal injury, intravenous unfractionated heparin is the first choice due to the short half-life and rapid reversibility. Low-molecular-weight heparin (LMWH) is an option if the bleeding risks are assessed to be low, but LMWH is avoided in renal failure due to bioaccumulation. There is no data about the timing of VTE prophylaxis, but the sooner it can be safely started, the better. Our protocol is to commence chemoprophylaxis 24 hours after the last stable (no increase in hemorrhage) CT.

Patients with TBI should be started early on nutritional support. Early nutrition support may reduce infectious complications and mortality. If possible enteral nutrition should be started 24 to 48 hours following admission with the aim of reaching goal within 5-7 days.

Post-traumatic seizures (PTS) can occur in patients with TBI with an incidence of 4% to 25%

within the first 7 days of injury. Risk factors for PTS after TBI are as follows: GCS less than 10; epidural, subdural, or intracerebral hematoma; cerebral contusion; depressed skull fracture; penetrating head injury; and seizures within the first 24 hours of injury.

Anticonvulsants can be used to decrease the incidence of early PTS during the first week of TBI. They are not recommended for long-term use to prevent late onset PTS. Phenytoin or valproate can be used for seizure prophylaxis. The use of steroids in TBI is not recommended and may be even harmful.

Surgical Management

Surgical options are considered using the following criteria.

Epidural—If EDH volume is more than 30 cm³, it should be evacuated regardless of the GCS score. Patients with anisocoria and coma should undergo hematoma evacuation as soon as possible. Patients can be managed nonoperatively, if they meet all of the following criteria: EDH volume is less than 30 cm³; thickness is less than 15 mm; midline shift is less than 5 mm; GCS is more than 8; and no focal neurologic deficit.¹⁷

Subdural—Patients with acute traumatic SDH with GCS less than 9 should have ICP monitoring. These patients can be watched nonoperatively if the SDH thickness is less than 10 mm and midline shift is less than 5. If the GCS decreases by 2 points from the time of admission and/or they have asymmetrical or fixed and dilated pupils and/or their ICP rises above 20, they should be taken to operating room (OR). Patients with a hematoma thickness more than 10 mm or midline shift more than 5 mm should be operated upon irrespective of the GCS score. Surgery should be conducted sooner rather than later to improve outcomes.¹⁸

Parenchymal Lesions—Patients with TBI can have either focal or diffuse parenchymal lesions. Diffuse or nonfocal injuries include cerebral edema or diffuse injury. Focal lesions include contusions, ICH, delayed traumatic ICH (DTICH), and infarctions. DTICH is defined as ICH, which was not initially present on admission CT scan but developed subsequently, mostly in the region of contusions.

Patients with parenchymal lesions should be operated on in the following situations: deteriorating

neurologic exam as evidenced by a decrease in GCS by 2 points; refractory ICP; signs of mass effect on CT scan such as basal cistern obliteration; GCS of 6 to 8 and fronto-temporal lesion of more than 20 cm³ with midline shift more than 5 mm and/or cisternal obliteration on CT scan; any patient with a lesion volume more than 50 cm³.

Patients who do not meet the aforementioned criteria and who have their ICP controlled medically can be monitored with serial exams and CT scans. Patients who have diffuse cerebral swelling and difficult to control ICP, can undergo decompressive craniectomy. Others may have focal decompression and lesion resection.¹⁹

Traumatic Posterior Fossa Mass Lesions—Patients with lesions in the posterior fossa leading to neurologic dysfunction or deterioration require emergent craniotomy as they have a tendency to worsen rapidly. If CT scans show signs of a mass effect such as distortion or compression of the fourth ventricle or hydrocephalus, suboccipital craniotomy should be performed.²⁰

Depressed Skull Fractures—Patients with depressed skull fractures may have dural penetration, hematoma formation, and wound contamination. The fracture can involve frontal sinuses and also major cosmetic defects. Surgery may be warranted if any of the aforementioned is present. It is also

recommended to operate if the bone is depressed the full thickness of the cranium, or if CSF leak or brain parenchyma is present in the open fractures.²¹

Outcomes

Patients after TBI may follow basic functions of emergence of consciousness, recovery of neuropsychologic functions, and return of functional capacity, or they can progress to coma and further deterioration leading to brain death (Table 50–5).²²

SPINAL CORD INJURY

Introduction

Traumatic spinal cord injury (TSCI) predominantly affects the young adult (age < 40 years). Annually there are 15 to 40 cases per million. MVA account for the majority (40%-50%) of TSCI. Falls (20%) and violence (14%) account for the rest. The level of injury also determines an individual's functionality. Injuries below T1 are likely to result in independent function, while injury above C6 requires almost complete dependency.²³

Facial fractures and TBI are not associated with an increased risk of TSCI.²⁴ Underlying spinal disease such as osteoporosis, rheumatoid arthritis, or ankylosing spondylitis (AS) can predispose to TSCI.

TABLE 50–5 Clinical features of various TBI outcomes.

	Brain Death	Coma	Vegetative State	Minimally Conscious State	Emergence From Minimally Conscious State
Eye Opening	None	None	Occasional	Occasional but inconsistent	Present
Visual Fixation or Pursuit	None	None	None	Occasional but inconsistent	Present
Spontaneous Movement	None	None	Purposeless	Present	Purposeful
Response to Pain	None	None, flexion or extension	Variable	Variable	Variable
Vocalization	None	None	None	Occasional but inconsistent	Present
Functional Communication	None	None	None	Occasional but inconsistent	Consistent

Spinal Cord Anatomy

The spinal cord extends from the medulla in the cervical region to the lumbosacral area. The spinal canal contains the spinal cord, CSF, epidural fat and vessels, and dura mater. On cross-section, the spinal cord fills about 50% of the spinal canal. The corticospinal tracts originating from cerebral cortex (upper motor neuron) cross over to the contralateral side in the medulla and form the lateral corticospinal tract. The corticospinal tract makes synapsis with the lower motor neurons in ventral spinal cord. The sensory input originates in the dorsal grey-matter neurons. Fibers carrying pain and temperature cross over immediately in the spinal cord and ascend up as lateral spinothalamic tracts. Proprioception and vibratory sensation ascend ipsilaterally in the funiculus gracilis and funiculus cuneatus. At the level of L1-L2, there is the conus medullaris, below which the spinal canal is filled by motor and sensory neurons forming the cauda equina.

Pathophysiology

A number of processes occur during spinal cord injury. Primary injury occurs at the time of direct impact to the spinal cord and secondary injury as a cascade of events after the moment of impact. Primary injury can happen due to extension, flexion, or rotation of the spinal cord. It happens when the above movements occur beyond the normal movement capacity of the vertebral column. Most of the information regarding the pathophysiology is derived from animal models and it is still not known how much intact spinal cord is required for neuronal function.

Proposed mechanisms of TSCI include the following:

1. Vascular abnormalities: Most of the impact is due to disruption of the microvasculature. Larger vessels are rarely injured. As the grey matter is highly metabolic, it is more vulnerable to ischemia and gets injured earlier. Further, there may be loss of autoregulation (the ability to maintain blood flow at various pressures) that can lead to further insults to the spinal cord, if the blood pressure varies due to other injuries. Paradoxically, to maintain perfusion to the spinal cord, maintenance
2. Free radicals: Free radicals such as superoxide are produced due to ischemia and these free radicals react with cell membranes causing lipid peroxidation, damaging cell membranes. Superoxides also damage mitochondrial DNA and associated enzymes, inhibiting sodium-potassium ATPase. All this leads to generation of toxic metabolites such as malonyldialdehyde, leading to cell death.
3. Excitotoxic glutamate and electrolyte imbalance: Glutamate accumulates due to ischemia in cells. It acts on N-methyl-D-aspartate receptors and opens calcium channels. The huge influx of calcium causes activation of lethal enzymes. The loss of ATP also leads to an increase in sodium and water within the cell bodies. It is also thought to lead to cell death especially in axonal and glial components of the white matter.
4. Inflammation: At the site of injury in spinal cord, the inflammatory cells secrete lytic enzymes and cytokines such as TNF- α , interleukins, and interferons. These lead to further cell damage.²⁵

Histologically, the spinal cord develops microhemorrhages within 30 minutes of trauma beginning anteriorly and moving posteriorly over the next 1 hour. These microhemorrhages coalesce and necrosis of the spinal cord extend beyond the initial impact of the injury. Edema begins within 6 hours of injury, maximizing in 48 to 72 hours.²⁶

Neurologic Injury Classification and Clinical Presentation

The American Spinal Injury Association (ASIA) classifies spinal cord injury based on the sensory and motor impairments in the spinal cord after TSCI. It assesses different dermatomes for light touch and pin prick sensation and 10 key muscle movements to establish the grading of TSCI. The maximum score is 100. Any sensory or motor response at the S4-S5 level indicates incomplete spinal cord injury. If both are absent then barring exception of injury at that level, it signifies complete cord

paralysis. Preservation of perianal sensation, rectal tone, or great toe flexion means intact S2-S5 and is called sacral sparing. “Spinal shock” is the loss of all muscle tone and reflexes. If the S2-S5 reflexes have not returned within 24 hours, the injury is called complete spinal cord injury (ASIA class A), which is associated with a poor prognosis and poor spinal cord function recovery (Figure 50–5).

Incomplete Spinal Cord Syndromes

Central Cord Syndrome

Patients’ central grey matter is affected with sparing of the surrounding outer spinal cord. Clinically, patients are often tetraparetic with sacral sparing; upper extremity function is often affected more than that of the lower extremities.

Anterior Cord Syndrome

Occurs due to injury of the anterior spinal artery affecting the anterior two-thirds of the spinal cord. Patients have both motor and sensory loss (pain, temperature). Proprioception is preserved due to sparing of the posterior spinal cord.

Posterior Cord Syndrome

A rare syndrome where there is loss of proprioception in an otherwise normal functioning spinal cord.

Brown-Sequard Syndrome

Injury to one side of the spinal cord leads to ipsilateral motor function and proprioception loss with contralateral pain and temperature loss. This syndrome usually occurs after penetrating spinal cord injury.²⁶

Prehospital Management

Emergency medical personnel are often the first responders for suspected spinal cord injury. Ten percent to 25% of patients can have TSCI after primary trauma during transport or early management. Patients with suspected cervical TSCI should have their spine secured using a rigid cervical collar and immobilization, which may include a backboard with straps. Patients who are awake and fully oriented (without intoxication) with no complaints of neck pain or tenderness and no neurologic deficit or distracting injuries do not need immobilization as is the case with patients with penetrating spinal injury. After initial resuscitation and, if necessary, spine immobilization, patients should be taken to the nearest medical center equipped to handle such injuries. Delay in transport leads to increased costs and less favorable outcomes.²⁷

Hospital Management

Radiography

Once the patient is safely transported to a hospital and undergoes initial resuscitation and clinical examination, the full extent of their spinal injury is assessed by different diagnostic modalities. The following scenarios guide which patient needs radiographic evaluation.

Awake, Asymptomatic Patient—Fully awake, oriented nonintoxicated patients with no neck pain or tenderness, who have no motor or sensory deficit and no major other injuries (which prevent full evaluation), need not have any imaging study.

Awake, Symptomatic Patient—These patients should have good-quality CT scans of the cervical spine. If that is not available, then 3-view cervical spine series (anteroposterior, lateral, and odontoid) should be taken. If there are no radiographic abnormalities and patient is still symptomatic, cervical immobilization can be discontinued in following situations: when the patient is asymptomatic; if dynamic flexion/extension of cervical radiographs are normal; if spine MRI done within 48 hours is normal; at the physician's discretion.

Obtunded Patient—These patients should undergo radiologic imaging. Thin-cut CT with axial, coronal, and sagittal reconstructions, making sure to visualize both bone and soft-tissue imaging, can be used

in the decision to remove cervical spine immobilization, especially if such patients are not expected to regain consciousness within 24 hours. Flexion/extension imaging should not be attempted. High clinical suspicion of TSCI should prompt expert clinical consult. MRI in TSCI has an added benefit of providing information regarding soft-tissue/ligamentous injury in the cervical spine.

Management

General Management

Patients with TSCI frequently have respiratory and cardiovascular dysfunction. Patients have reduced vital and inspiratory capacity. They may have frequent hypoxemia, which may exacerbate cord ischemia. Hypotension is frequent after TSCI and may be due to hypovolemia or neurogenic shock. Neurogenic shock is the sudden loss of sympathetic tone as a result of injury to the cervical and upper thoracic spinal cord. Neurogenic shock is manifested by hypotension and bradycardia. Patients who were aggressively managed with close monitoring of vital signs such as blood pressure and oxygen saturation had improved outcomes. Intensive care unit monitoring is recommended in such cases. Hypoxemia should be treated with supplemental oxygen as necessary. The mean arterial blood pressure should be maintained between 85 and 90 mm Hg for the first 7 days of injury. Vaso-pressors can be used if required for that purpose.²⁷

Pharmacotherapy

Use of steroids such as methylprednisolone is associated with complications such as wound infection, hyperglycemia, and even death and is not recommended according to recent guidelines. GM-1 ganglioside (GM) is a natural compound thought to have antiexcitatory properties and neuronal regeneration. Patients receiving GM initially showed improvement in neurologic recovery, which was subsequently lost. It is, therefore, also not recommended to use in acute TSCI. Other agents studied have not been shown to improve outcomes.²⁷

Nutrition

Patients with TSCI have a catabolic state due to the intense reaction of the body to trauma. This leads to breakdown of muscle mass and loss of proteins, immunosuppression, and loss of gastrointestinal

barrier breakdown. It makes intuitive sense to start feeding sooner than later. Although early nutrition in these patients have not shown to improve neurologic outcome, nutritional support within the first 72 hours of injury is recommended.²⁸

Deep Vein Thrombosis and Thromboprophylaxis

Patients with TSCI have an increased incidence of deep vein thrombosis (DVT) (10%-18%) and the majority occur within the first 3 months of injury. Patients with TSCI should be started on both pharmacologic and mechanical DVT thromboprophylaxis. Low dose heparin, low-molecular-weight heparin or oral anticoagulation can be used but not alone. Mechanical thromboprophylaxis including rotating beds, pneumatic compression stockings, or electrical stimulation should be used additionally. Prophylaxis should be continued for 3 months and then discontinued. Inferior vena cava filters are not recommended unless anticoagulation is contraindicated or the patient has developed DVT or pulmonary embolism while receiving pharmacologic prophylaxis. Ultrasound Doppler studies should be used for diagnosis of DVT.²⁹

Management of Specific Injuries

Occipital condyle fractures are rare injuries that should be suspected in patients with high impact trauma, lower CN deficits, and loss of consciousness and neck pain. CT scan is recommended for fracture evaluation. External cervical immobilization is recommended for all types. If bilateral, more rigid immobilization with a halo device is recommended. Surgery (occipitocervical stabilization and fusion) is done in cases with associated atlanto-occipital ligament injury or instability.³⁰

Atlanto-occipital dislocation (AOD) is frequently missed and should be suspected in patients with TBI. The condyle-C1 interval should be measured on CT scan for its diagnosis (mostly in pediatric patients). A lateral cervical radiograph showing basion-axial interval-basion dental interval can also demonstrate this injury. Presence of upper cervical prevertebral soft-tissue swelling raises suspicion of AOD. Patients with these injuries often have or may develop neurologic deficits. These injuries should always be treated surgically with internal fixation and fusion.³¹

Isolated atlas fractures can be diagnosed with plain radiography (open mouth radiograph) or CT. They can be of 3 types, anterior or posterior arch fractures (Landell type 1), burst fractures (Landell type 2), and lateral mass fractures (Landell type 3) (Figures 50-6a and 50-6b).

MRI can assess whether the transverse atlantal ligament is intact or not, which will determine if the fracture is stable or not. In general, type 1 and type 3 fractures are considered stable and may be treated with collar or halo. Type 2 fractures may need surgical stabilization and fusion.³²

C2 dens fracture: Forceful flexion-extension of the head in the sagittal plane may result in fracture of the odontoid process (dens). Three types of fractures are identified; type 1 fracture occurs above the transverse ligament and is stable. Type 2 fracture results in complete disruption of the base of dens and is unstable, requiring surgical management. Type 2 has been further divided into types 2A, 2B, and 2C depending on whether it is nondisplaced, displaced amenable to anterior fixation, and displaced or communicated amenable to posterior fixation/fusion, respectively. Type 3 fractures involve the extension of fracture through the body of C2 and are considered mechanically unstable.³³

Subaxial cervical spinal injuries can include burst fractures, unilateral or bilateral facet dislocation, and other bony injuries. Patients with these injuries can be managed with external or internal immobilization/fixation. The goal is to restore alignment and decompress the spinal canal. Both anterior and posterior approaches are good surgical options. For patients with incomplete spinal cord injuries and canal compromise, surgical decompression within 24 hours of injury is recommended.³⁴ Patients who have AS should undergo thorough investigation with CT scan or MRI, even in minor trauma. AS patients requiring surgery should have either posterior fixation or combined anterior and posterior fixation but not stand-alone anterior fixation due to high failure rates.³⁵

Acute traumatic central cord syndrome (CCS) is a clinical entity that is suspected when upper extremities are weaker than lower extremities and is most commonly associated with cervical spondylosis or ossification of the posterior longitudinal ligament. Patients to be diagnosed with CCS

(a)

(b)

FIGURE 50–6 C1 comminuted burst fracture involving (A) the right anterior arch and (B) the left posterior arch. This patient was treated in a halo brace.

should have 10 points lower on the ASIA classification motor score in the upper extremities as compared to lower extremities. CCS is thought to be due to disruption of the corticospinal tract. It can be associated with other injuries such as fractures and dislocations. Surgical decompression is considered advisable in many circumstances.³⁶

Vertebral artery injuries (VAI) (nonpenetrating cervical trauma) are usually seen in patients with fractures through the foramen transversarium, facet fracture-dislocation, or vertebral subluxation. The modified Denver screening criteria in patients with blunt cervicovertebral injury should prompt VAI evaluation. CT angiography is a good, quick screening tool (Figures 50–7a and 50–7b).

(a)

(b)

FIGURE 50–7 (A) C2 vertebral and bipedicular fractures in elderly male after a fall as seen on axial CT. The fracture extends to the right foramen transversarium. (B) CT angiogram reveals luminal hypodensities consistent with a small vertebral artery dissection. The patient was placed on antiplatelet therapy (aspirin).

Angiography or MRI may also be used for diagnosis. Symptomatic patients may be treated with antiplatelet therapy, depending on their risk-benefit ratio. Asymptomatic VAI need not be treated.³⁷

General Postoperative Management

Leon Boudourakis, MD, MHS and Adel Bassily-Marcus, MD

KEY POINTS

- 1 It is of the utmost importance that the staff of the intensive care unit (ICU) understands exactly the type and purpose of each of the foreign bodies and tubes as well as how these tubes should be managed.
- 2 The aggregate of evidence from the last 15 years generally supports the notion that limited transfusion thresholds are correlated with superior outcomes in most patient populations.
- 3 Early parenteral nutrition (< 7 days post-ICU admission) has been associated with increased risk of nosocomial infections without benefit.
- 4 Stress dose steroids should only be considered in refractory septic shock after fluids have been given. There is no benefit to performing adrenocorticotrophic hormone (ACTH) stimulation test or random cortisol level.
- 5 Early mobility decreases length of stay and ventilator duration, and it has been shown to be cost-effective.

INTRODUCTION: INTENSIVE CARE UNIT VERSUS POSTANESTHESIA CARE UNIT

Postoperative patients who require critical care include: those planned for intensive care unit (ICU) admissions because of an anticipated lengthy operative course and recovery and those requiring ICU care because of unforeseen clinical circumstances or emergencies. Patients who require standard immediate postoperative care are generally admitted to a postanesthesia care unit (PACU). Depending on a hospital's unique capabilities, a PACU is capable for caring for the general ongoing mechanical ventilation and hemodynamic needs of a patient, under the supervision of an anesthesiologist.

Though a PACU can and should be capable of functioning at the same level of an ICU, in reality the

day-to-day comprehensive multidisciplinary management is efficiently accomplished in the medium and long-term in a formal ICU with trained intensivists. In the circumstance where a PACU cares for patients who are awaiting an ICU bed, formal consultation with an intensivist for ongoing care is highly valuable.

There are some patient populations, such as those undergoing liver transplant, cardiac and trauma surgery, for whom assured direct postoperative admission to an ICU and avoiding the PACU altogether are essential to ensure optimal care by experienced specialized staff.

Hand-Offs

A unique aspect of the critical care management of surgical patients is that the information about the patient needed by the intensivist from the

preoperative and intraoperative care is often fragmented. In the United States, surgical patients are always followed primarily by the surgeon(s) who performed the operation. Subspecialists who cared for the patient preoperatively and the anesthesiologist who cared for the patient intraoperatively may have important information relevant to the ICU clinicians. For example, the estimated blood loss value may vary widely depending on who reports these data (surgeons often underestimate blood loss). Data about unforeseen difficult airways, intraoperative hypotension, greater than expected blood loss, and other complications are often not readily available or communicated to the ICU, and the intensivist should be aware of this phenomenon and assured that they have the most accurate and comprehensive picture of the patient admitted to the ICU. When feasible, the intensivist should make every effort to begin their consultation intraoperatively. Although not practical in some situations, this certainly helps the ICU ensure continuity of care for patients who are in the extremes of illness. At our institution, the intensivist has been called as a consultant to the operating room to assist in unusual circumstances such as patients with severe hypoxemia, unusual new echo findings, persistent and increasing vasopressor requirements, etc.

Tubes/Drains/Stoma/Surgical Site

Unlike standard medical ICU patients, the surgical ICU patient can have many foreign bodies in the form of tubes, drains, and surgical-related phenomena such as an open abdomen, stoma, flap, altered anatomy, and complicated surgical incision. It is of the utmost importance that the ICU staff understands exactly the type and purpose of each of these as well as how these tubes should be managed. Some tubes are so-called critical and their inadvertent removal can have potentially devastating consequences. Suction tubes come with a variety of suction methods (self-suction, continuous suction, intermittent suction, suction with concomitant irrigation, etc). The quality of drain output (bilious, bloody, serous, purulent, etc), quantity, and changes to such output overtime can give the intensivist vital information. Though a comprehensive description

FIGURE 51–1 Chest tube.

and purpose of every possible surgical device is beyond the scope of this text, we describe some of the more common ones.

Chest tube/drain—Flexible plastic tube inserted through chest wall into pleural space usually to remove air or fluid/blood ([Figure 51–1](#)).

Pigtail drain—Drain with a coil at the end, which helps keep it in place and allows for more effective drainage through the small holes in the end; typically placed by interventional radiology though sometimes also used as a closed-chest suction drain ([Figure 51–2](#)).

Hemovac—Similar to a JP/Blake but much higher suction power; often used in orthopedics

FIGURE 51–2 Pigtail drain.

FIGURE 51-3 Hemovac drain.

and helpful for removing/draining blood ([Figure 51-3](#)).

Sump drain—Also known as “Abramson triple lumen drain.” This is a large drain with 3 ports, typically used with wall side suction and simultaneous irrigation; often used to continuously irrigate a surgical bed postoperatively ([Figure 51-4](#)).

Jackson Pratt—Also called a “JP drain”; closed suction that comes in flat and round forms and in various sizes connected to a grenade-shaped bulb via plastic tubing ([Figure 51-5](#)).

Blake—Similar to JP drain, more rigid, designed differently; thought to clot less often. Often

FIGURE 51-4 Sump drain.

FIGURE 51-5 Jackson Pratt (JP) drain.

tunneled with a sharp metal applicator that is then removed ([Figure 51-6](#)).

Penrose—Yellow-colored soft rubber/foppy tube that is often used to keep a surgical site open for continuous drainage after infection/abscess ([Figure 51-7](#)).

Loop ostomy rod—This is a temporary device left under a loop ileostomy or colostomy to prevent retraction into the peritoneum; usually removed by postoperative day 5.

T-tube—A drain shaped like a T placed into the biliary system, usually the common bile duct.

GJ tube/Moss tube—This tube has 2 ports (1 to stomach and 1 to jejunum); often used for feeding in patients not tolerating gastric feeds.

FIGURE 51-6 Blake drain.

FIGURE 51–7 Penrose drain.

Fluid Management

A detailed discussion of fluid management and fluid responsiveness is a complicated and controversial topic beyond the scope of this chapter. Some key elements are universal to the surgical patient, however. Information about intraoperative fluid and blood loss coupled with fluid/blood-product administration can give the intensivist a clue about the resuscitation status of a newly admitted patient. Physical examination, though always important, is not the most accurate means of assessing volume status in this patient population. Fluid responsiveness can be assessed with a variety of more invasive and noninvasive means such as goal-directed cardiac ultrasound (feasibility and potential clinical utility of goal-directed transthoracic echocardiography performed by noncardiologist intensivists using a small hand-carried device in critically ill patients¹) and pulse contour analysis. Focused transthoracic cardiac ultrasound is a method that is noninvasive and is gaining popularity in the assessment of fluid status.²

Central venous pressure measurement has been proven to not correlate with fluid status when spot-checked or when trended over time.³ The use of a Swan–Ganz catheter (often called a pulmonary artery catheter) is used routinely during cardiac surgery and liver transplantation to measure cardiac index and calculate systemic vascular resistance, but its value has not been shown in other patient populations.

Rapid administration of small boluses of isotonic fluid with real-time monitoring of a patient's clinical response is a time-proven method in the initial resuscitation of postoperative ICU patients. Isotonic fluids should generally be the fluid of choice. pH neutral fluids should be used primarily as massive quantities of sodium chloride will cause an iatrogenic hyperchloremic metabolic acidosis. The intensivist should keep in mind that a patient's output may be substantially higher than urine output given drain output, etc.

Albumin is commonly used as a resuscitative fluid; however, its use is controversial. Most intensivists would agree that its utility makes most sense in patients with hypoalbuminemia secondary to cirrhosis. Synthetic starches are no longer used clinically as they can contribute to renal injury and may contribute to increased mortality.

Blood Transfusion

The aggregate of evidence from the last 15 years generally supports the notion that limited transfusion thresholds are correlated with superior outcomes in most patient populations. These include postoperative patients and patients with resuscitation for septic shock. A recently published study in the *New England Journal of Medicine* randomized 461 patients to a restrictive versus a liberal (hemoglobin threshold of 7 vs 9, respectively) transfusion strategy in patients with acute upper gastrointestinal bleeding. The rate of recurrent bleeding was lower and the survival was higher in the restrictive group.

Patients with active acute coronary syndromes have been shown to do poorly when severely anemic. Likewise, restrictive strategies for transfusion have not been shown to be superior in patients after heart surgery.⁴

Although restrictive transfusion strategies are certainly applicable to most patients in the ICU with anemia or minimal bleeding, it should be noted that aggressive use of packed red blood cells, fresh frozen plasma, and platelets along with minimal to no crystalloid should be the strategy during acute and exsanguinating hemorrhage, particularly in trauma patients. In these circumstances, crystalloid use should be minimized as it contributes to hypothermia, dilution of coagulation factors, and

promotes acidosis. Trauma surgeons often say “you don’t bleed crystalloid; you bleed blood.”

Nutrition

Although historically the surgeon dictated the timing of initiation for feeds based on such things as physical examination, fatus, nasogastric tube output, and bowel movements, such clinical practice is not evidence driven. Although the consequences of this practice may not be substantial in the usual surgical floor, such means of determining when to feed a critically ill patient may lead to deleterious outcomes. The urgency of initiating feeding in large part depends on the preoperative nutritional status of the patient. Patients who have been in the hospital for several days or weeks with inadequate nutritional support who subsequently require ICU care are in more urgent need for expeditious nutritional support. Undernutrition is prevalent in all ICUs and often in surgical ICUs. Having a nutrition protocol helps narrowing the gap between what the patient is getting and what the caloric goal is, though this is less important in the first week of critical illness. Initial low-volume (ie, trophic) enteral nutrition resulted in clinical outcomes similar to those of early full-energy enteral nutrition but with fewer episodes of gastrointestinal intolerance.⁵ However, restriction of nonprotein calories (permissive underfeeding) was not associated with lower mortality than that associated with planned delivery of a full amount of nonprotein calories.⁶

A few practices that should be standard are worth mentioning. Intermittent interruption of enteral feeding during an ICU course can contribute to malnutrition in the patient who is in the ICU for over several days. Practices such as NPO before planned procedures, delayed and cancelled operative times, computed tomography (CT) scan, and interruption for various other reasons become cumulative and can substantially contribute to patients receiving suboptimal feeds. It is our practice to minimize this phenomenon by minimizing reasons why patients’ feeds are interrupted. For example, patients with endotracheal tubes or a cuffed tracheostomy have protected airways, and several planned procedures or operations can safely be accomplished with enteric feeds continued until the timed event. It

is customary to establish an NPO status only if the procedure will entail surgery in the abdomen or airway, or the patient must be positioned in the prone position. Thus patients scheduled for orthopedic, brain, plastic, and extra-abdominal general surgery procedure can be spared unnecessary interruption of feeds. Given the nutritional needs are complex in this population, a dedicated nutrition team trained in critical care nutrition is an essential element to the care of the surgical ICU patient. Early enteral nutrition has been shown to improve infectious complications and mortality when compared to late enteral nutrition including in pancreatitis patients. Early parenteral nutrition (< 7 days post-ICU admission) has been associated with increased risk of nosocomial infections without benefit.⁷

Mechanical Ventilation

Principles of ventilation in a surgical ICU are no different from those in any other ICU. There are, however, different practices based on the expertise and biases of individual ICUs. Cardiac surgery ICUs tend to use pressure control ventilation, whereas trauma ICUs tend to more heavily rely on airway pressure release ventilation. Most standard surgical ICUs use either volume control (guaranteed volume) modes or dynamic hybrid modes such as volume-targeted pressure control mode (eg, pressure-regulated volume control [PRVC]).

Regardless of the mode or ventilator used, the surgical intensivist must be aware of the forces that influence mechanical ventilation in patients who undergo abdominal surgery. This is especially true in trauma and emergency surgery where there is often edema of the internal organs, and the associated increased abdominal pressure pushes upward on the diaphragm, effectively reducing functional residual capacity. This contributes to atelectasis and ventilation/perfusion (V/Q) mismatch.^{8,9} When abdominal pressure begins to impair function in the pulmonary, renal, cardiovascular, or gastrointestinal systems, abdominal compartment syndrome should be recognized early and addressed.

Liberation From Ventilator

Successful liberation from mechanical ventilation relies on the application of clinical judgment and

medical and nursing intervention. Predictors of successful extubation have significant limitations; some remain complicated and cumbersome to be used at bedside. Paired sedation interruption with daily spontaneous breathing trial¹⁰ (SAT + SBT) has been shown to improve outcome, including more ventilator-free days and less ICU and hospital length of stay (LOS), and 1-year mortality.

Utilizing paired SAT + SBT (spontaneous breathing trial + spontaneous awakening trial) as part of the ABCDEF bundle is an essential part of successful liberation from mechanical ventilation. Tools are available on this website published by the society of critical care medicine: <http://www.iculiberation.org/news/Pages/Webcast-Explores-Implementing-New-ABCDEF-Bundle-in-Your-ICU.aspx>.

Postextubation Failure

Extubation attempts may fail in up to 23.5% of patients and lead to an increased hospital mortality of 30% to 40%. The use of postextubation noninvasive ventilation (NIV) outside of exacerbation of chronic obstructive pulmonary disease (COPD) should be cautioned as it leads to unnecessary delay in reintubation and worsened outcome particularly in surgical patients.^{11,12} High-flow nasal cannula (HFNC) oxygen has been used in hypoxemic respiratory failure and shown to improve 90-day mortality when compared with NIV.¹³ The routine application of HFNC to patients in the setting of extubation failure due to hypoxemia is feasible but has not been studied to date.

Sedation

The Society of Critical Care Medicine published updated clinical practice guidelines for adult ICU patients in 2013, which are applicable to the surgical ICU. Although there is variability among ICUs in terms of practice norms, an emphasis on minimizing pain and agitation while also preventing delirium should be the primary goal. The impact of delirium in the ICU on hospital LOS, long-term cognitive impairment, and mortality cannot be overemphasized.^{14,15} The Vanderbilt University Medical Center Delirium and Cognitive Impairment Group have created www.icudelirium.org that provides medical professionals with a variety of pearls and tools we use in our practice. For

example, ABCDEF is the bundle of measures which includes Assess for and manage pain, Both Spontaneous awake and breathing trials, attention to Choice of sedation and analgesia, Delirium monitoring and management, Early mobility, and Family engagement.

Though any patient who is newly intubated requires analgesia, unique to surgical patients is incisional pain. Analgesia should therefore be the primary and initial focus for patient care. Multimodal therapy including narcotic drip/bolus titration, enteral/IV acetaminophen, and neuroleptics could be utilized. Nonsteroidal agents have a role in the patient without precarious renal function and with low risk of bleeding. Dexmedetomidine, though not a primary analgesia agent, is narcotic sparing and has pain-relieving properties. Low-dose ketamine drips for patients with refractory pain or a significant history of narcotic use previous to admission can attenuate subjective pain scores.

Validated sedation scales such as The Richmond Agitation-Sedation Scale (RASS) or The Riker Sedation-Agitation Scale (SAS) are paramount to goal-directed delivery of sedatives by the nursing staff. We use the RASS that takes less than 20 seconds to perform, and has been shown to be highly reliable and effective. Noncontinuous sedation protocols have been shown to decrease ICU LOS when compared with continuous sedation with daily interruptions.¹⁶

Abdominal Compartment Syndrome

The surgical intensivist should always keep in mind the phenomenon of abdominal compartment syndrome. The World Abdominal Compartment Society (www.wsacs.org) provides consensus guidelines on this pathology that should be reviewed.

Many postlaparotomy patients have some element of abdominal hypertension. A normal intra-abdominal pressure in most critically ill adults is between 5 and 7 mm Hg. When this pressure is associated with new organ dysfunction and limits perfusion to vital organs (typically when 20 mm Hg with or without an abdominal perfusion pressure < 60 mm Hg), treatment needs to be initiated emergently. Although sedation/analgesia, body positioning, gastric/colonic decompression, and fluid resuscitation/diuresis may be attempted initially,

rapid correction with either percutaneous drainage or laparotomy (ie, relaparotomy with abdominal fascia left open) should be performed.

The intensivist should have a low threshold of measuring abdominal pressures with either a standard commercial device, or a Foley catheter with 50 mL injected into bladder connected to standard pressure transducer in the supine and flat patient. It is important to have a baseline pressure and frequent serial abdominal examinations. The intensivist should be aware that abdominal compartment could still develop in a patient with an incompletely open abdomen if the fascia is still under tension or the laparotomy was limited in length. Although these patients often respond seemingly well with initial, intermittent fluid boluses, their underlying pathology worsens over time.

Prophylaxis

Deep Vein Thrombosis

Mechanical and chemical deep vein thrombosis (DVT) prophylaxis is mandatory for the vast majority of patients in the surgical ICU. Although some surgeons are reluctant to begin chemoprophylaxis in the immediate postoperative period, general guidelines should be implemented at each institution to ensure its use. At our hospital, patients with traumatic brain injury are routinely started on chemoprophylaxis 48 to 72 hours after admission if there is no evidence of continued bleeding on CT scan.

Inferior vena cava filters are generally reserved for those patients with a long-term contraindication to chemoprophylaxis, patients with acute DVT and a contraindication to systemic anticoagulation, and patients diagnosed with a new DVT or pulmonary embolism while already on systemic anticoagulation.

Stress Ulcer

The absolute indications for stress ulcer prophylaxis include severe sepsis or septic shock, mechanical ventilation more than 48 hours, major burn injury, and patients with coagulopathy. In practice, stress ulcer prophylaxis is also used for most ICU patients, as well as elderly patients on NSAIDs and those on high-dose steroids (> 250 mg hydrocortisone/d). These recommendations for trauma ICU patients,

which are applicable to most postoperative patients, are readily available at www.east.org.

Effective prophylaxis includes proton pump-inhibiting agents (PPI) and H₂-blocking agents. Although patients who are tolerating feeds are typically at less risk for developing stress ulcers, the indications for its use are not related to the NPO status of the patient. Thus patients who do not meet the aforementioned criteria who are NPO do not need prophylaxis, and patients who do meet criteria who are tolerating enteral feeds still need chemoprophylaxis. PPI use has been linked to increased C diff rates as well as increased ventilator associated pneumonia.^{17,18}

Multidrug Resistance

Antibiotic stewardship is of the utmost importance in the surgical ICU. Antibiotic use is divided into its use in surgery for incisional infection prophylaxis and actual treatment. Guidelines mandate less than 24 hours use when used for prophylaxis; whether that dictates one dose intraoperatively only versus continued dosing for less than 24 hours is individual preference. The exception is in cardiac surgery patients following sternotomy and following transplant surgery in whom 48 hours is preferred—though with limited evidence. Notoriously, ENT/OMFS/Ophthalmology/Plastic surgeons often request prophylaxis for extended durations—it should be emphasized this practice is not ideal and institutional guidelines should be established to limit confrontation in these circumstances.

STEROIDS

Steroids are often given to critically ill surgical patients for transplant rejection prevention, vasogenic edema (eg, brain tumors, spinal cord compression, acute pneumococcal meningitis), reduction of edema (eg, airway edema, laryngeal surgery), COPD exacerbation, to improve postoperative nausea, vomiting, headache from vasospasm following subarachnoid hemorrhage.

Administration of steroid to patients with sepsis has been controversial since the 1950s where high-dose (30 mg/kg of methylprednisolone) steroids led to conflicting results.¹⁹ Studies showed improving mortality and others showed worsening mortality rates. In 2002, Annane and colleagues²⁰ demonstrated

that septic-shock patients who have poor response to adrenocorticotrophic hormone (ACTH) stimulation test and received low dose stress dose steroids had reduced risk of death without increasing adverse events. This was further tested in a large multicenter randomized controlled trial (CORTICUS)²¹ where there was no difference in mortality rates between the treated group and control. Although steroid therapy should not be used in all patients with septic shock, it should be considered in persistent shock despite administration of fluids and vasopressors. The SCCM recommends using a maximum of 200 mg/d of hydrocortisone in refractory septic shock (defined as the need for increasingly higher doses of vasopressors or the need for a second vasopressor after adequate fluid resuscitation). There is no benefit from performing ACTH stimulation tests as critically ill patients with subnormal total cortisol had normal free cortisol.²² There is insufficient evidence in a meta-analysis to support either gradual or abrupt interruption of steroid treatment following shock reversal.²³

Recovery after prolonged exposure to oral steroids is highly variable and may take as long as 1 year. Consider stress dose steroids (low dose, 200 mg/d hydrocortisone) for patients who received high-dose steroids (> 200 mg/d hydrocortisone) following a major surgical procedure. Consider 8 mg dexamethasone to prevent adrenal insufficiency from all commonly performed surgeries (hernia repair, cholecystectomy, hysterectomy, bowel resection, joint, and vascular procedures).

A single dose of etomidate blocks cortisol synthesis resulting in primary adrenal insufficiency lasting for up to 48 hours.²⁴ Hydrocortisone administration following single-dose etomidate did not benefit to overcome etomidate-related adrenal insufficiency.²⁵ The practical/clinical implications of patient physiology following the administration of etomidate continue to be controversial.

MOBILIZATION

Early mobility includes a spectrum from passive range of motion to active range of motion, to sitting with legs dangling, standing, and walking. For patients in the surgical ICU, early mobilization is particularly an important aspect of recovery. Its use prevents deconditioning and is an integral part of

delirium prophylaxis and treatment. Studies clearly show that early mobility decreases days on the ventilator and LOS.²⁶ It has been shown to be cost-effective and justifies a dedicated mobility team that works in conjunction with primary nursing team particularly in the challenging population.²⁷

Short of orthopedic procedures which may limit weight bearing status, the surgical intensivist should not be intimidated by large surgical wounds, number of tubes, etc. At our institution, we routinely get patients out of bed who are intubated on postoperative day 1. Although patients with an open abdomen, brain intraventricular devices, or several drains/tubes, present some logistical nursing challenges, their presence is by no means a contraindication to mobilization. Patients with low dose or deescalating dosing of vasopressors are also safe for mobilization.

“Mobilization teams” have been implemented by some institutions; however, early mobility can be performed by collaboration of the interdisciplinary team members including nurses, physical therapists, occupational therapists, and physicians. Prioritizing the efforts and working as unified team with proper staffing, training and leadership supports are imperative for the success of the mobilization mission.

Posttransplantation Care

Pankaj Kapadia, MD and
John M. Oropello, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 The main reasons for reoperation after liver transplantation are postoperative bleeding, vascular and biliary complications, and intraabdominal sepsis.
- 2 Surgical complications after renal transplantation including graft thrombosis, renal artery stenosis, urinary leak, or urinary obstruction have an incidence of 5% to 10% and remain important causes of graft loss.
- 3 After pancreatic transplant, a sudden increase in amylase and lipase with a change in exogenous insulin requirements is predictor of graft ischemia or rejection.
- 4 It is important for an intensivist to be familiar with early detection and treatment of infection and immunosuppressive medications and their side effects in the posttransplant patient.

INTRODUCTION

This chapter discusses early postoperative care, early recognition and management of complications, antimicrobial prophylaxis, and immunosuppressant drugs and their side effects in the management of the posttransplant liver, kidney, pancreas, and small intestine recipient.¹⁻⁸ Indications for transplantation and preoperative management are not discussed in this chapter.

POSTOPERATIVE CARE AND CRITICAL CARE AFTER LIVER TRANSPLANTATION

There are 3 major types of liver transplantation (LT): cadaveric orthotopic LT (OLT), where a whole organ is transplanted from a deceased donor (most common); cadaveric OLT by split LT, where the recipient receives 1 lobe of the liver from a deceased donor;

and live donor OLT, where the donor undergoes either a right or left hepatic lobectomy. In the case of split or living donor liver transplants, adult recipients usually receive the larger right lobe; children are ordinarily transplanted the smaller left lobe.

OLT requires surgical anastomosis of the hepatic artery, portal vein, bile duct, and inferior vena cava from donor to recipient, and postoperative complications are often related to dysfunction at these anastomotic sites.

Recovery in the Immediate Postoperative Period

Most of the patients after LT, even after an uncomplicated operating room course, are monitored in the ICU. Uncomplicated cases usually transfer to an inpatient liver transplant unit within 24 to 72 hours but complicated cases may require ICU care for weeks. Fifteen percent to 20% of liver transplant patients are taken back to the operating room during the

transplant admission. The main reasons for reoperation include postoperative bleeding, vascular and biliary complications, and intraabdominal sepsis.

In the ICU, frequent hemodynamic assessments are commonly performed using vital signs and non-invasive monitoring (eg, ultrasonography). A preexisting pulmonary artery catheter is utilized if placed intraoperatively for more hemodynamically challenging cases or those with pulmonary hypertension. Vital signs, intake, output, physical changes in drain output, bile production (if a biliary drain [eg, T-tube] is present), abdominal drain (eg, Jackson–Pratt) output, and any signs of postoperative bleeding are recorded hourly. The initial postoperative level of liver biochemistries, that is, alanine transaminase (ALT), aspartate aminotransferase (AST), and bilirubin, may not correlate with liver function in the first day or first 2 days after transplant. Therefore, most centers rely on the serial assessment of international normalized ratio (INR) and lactate along with complete blood count, arterial blood gas, electrolytes, glucose, blood urea nitrogen, and creatinine as well as the liver biochemistries (ALT, AST, bilirubin, and alkaline phosphatase) analyzed every 6 hours within the first 2 days. The clinical picture (eg, hemodynamics, renal function, and neurological status) also provides important information about graft function.

Increased INR is usually not treated with fresh frozen plasma (FFP) because it may mask allograft dysfunction and potentially increase the incidence of hepatic artery thrombosis (HAT) or portal vein thrombosis. Thrombocytopenia is also very common after LT, however platelet transfusions are also avoided because they may increase the chances of HAT. If there is significant bleeding, FFP and platelet transfusions may be indicated but the decision to transfuse should be made in concert with the transplant surgeon.

Assessment of Liver Graft Function

Graft edema, any unusual or discolored appearance of the allograft in the operating room, inability of the patient to raise the core body temperature, hemodynamic instability, hypoglycemia, dramatic increases in potassium, prothrombin time or INR, and lactate all signal inadequate allograft function. Inadequate urine output or acute kidney injury is also common

in this setting, but may be caused by factors other than graft dysfunction such as acute tubular necrosis (ATN) or immunosuppressive drugs such as cyclosporine or tacrolimus.

Doppler ultrasonography (DUS) is routinely done on the first postoperative day to assess patency of the hepatic arteries and portal veins to rule out HAT, stenosis, or portal vein thrombosis. DUS also assesses for fluid collections, hematomas, and abscesses. As the hepatic artery supplies blood to the biliary ducts, HAT is associated with bile leaks. Follow up DUS is performed if the initial findings are equivocal or there is a sudden deterioration in graft function or elevation of LFTs.

Split cadaveric and live donor lobe transplants may be associated with initially higher ALT and AST due to raw liver surfaces as well as more prolonged lactate and INR elevation due to smaller liver mass relative to recipient size. Elevated INR may also occur in standard cadaveric OLT when the overall liver mass is small. Recipients of split and living donor transplants often become hypophosphatemic and require rigorous phosphorus supplementation due to the metabolic needs of regenerating liver tissue.

Recognition and Management of Early Complications

Medical Complications

Sepsis—The risk of infections is increased after LT and bacterial infections are more common than fungal infections. Deep surgical space infections and biliary leaks are common sources of infection. All potential sites for infection should be explored and, if possible, eliminated (catheters, hematomas, or fluid collections suspicious for abscess).

Respiratory Complications—Patients that are critically ill prior to LT are at increased risk for prolonged mechanical ventilation due to debilitating conditions and concomitant loss of muscle mass. Those with liver graft dysfunction, extrahepatic organ dysfunction, or sepsis are also more likely to require prolonged ventilator support. Transient severe pulmonary edema may occur due to systemic inflammatory response syndrome (SIRS) or sepsis, or much less commonly transfusion-related lung injury. Although pneumonia is possible early after

LT, pulmonary infiltrates are usually due to noncardiogenic pulmonary edema from systemic inflammation or sepsis originating from the abdomen. Patients intubated postoperatively for more than 7 to 10 days should be evaluated for tracheostomy.

Hepatopulmonary syndrome (HPS) is defined by the triad of liver dysfunction or portal hypertension, abnormal gas exchange, and evidence of pulmonary vascular shunts resulting in hypoxemia. Patients with HPS have an increased length of stay in the ICU (median 4 days) and hospital (median 39 days). LT may be curative, however, the median time to cessation of oxygen is 4.5 months in some series. Right pleural effusions are common after liver transplant due to operation near the right diaphragm, but do not usually cause respiratory failure. Postoperative right pneumothorax may occur less commonly.

Cardiovascular Complications—Liver failure typically results in a hyperdynamic circulation with elevated cardiac index and low blood pressure. A patient receiving a transplant before severe liver failure is manifest, for example, hepatic tumors or living-related donor recipients, may not have a hyperdynamic circulation. If present prior to LT, the hyperdynamic state does not resolve immediately after LT and may persist for weeks or longer. Mild to moderate portopulmonary hypertension in the setting of high cardiac output (CO) usually resolves with successful LT.

The majority of low CO states in the ICU after LT are caused by volume loss usually from bleeding, third spacing, and/or a stunned myocardium due to SIRS or sepsis. Dynamic left ventricular outflow tract obstruction due to decreased LV preload in the setting of inotropes is also a potential cause of low CO post-LT. Rarely, low CO may be caused by an acute myocardial infarction. Other causes of low CO after LT include cirrhotic cardiomyopathy or cardiomyopathies associated with alcohol, hepatitis, or hemochromatosis, although these should have been screened out during the preoperative work up.

Management of hemodynamic instability includes treatment of the causative factors. Central venous pressure measurement is a poor guide for intravascular volume and adequate resuscitation both in the ICU and in the operating room. No relationship between CVP and liver graft outcome

has been demonstrated subsequent to an uncontrolled observational study to the contrary. The use of CO trending and mixed venous blood gases via a pulmonary artery catheter (often present in the immediate postoperative period after intraoperative placement), and or serial echocardiography, coupled with lactate trends are helpful to guide hemodynamic management. Although there are no randomized control trials to support the use of colloids over crystalloids after LT, albumin 5% is preferred for volume resuscitation after LT due to hypoalbuminemia and to limit positive fluid balance.

Hypertension may develop posttransplant and is more common in patients with preexisting hypertension. Hypertension can be caused or exacerbated by immunosuppressive drugs such as tacrolimus, cyclosporine, and steroids. The treatment may include diuresis in the setting of fluid overload or the addition of antihypertensive agents.

Renal Dysfunction—The incidence of acute renal failure after LT varies widely in the literature, ranging between 27% and 67%. The most important risk factor for postoperative renal dysfunction is pretransplant renal dysfunction (ie, hepatorenal syndrome or ATN). Most kidneys recover with time and only a small percentage of patients develop chronic kidney failure. Management of renal failure in the posttransplant period includes renal replacement therapy and judicious use of immunosuppressants, particularly, nephrotoxic calcineurin inhibitors (ie, tacrolimus or cyclosporine) or a calcineurin inhibitor-sparing protocol (eg, mycophenolate mofetil, steroids, monoclonal antilymphocyte antibodies) at the discretion of the transplant team. In hemodynamically unstable patients and particularly those with primary nonfunction or poor early graft function, continuous veno-venous hemofiltration is the preferred modality for renal replacement and should be started as early as feasible to maintain metabolic homeostasis during this critical time of multiorgan dysfunction.

Neuropsychiatric Complications—Neuropsychiatric complications occur in up to 30% of liver transplant patients and often require prolonged management in the ICU. Complications include encephalopathy (delirium), tremors, myoclonus and less commonly seizures (including nonconvulsive status epilepticus), meningitis, ischemic stroke, intracerebral hemorrhage, and subarachnoid hemorrhage.

Delirium is common after LT. Treatment with antipsychotic medications may be required (eg, haloperidol or risperidone). It may be due to preexisting hepatic encephalopathy, postoperative liver graft dysfunction, renal failure, sepsis, or side effects of immunosuppressive medications such as steroids and calcineurin inhibitors (see later under Immunosuppressive Drugs). If there are no focal deficits and the patient is hemodynamically and or respiratory unstable, computed tomography (CT) imaging may be postponed or avoided. However, if the patient exhibits focality or seizures, emergent CT should be performed. Ischemic stroke, subarachnoid, and subdural hemorrhages are uncommon but possible. Central nervous system infections such as meningitis and brain abscess are unusual but possible in these immunocompromised patients.

Surgical Complications

HAT occurs in less than 2% to 3% of patients after LT. Thirty percent develop signs of acute hepatic necrosis with high transaminases, sepsis, mental status changes, and coagulopathy, but may the presentation be more subacute with progressive biliary infections and hepatic dysfunction. Suspicion of HAT should be immediately investigated with DUS and potentially confirmed by an arteriogram or exploratory laparotomy depending on the level of surgical concern. HAT within the first week after OLT is an indication for relisting for retransplantation. Portal vein thrombosis is also diagnosed by DUS. If the diagnosis is made during the ICU stay, the patient may undergo thrombectomy depending on the degree of occlusion and collateral circulation.

Biliary complications remain frequent after LT varying between 1.6% and 18% and include bile leaks, bilomas, and strictures. Early bile leaks should be suspected in any patient with constant abdominal pain, or unexplained fever or sepsis after liver transplant. Most leaks occur from the biliary anastomosis and present early. Many require abdominal washout and surgical repair, although endoscopic stenting may be successful. Late bile leaks (after 30 days) are rare, however late strictures are the most frequent cause of biliary complications after LT and are often associated with recurrent cholangitis. Treatment of anastomotic strictures usually requires endoscopic

stenting; intrahepatic strictures are more complex and may lead to retransplantation.

Nutritional Management

In uncomplicated liver transplants an oral diet can be started within the first 1 to 2 days after surgery. A protein-rich diet is recommended, as the liver patient needs 1.5 to 2 g protein per kg body weight per day. If oral intake is not sufficient, postpyloric feeding through a tube should be considered. Parenteral nutrition should be initiated only if tube feeding is not possible due to intestinal complications and prolonged nothing by mouth (NPO) (eg, > 3-7 days) is anticipated. Both steroids and calcineurin inhibitors may cause hyperglycemia and this will be even more pronounced in patients with preexisting diabetes mellitus. Hypoglycemia may be a sign of liver graft dysfunction or excess insulin dosing.

POSTOPERATIVE RENAL TRANSPLANTATION CARE

Early Postoperative Management

Intensive care unit observation is usually not required after renal transplant except under special circumstances involving hemodynamic or respiratory instability.⁹ Once the patient is stable hemodynamically and has recovered from anesthesia, transfer to the floor is initiated. Volume status needs to be monitored closely. Additional evaluation includes a full electrolyte panel, complete blood count, chest X-ray, and an electrocardiogram. The intraoperative anesthetic record, blood loss, volume replacement, and the operative report should also be reviewed to identify intraoperative events or complications with potentially adverse sequelae. Voluminous urine output after surgery is a sign of good graft function. A brisk large volume diuresis following graft revascularization may be due to preoperative volume overload, osmotic diuresis in previously uremic patients, intraoperative mannitol or furosemide, or vigorous intraoperative intravenous crystalloid or colloid fluid administration.

In low urine output states, the Foley catheter should be irrigated to rule out obstruction and to flush out blood clots. Evaluation of the kidney by ultrasound to determine blood flow, patency of

the renal vessels, and for evidence of urinary tract obstruction is important. The absence of blood flow to the allograft or tract obstruction (eg, ureteral torsion) requires urgent evaluation by the surgical team for possible reexploration. Fluid replacement should equal urine output with 1/2 normal saline because the sodium concentration of the urine from a transplanted kidney is about 60 to 80 mEq/L. Patients who are anuric or oliguric should receive conservative fluid management and diuretics if intravascularly volume repleted or volume overloaded. Renal replacement therapy is necessary if there is inadequate recovery of renal function.

Assessment of Graft Function

Immediate Graft Function—In patients with immediate graft function the serum creatinine commonly decreases by 1.0 to more than 4.0 mg/dL daily. These patients are usually discharged on postoperative day 4 or 5 following successful Foley catheter removal and voiding trial.

Slow Recovery of Graft Function—Patients with slow recovery of graft function are generally non-oliguric and experience a slow decline in serum creatinine. The level typically decreases by 0.2 to 1.0 mg/dL daily. Attention must be given to fluid management. These patients usually do not require dialysis unless complicated by hyperkalemia or fluid overload. Patients who are at high risk for obstruction such as diabetics with neurogenic bladder or male patients with benign prostatic hypertrophy may require a Foley catheter for a longer time period of monitoring.

Delayed Graft Function—The incidence of delayed graft function (DGF) ranges from 10% to 60% and can often be anticipated based on recipient and donor factors. Unless these patients have adequate residual urine output from the native kidneys, most patients are oliguric or anuric and will require temporary dialysis support for volume, hyperkalemia, or uremia. Donor factors for DGF include age (< 10 or > 50), donor macrovascular or microvascular disease, prolonged use of vasopressors, donation after cardiac death, nephrotoxic agents, and prolonged ischemia time. Intraoperative factors include hemodynamic instability and prolonged rewarming time (anastomotic time). Recipient factors include diabetes, age, male gender, African American race,

peripheral vascular disease, duration of dialysis before transplant, and early high-dose calcineurin inhibitors.

Surgical Complications

Surgical complications after renal transplantation have an incidence of 5% to 10% and remain an important cause of graft loss.

Graft Thrombosis

Graft thrombosis may be arterial or venous and usually occurs within the first 24 to 72 hours. The incidence ranges from 0.5% to 5%. Renal artery thrombosis may present with sudden cessation of urine output and the diagnosis is made by DUS which shows the absence of arterial inflow and nonperfusion of the transplant kidney. Renal artery thrombosis is a catastrophic complication and almost invariably results in graft loss. With renal vein thrombosis, the clinical presentation includes a sudden decrease in graft function, hematuria, pain, and swelling over the graft. Diagnosis is confirmed by DUS. Urgent exploration and allograft thrombectomy is required.

Renal Artery Stenosis

The incidence of renal artery stenosis ranges from 2% to 10%. The presentation is later, from a few months to 2 years posttransplant with sudden onset of refractory hypertension associated with peripheral edema and graft dysfunction. The anastomotic site is the most common location. Initial screening is performed with DUS and may be followed by magnetic resonance angiogram or CT angiogram. The gold standard for diagnosis remains the arteriogram. The treatment is percutaneous transluminal angioplasty with or without stent placement.

Urological Complications

Urological complications after kidney transplantation have an incidence of 2% to 10%. They may present either as a urinary leak or urinary obstruction. Symptoms and signs include pain and swelling over the graft, fever, decreased urine output, an elevated serum creatinine, and urine draining from the skin incision. Urinary leaks usually occur early after transplantation. Analysis of fluid drainage from the wound will typically demonstrate an elevated

creatinine concentration compared to the serum creatinine. Small leaks can be managed by placing a Foley catheter for bladder decompression. Open operative repair and drainage is usually required for larger leaks. Obstruction of the urinary tract often presents with findings similar to acute allograft rejection with a fall in urine output, tenderness over the graft, and fever. Ultrasound confirmation of hydronephrosis is required for diagnosis. Treatment includes percutaneous nephrostomy, balloon dilation of the stricture, and stent placement. If endoscopic techniques fail to resolve the obstruction, open surgical repair is indicated.

POSTOPERATIVE PANCREAS AND SMALL BOWEL TRANSPLANTATION CARE

Only 1 of 10 pancreas transplants are isolated, that is, only pancreas, and these few are performed in complicated diabetics without nephropathy. The majority of pancreas transplants are simultaneous pancreas–kidney transplants in patients with diabetic nephropathy. A pancreas transplant may also be done subsequent to a successful kidney transplant. Occasionally a pancreatic transplant is performed simultaneously with small bowel transplantation.

In terms of exocrine drainage, currently most pancreas transplants are enteric drained rather than bladder drained.

Pancreas Transplant Care

Early Assessment of Allograft Function

The appearance and texture of the pancreas on completion of the procedure is essential because pancreatitis and allograft edema are common at the time of reperfusion. In this setting, osmotic diuretics are frequently administered to decrease edema and improve microvascular perfusion. A similar strategy is used with intestinal allografts to limit edema and bowel distention. The failure of an allograft to respond to intraoperative interventions aimed at reducing edema is a signal to maintain close surveillance of allograft function perioperatively. Donor risk factors associated with intestinal allograft thrombosis include increased donor age,

hemodynamic instability, catecholamine requirements, and acidosis.

Support of the Transplanted Pancreatic Allograft

Optimal support for the pancreatic allograft focuses on the detection and prevention of rejection and thrombosis, the 2 most common causes of pancreatic graft failure.

Although never scientifically validated, prophylactic anticoagulation involving low-dose systemic heparin in the operating room with dose escalation through the first week (due to decreasing bleeding risks) after transplantation, supplemented with aspirin therapy, is routine.

Pancreatitis and pancreatic ischemia typically present as abdominal pain, peritonitis, ileus, and fever. Serum amylase and lipase correlate poorly with the severity of allograft pancreatitis, with post-transplant hyperamylasemia observed in greater than 30% of recipients; however, trend analysis is helpful. In particular, a sudden increase in amylase and lipase with a change in exogenous insulin requirements is predictor of graft ischemia or necrosis. The use of DUS is sensitive in the diagnosis of thrombosis. The “gold standard” for confirming rejection remains a pancreas graft biopsy. Any form of pancreatic rejection is treated aggressively.

Pancreas transplants with exocrine drainage via the bladder have the advantage of closer monitoring for rejection via urine analysis, however more complications occur including urethritis (greater in males), bladder infection, and acid-base abnormalities, specifically metabolic acidosis due to loss of bicarbonate in the urine.

Small Bowel Transplant Care

There are fewer serum markers and radiologic modalities to guide the management of intestinal transplant recipients. In this population, clinicians only have physical examination, ostomy output, laboratory analysis for hyperkalemia, metabolic acidosis and lactate, and endoscopy. Appropriate volume resuscitation is challenging because volume depletion occurs secondary to inflammation and poor fluid absorption from the transplanted intestine in addition to ileostomy losses. These patients are malnourished with low albumin levels. In some cases,

the intestinal graft may become very edematous and the transplant surgeon may request fluid restriction and diuresis. Albumin 5% or 25% for fluid resuscitation is preferred in these transplants when volume limitation is the goal. Managing the fluid status requires a clinical assessment of systemic perfusion and a hemodynamic assessment of the intravascular volume. Cardiac and pulmonary ultrasound and lactate trends can help to guide fluid management.

Rejection usually occurs within the first month posttransplant. In many centers, serial endoscopy and biopsy are performed twice a week for the first month. After the first month, endoscopies are performed less frequently. The treatment of rejection involves bolus doses of corticosteroids and intensification of the baseline immunosuppressive regimen. Plasmapheresis may be initiated within 24 hours of transplant to reduce intestinal graft rejection in patients with high levels of donor specific circulating antibodies. The effectiveness of plasmapheresis in this setting is under investigation.

Intestinal transplant recipients typically have malnutrition and protein deficiency that results in low oncotic pressure and further loss of intravascular fluid. If anticipated to be NPO for more than about 3 days, total parenteral nutrition is resumed postoperatively. Once anastomotic integrity is established, enteral feeds are initiated and advanced gradually as tolerated. Most patients continue to need supplemental intravenous fluids and electrolytes due to stoma loss during the first posttransplant year.

Posttransplant Lymphoproliferative Disease

Posttransplant lymphoproliferative disease develops in up to 30% of the recipients of intestinal transplant and is usually associated with Epstein–Barr virus (EBV) infection. Treatment principles include a substantial decrease in the immunosuppression regimen and antiviral therapy.

POSTTRANSPLANTATION INFECTIONS

The risk of infection after transplantation changes over time ([Figure 52–1](#)), with modifications in immunosuppression, also depending on the type of organ transplanted. It can be difficult to differentiate rejection or noninfectious inflammation from infection as

no assays can accurately distinguish between these entities. Currently, the clinician assesses a recipient's risk of infection while considering the risk of allograft rejection, the intensity of immunosuppression, and other factors that may contribute to infection. Prophylactic strategies are based on the patient's known or likely exposures to infection according to the results of serologic testing and epidemiologic history. The risk of infection in the transplant recipient is a continuous function of the interplay between these factors. Prophylactic antimicrobial regimens vary depending on the transplant center and the type of transplant. All patients receive usual antibacterial surgical prophylaxis and trimethoprim–sulfamethoxazole (Bactrim) prophylaxis against *Pneumocystis jirovecii*. Antifungal prophylaxis is given depending on the organ transplanted, previous infection, and risk factors such as renal failure. Specific antiviral prophylactic regimens are determined by prior history of viral infections in the recipient and the organ donor. The major risks are herpes virus infection or reactivation, particularly cytomegalovirus (CMV) and EBV, hepatitis C virus (HCV) and hepatitis B virus. There is a very high risk of infection in seronegative recipients receiving an organ from a seropositive donor.

Early Posttransplantation Period

The first month after transplant is a vulnerable time for nosocomial bacterial infections including multidrug-resistant organisms related to complicated surgery. Venous and urinary catheterization and intubation add to the risk, as sicker patients tend to have more invasive devices for longer time periods. Opportunistic infections are generally absent during the first month after transplantation because the full effect of immunosuppression is not yet manifest. Unexplained early signs of infection, such as hepatitis, pneumonitis, encephalitis, rash, and leukopenia, may be donor-derived. Therapy may be empiric or determined by antimicrobial susceptibility data.

Intermediate Posttransplantation Period

The full effect of immunosuppressive medications typically manifest in months 1 to 6 posttransplant. This is when opportunistic infections tend to be most common. Viral pathogens and allograft rejection

FIGURE 52–1 Timeline of common infections after transplantation.¹⁰ (Reproduced with permission from Wolf K, Johnson RA, Saavedra AP: Fitzpatrick's Color Atlas and Synopsis of Clinical Dermatology, 7th edition. New York: McGraw-Hill Medical; 2013.)

are responsible for the majority of febrile episodes that occur during this period. Trimethoprim–sulfamethoxazole prophylaxis generally prevents most urinary tract infections and opportunistic infections such as *P jirovecii* pneumonia, *Listeria monocytogenes* infection, *Toxoplasma gondii* infection, and infection with sulfa susceptible nocardia species. Infection due to endemic fungi, aspergillus, cryptococcus, *Trypanosoma cruzi*, or *strongyloides* may occur. Herpes virus infections are uncommon with antiviral prophylaxis. However, other viral pathogens, including polyomavirus BK, adenovirus, and recurrent HCV have emerged.

Late Posttransplantation Period

Beyond 6 months posttransplant, most stable patients are on reduced doses of immunosuppression and therefore have decreased risk for

opportunistic infections. CMV, EBV, herpes simplex virus, and hepatitis viruses remain a concern, but more commonly transplant patients are infected with seasonal respiratory and gastrointestinal viruses, community-acquired pneumonias and urinary tract infections during this period. In those who require a higher level of immunosuppression, the risk for opportunistic infections may be as high as during the 1 to 6 months posttransplant period. This includes an increased risk for infections with *P jirovecii*, nocardia, varicella, and aspergillus.

IMMUNOSUPPRESSIVE DRUGS

Immunosuppression protocols vary from center to center and the transplant team determines the immunosuppressive regimens that are used

posttransplantation. The intensivist should be familiar with the agents given, what levels to monitor, and the side effects and how they relate to the critical care management. The goal of immunosuppression is to prevent graft rejection while minimizing infection and other side effects. The current initial (ie, for induction) immunosuppression regimens used in solid organ transplants usually consists of a corticosteroid, a calcineurin inhibitor, and an antiproliferative agent. Monoclonal antibodies to lymphocyte receptors may also be used for induction, acute steroid resistant rejection or to reduce calcineurin inhibitors. In patients with corticosteroid intolerance, antiproliferative agents can be increased to reduce corticosteroid use. When renal toxicity is a concern, for example, pretransplant renal failure in a liver transplant patient, corticosteroids and antiproliferative agents may be preferentially used over calcineurin inhibitors.

Corticosteroids

Corticosteroids (eg, methylprednisolone and prednisone) decrease inflammatory proteins and are a cornerstone of immunosuppression. Side effects relevant to postoperative critical care management include mood changes, encephalopathy, hypertension, gastritis, hyperglycemia, hypokalemia, metabolic alkalosis, myopathy, and increased risk of infection.

Calcineurin Inhibitors

Cyclosporine and tacrolimus (Prograf, FK-506) are interleukin-2 (IL-2) inhibitors. They initially require daily monitoring of drug trough levels. The target levels vary with the overall immunosuppressive regimen, the type of transplant, underlying graft function, associated organ function, and the presence of infection. Nephrotoxicity and neurotoxicity remain the most important adverse side effects. Cyclosporine is associated with less neurotoxicity than tacrolimus. Neurotoxic side effects include tremors, headaches, dysarthria, neuropathies, delirium, cognitive impairment, somnolence, seizures, posterior reversible encephalopathy syndrome, and coma. Hypomagnesemia increases neurotoxicity and magnesium replacement with the avoidance of hypomagnesemia is important in patients receiving calcineurin inhibitors.

Antiproliferative Agents

Mycophenolate mofetil (Cellcept) and azathioprine (Imuran) are antimetabolite purine synthesis inhibitors. They are not nephrotoxic or neurotoxic. Side effects include myelosuppression with leukopenia and thrombocytopenia and gastrointestinal symptoms including vomiting, ileus, and oral ulcers. Azathioprine is usually not used as a first-line agent but may be substituted in patients who do not tolerate mycophenolate because of gastrointestinal side effects.

Sirolimus (Rapamune) inhibits IL-2 postreceptor, downstream in the signal cascade, preventing proliferation of T lymphocytes and reducing antibody production. It lacks the neurotoxicity and nephrotoxicity of the calcineurin inhibitors and is a long-term alternative to tacrolimus or cyclosporine in patients with renal dysfunction as a result of calcineurin toxicity. It is avoided in the early posttransplant period due to delayed wound healing and should be avoided in patients with nonhealing wound infections. Other adverse effects include bone-marrow suppression and it has been associated with an increased incidence of HAT after LT.

Monoclonal antibodies (eg, basiliximab) block IL-2 receptors on activated T-lymphocytes thwarting their multiplication and expansion. They have minimal side effects compared to muromonab-CD3 (Orthoclone OKT-3), a monoclonal antibody to T cell CD3 receptors that first activates T cells, causing systemic inflammation, before removing T cells from the circulation thus having significantly more side effects including fever, headache, nausea, and noncardiogenic pulmonary edema.

CONCLUSION

The maturation of solid organ transplantation as a clinical entity has brought new challenges for intensivists managing these patients. The relaxation of recipient criteria combined with expansion of the donor pool has resulted in sicker patients receiving transplants. Donor factors, recipient comorbidities, and intraoperative events play a critical role in determining the postoperative course.

Posttrauma Care

J. David Roccaforte, MD

KEY POINTS

- 1 Survival outcomes in trauma patients over the last 30 years have largely resulted from the adoption of the damage-control strategy than from all other improvements in trauma care combined.
- 2 Damage-control strategy involves an abbreviated laparotomy, surgical control of arterial bleeding, temporary control of enteric spillage, stabilization of long bone fractures, abdominal packing to control venous bleeding, and temporary wound closures to accommodate swelling and to avoid compartment syndrome.
- 3 In severely injured trauma patients, the initial hypotension is a consequence of uncontrolled bleeding. Oxygen-carrying capacity must be maintained with red blood cells, the coagulation system must be supported with plasma and platelets, and after meeting those 2 objectives, any remaining hypovolemia can be corrected with balanced crystalloid.
- 4 Endpoints of resuscitation can monitor regional organ-specific function (eg, urine output, ST-segment abnormalities, and mental status), or global perfusion (lactate, base deficit).
- 5 An acute traumatic coagulopathy can be observed within 30 minutes postinjury. Thromboelastography-guided resuscitation, using targeted platelets, plasma, cryoprecipitate, or other directed therapy may be the optimal strategy once the surgical bleeding has been addressed.
- 6 Abdominal compartment syndrome is important to recognize in the resuscitation of the trauma patient. Definitive treatment is surgical decompression of the abdominal fascia. Intraperitoneal dialysis with a hypertonic glucose solution is a promising intervention to optimize bowel wall perfusion, minimize inflammation, and more rapidly decrease edema.
- 7 Traumatic brain injury frequently accompanies major blunt trauma. Managing elevated intracranial pressure (ICP) in the setting of severe bleeding, hypovolemia, and shock is particularly challenging. In the presence of elevated ICP, optimizing cerebral perfusion pressure becomes the priority.
- 8 Corticosteroids for spinal cord injury are no longer recommended.
- 9 Pulmonary contusion is unique to trauma and can occur directly from blunt injury or indirectly from the blast effect and pressure wave created by a projectile passing through the tissue.
- 10 Blunt cardiac injury following thoracic trauma is a potentially lethal syndrome. In extreme cases, it can lead to cardiac rupture, valvular dysfunction, or coronary occlusion.

—Continued next page

Continued—

Mortality is typically from malignant arrhythmias.

- 11 Mechanical limb compression, prolonged ischemia, blast effect, and vascular insufficiency are all factors which can contribute to delayed myonecrosis.
- 12 Damage-control laparotomy with an open abdomen is not necessarily a contraindication to enteral nutrition.

- 13 Trauma patients are at elevated risk for posttraumatic stress disorder, and early screening and treatment can begin during their ICU stay.
- 14 Physical and occupational therapy availability for trauma patients in the ICU enhances their recovery, and eases the transition to their next phase of care.

DAMAGE-CONTROL STRATEGY/INTEGRATION WITH CRITICAL CARE

Despite the publication of over 2000 studies on damage-control strategy for trauma in peer-reviewed journals, not even 1 provides prospective, randomized, and class-1 evidence supporting the practice.¹ Nevertheless, among experienced experts in trauma, the nearly universal opinion is that survival outcomes over the last 30 years have benefitted more from the adoption of the damage-control strategy than from all other improvements in trauma care combined.

Prior to the current era of damage-control strategy, surgeons attempted the definitive operative repair of all injuries in a single, often prolonged procedure. In contrast, the damage-control strategy only temporizes the immediate life-threatening injuries at the first operation, and then addresses lower-acuity injuries later, in multiple, staged procedures. Physiologic stabilization of the severely injured patient in an intensive care unit (ICU) in between, and after the staged surgical procedures is integral to the damage-control strategy. As a consequence, it is imperative that intensivists who manage trauma patients have an overall understanding of the damage-control strategy,² as well as in-depth knowledge of critical care objectives and pitfalls specific to trauma patients.

Since the late 1980s, the surgical management of the unstable trauma patient has evolved

from a thorough and definitive treatment at the first operation to a damage-control strategy. Specifically, damage-control involves an abbreviated laparotomy, surgical control of arterial bleeding, temporary control of enteric spillage, stabilization of long bone fractures, abdominal packing to control venous bleeding, and temporary wound closures to accommodate swelling and to avoid compartment syndrome. The first operation is completed as expeditiously as possible, ideally within an hour, at which time the patient, likely still in shock, and consequently cold, acidotic, and coagulopathic, is brought to the safe harbor of an ICU where resuscitation is continued, coagulopathy is corrected, and physiologic homeostasis restored.

Early Goals

Resuscitation/Transfusions/Fluid Management

Frequently, with severely injured trauma patients, the initial hypotension is a consequence of uncontrolled bleeding. As described elsewhere, a massive transfusion strategy will have been implemented and continued intraoperatively while surgeons attempt to control the sources of bleeding. The main benefit of massive transfusion protocols is to expedite red cell and blood-product availability to prevent death by exsanguination from uncontrolled surgical bleeding. Although the specific ratios of packed red blood cells (PRBCs) to fresh-frozen plasma (FFP), to platelets are debatable, the objectives of

resuscitation, transfusions, and fluid management are not. Oxygen-carrying capacity must be maintained with PRBCs, the coagulation system must be supported with FFP and platelets, and after meeting those 2 objectives, any remaining hypovolemia can be corrected with balanced crystalloid.³ During periods of uncontrolled bleeding, oxygen-carrying capacity and coagulation status can change quickly. The inherent delay in obtaining laboratory measurements means that objective data are already old by the time they arrive back to the provider, and thus during periods of rapid, uncontrolled bleeding, presumptions regarding deficits must be inferred (eg, transfusion of PRBC:FFP:platelets in a 1:1:1 ratio) so as to avoid any episodes of undertreatment. Once rapid exsanguination from surgical bleeding has been controlled, the massive transfusion protocols should be terminated. Further blood and blood-product transfusions should be directed at correction of documented deficits in oxygen-carrying capacity or coagulopathy, not simply at blindly fulfilling preordained ratios.

The degree of anemia and hypovolemia that any individual patient might be able to tolerate during the early phase of resuscitation is variable, and will depend on the patient's cardiac status, presence or absence of vascular disease, and most importantly, presence or absence of a concomitant head injury with elevated intracranial pressure (ICP). If elevated ICP is suspected, then mean arterial pressure (MAP) should be high enough to maintain a cerebral perfusion pressure (CPP) = (MAP – ICP) of 55 mm Hg or more.

No ideal single marker of resuscitation adequacy exists. Each has its pitfall (see also Chapter 73). For example, serum lactate may be elevated in a perfectly resuscitated patient with baseline liver insufficiency. Base deficit values will be acutely elevated from a benign hyperchloremic acidosis if normal saline (or its equivalents) are used for resuscitation, even though intravascular volume and perfusion may be normal. A safer strategy is to initially collect data for as many endpoints of resuscitation as possible, and over the initial few hours, narrow the focus on those with the best signal-to-noise ratio, individualized to each patient.

Endpoints of resuscitation can monitor regional organ-specific function (eg, urine output, ST-segment

TABLE 53–1 Endpoints of resuscitation—markers of regional perfusion.

Regional Markers	Notes/Pitfalls
Capillary refill	Unknown baseline for comparison
CPK levels	Too slow for acute changes
Echocardiography	Requires special operator skills Absent esophageal or gastric pathology
Electrocardiogram	Unknown baseline for comparison
Jugular bulb saturation	Not routinely available
Mental status	Unavailable during general anesthesia Unreliable with intoxication
NIR spectrometry	Not routinely available
Sublingual tonometry	Not routinely available
Troponin levels	Too slow for acute changes
Urine output	Unreliable with acute or chronic renal failure, SIADH, or neurogenic DI

CPK, creatinine phosphokinase; DI, diabetes insipidus; NIR, near infrared; SIADH, syndrome of inappropriate antidiuretic hormone.

abnormalities, and mental status) (Table 53–1), or global perfusion (lactate, base deficit) (Table 53–2). Ideally, specifically tailored for each patient, 1 global and 1 local marker of resuscitation will be monitored that together optimize sensitivity and specificity for diagnosing shock and recovery.⁴

Coagulopathy/Temperature

The “lethal triad of death” describes the downward spiral of physiologic homeostasis in a patient with uncontrolled hemorrhage and shock. Obviously, if shock is the initial cause of the patient's lactic acidosis, coagulopathy, and hypothermia, even after visible bleeding has been successfully controlled, then inadequate attention to the correction of coagulopathy and hypothermia will lead to continued deterioration. It is during the second phase of damage control, in the ICU, that coagulation system support and aggressive rewarming occur. Classically, the coagulopathy associated with trauma and massive resuscitation was thought to be simply a

TABLE 53–2 Endpoints of resuscitation—markers of global perfusion.

Global Markers	Notes/Pitfalls
Anion gap	May be elevated for reasons other than lactic acidosis
Base deficit	May reflect nonanion gap acidosis
Cardiac output	Requires pulmonary artery catheter Abnormal in shock syndromes in addition to hypovolemia
Core temperature	Hypothermia is a marker of late or advanced shock Fever is the most common transfusion reaction
ETco ₂ P _a co ₂ -ETco ₂ gradient	Elevated with chronic obstructive pulmonary disease
Heart rate	Unknown beta-adrenergic blocker use
Lactate	Impaired clearance with hepatic dysfunction
Mean arterial pressure	Generally well compensated until late Unknown baseline
pH	May reflect respiratory and/or nonanion gap acidosis
P _a O ₂ P _a O ₂ :FiO ₂	Lower from the following: <ul style="list-style-type: none">• Shunt (eg, pulmonary contusion, aspiration)• Hypovolemia-related V/Q mismatch Hypoxemia from shunt does not generally respond to supplemental oxygen Hypoxemia from V/Q mismatch easily corrected with supplemental oxygen
Pulse pressure	Difficult to interpret if accompanied by bradycardia
Respiratory systolic pressure variation	Difficult to interpret with obesity or with abdominal compartment syndrome
SvO ₂	Requires pulmonary artery catheter Abnormal in shock syndromes other than hypovolemia

ETco₂, end-tidal carbon dioxide; FiO₂, fraction of inspired oxygen concentration; P_aco₂, partial pressure of arterial carbon dioxide; P_aO₂, partial pressure of arterial oxygen; SvO₂, mixed venous oxygen saturation; V/Q, ventilation/perfusion.

consequence of clotting factor and platelet dilution, consumption, and dysfunction. More recently, data have emerged which demonstrate that an acute traumatic coagulopathy can be observed within 30 minutes postinjury, more quickly than can be explained by acidosis, consumption, or dilution, indicating that a more complex process is involved. Ongoing research to elucidate the underlying etiology has focused on catecholamine, and inflammatory mediators, protein C activation, and shedding of glycocalyx. Regardless of the underlying complex initial biochemical pathophysiology, by the time a patient survives the first phase of damage control and is transferred to the ICU, the classic concerns

of clotting factor and platelet dilution and hypothermia must be addressed.⁵

Thromboelastography (TEG) is a real-time measure of whole blood clotting. Results are available within 10 to 45 minutes—too slow to be useful in the acutely exsanguinating patient, however once surgical bleeding has been addressed, it should be considered. TEG data graphically reveal abnormalities in platelet function, intrinsic, extrinsic pathway integrity as well as fibrinogen deficits and thrombolysis. TEG-guided resuscitation, using targeted platelets, FFP, cryoprecipitate, or other directed therapy may be the optimal strategy during this phase, and likely superior to blindly

continuing a massive transfusion protocol following predetermined ratios.⁶

Abdominal Compartment Syndrome

Intra-abdominal hypertension causes symptoms of abdominal compartment syndrome (ACS) when intra-abdominal pressure (IAP) exceeds systemic venous pressure. IAP is traditionally approximated by transducing an indwelling bladder catheter after instillation of saline, which establishes a continuous fluid column from the bladder to the pressure transducer. The transducer is zeroed at the symphysis pubis. Normal IAP is 3 to 10 mm Hg. With mild elevations up to 15 to 20 mm Hg, bowel becomes congested, renal and portal veins may collapse, and urine output may decrease. Provided that the systemic arterial blood pressure and intravascular volume can tolerate it, aggressive diuresis at this stage may be able to break the vicious cycle of increased bowel edema leading to increased venous congestion leading to decreased abdominal organ perfusion, increased edema, and increasing IAP. Because capillary fluid extravasation during the early post-trauma period is largely driven by the inflammatory response to trauma, diuresis usually fails to reverse the progression ([Figure 53–1](#)).

Once IAP rises more than 25 mm Hg, urine output is severely impaired, bowel perfusion is compromised, and airway pressures rise as a consequence of cephalad pressure on the diaphragm. At IAP more than 30 mm Hg, bowel ischemia, renal failure, and hypoxia from severe atelectasis are usually observed. The definitive treatment of ACS is to surgically decompress the abdominal fascia. Often at the initial damage-control operation, even if no intra-abdominal injury is found, ACS is anticipated and the abdominal fascia is left open prophylactically until the inflammatory response subsides and sequestered, third-space fluid is mobilized.⁷ Intra-peritoneal dialysis with a hypertonic glucose solution is a promising intervention to optimize bowel wall perfusion, minimize inflammation, and more rapidly decrease edema.⁸

Other Early Trauma ICU Concerns

During the second phase of damage control, the focus remains on resuscitation. Gradual physiologic improvement should be observed over the

subsequent 24 to 48 hours at which time the patient returns to the operating room for definitive repair of remaining injuries. If a patient's condition continues to deteriorate, serious consideration must be given to a missed vascular injury. Interventional radiology may be utilized to diagnose and possibly embolize arterial bleeding that cannot be accessed surgically. Alternatively, a return to the operating room earlier than planned may be required.

The second phase of damage control in the ICU provides the opportunity to repeat and document a thorough baseline head-to-toe physical examination. Commonly, minor extremity fractures may be missed which can be associated with significant long-term disability, if not treated appropriately. Additionally, any extremity swelling should raise the concern of limb compartment syndrome and monitored with serial creatine kinase (CK) levels or intramuscular pressure transduction as appropriate. Perioperative prophylactic antibiotics should be given⁹ and a nutritional plan established.

Any vascular access obtained in the field, or in less-than-sterile conditions, should be removed and replaced if needed. If the patient's cervical spine cannot be cleared, then the extrication collar placed by EMS for cervical immobilization must be replaced with a collar designed for longer-term usage such as a Miami-J or Philadelphia-type collar. Extrication collars are made of thin, hard plastic with minimal padding, designed to be placed in tight quarters and they (as well as backboards) can cause decubitus ulcers within hours.

The patient's family or friends should be updated as to the patient's condition, and also queried regarding the patient's comorbidity, medications, allergies, and social history. Often, details of the patient's history emerge during these conversations which significantly alter the care plan.

Organ-System Supportive Care

Neurologic (See Also Chapters 48 and 50)

Traumatic Brain Injury—Traumatic brain injury (TBI) frequently accompanies major blunt trauma. Managing elevated ICP in the setting of severe bleeding, hypovolemia, and shock is particularly challenging. In the absence of head injury, during resuscitation, the mean arterial blood pressure

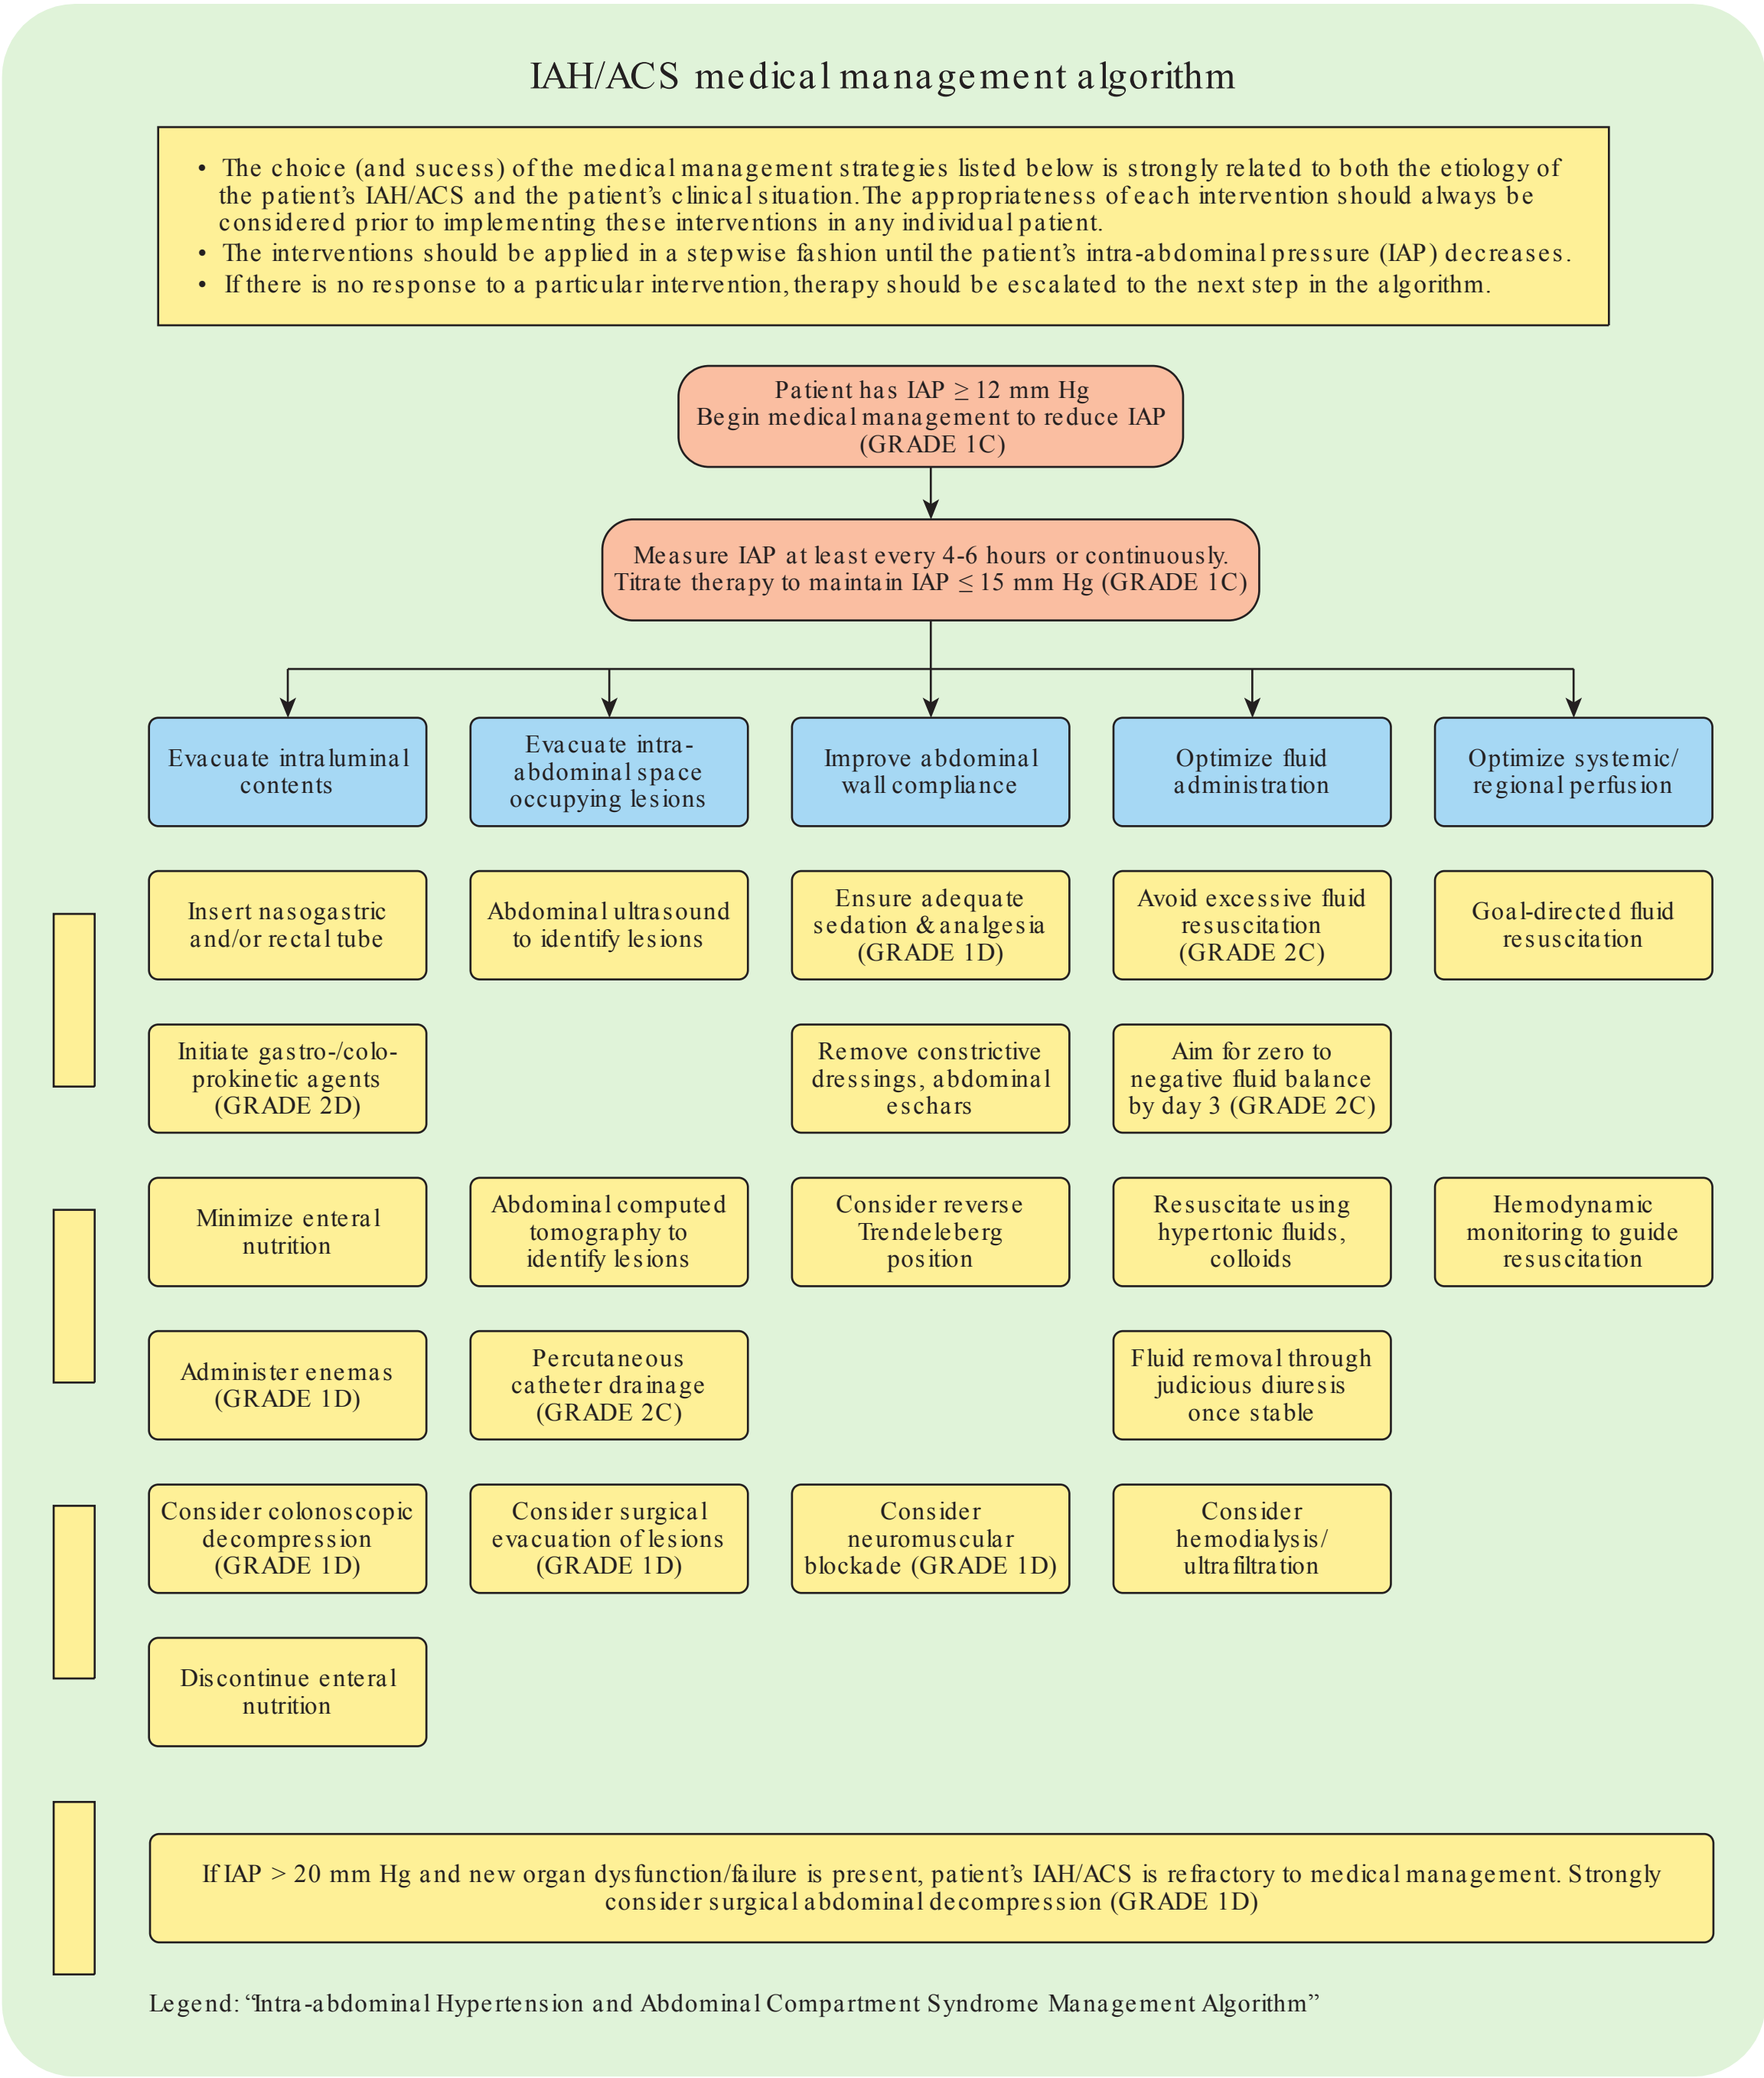

FIGURE 53–1 Intra-abdominal hypertension and abdominal compartment syndrome management algorithm. (Reproduced with permission from Kirkpatrick AW, Roberts DJ, De Waele J, et al: Intra-abdominal hypertension and the abdominal compartment syndrome: updated consensus definitions and clinical practice guidelines from the World Society of the Abdominal Compartment Syndrome, Intensive Care Med 2013 Jul;39(7):1190-1206.)

(MAP) is targeted to be as low as possible so as to minimize additional bleeding while at the same time maintaining organ perfusion. However in the presence of elevated ICP, optimizing CPP becomes the priority.

$CPP = MAP - (\text{the higher of ICP or central venous pressure})$

In order to accurately calculate CPP, arterial blood pressure, central venous pressure, and ICP must be monitored directly. ICP is monitored either via ventriculostomy and intraventricular catheter or by a parenchymal or subarachnoid transducer (see also Chapter 101). Interventions to consider which optimize CPP are head-of-bed elevation, cerebral spinal fluid drainage (if a ventriculostomy is present), judicious diuresis with osmotic agents such as mannitol (used with discretion in the presence of hypovolemia), intravascular hypertonic saline, deep sedation to achieve burst suppression on EEG, and alpha-agonist vasoconstriction. Interventions which have not shown to be of benefit or which may be harmful include hyperventilation, corticosteroids, and hypothermia.

Current recommendations for the ICU management of TBI can be found in the Guidelines for the Management of Severe Traumatic Brain Injury¹⁰ which is published and updated by the Brain Trauma Foundation and available on-line.

Spinal Cord Injury and C-Spine Clearance—As soon as possible upon admission to the ICU, a thorough neurologic exam should be repeated. Any paraplegias or hemiplegias should raise the suspicion of spinal cord injury (SCI). Cervical and thoracolumbar vertebral immobilization should be maintained until the patient can cooperate with an appropriate examination, or until radiographic studies can be obtained which demonstrate absence of both bony injury (computed tomography [CT] scan) and soft-tissue ligamentous injury (magnetic resonance imaging). If the patient is known to have a spinal cord transection, any accompanying hypotension, bradycardia, or shock should be treated supportively. Anticipate the need for ongoing respiratory support for cervical spinal cord injuries. Corticosteroids for SCI are no longer recommended.

The prerequisite to the clinical clearance of a suspected or potential cervical SCI requires first the evaluation of any radiographic studies and confirmation of the absence of bony fractures or alignment

abnormalities. In order for the cervical spine to be clinically cleared, the patient must be able to (1) focus fully on the exam (no distractions), (2) localize and discriminate mildly noxious stimuli, and (3) move and feel all extremities. A practical method of assessing distraction from any cause is to apply a mildly noxious stimulus to the patient's extremities and query if they feel discomfort. This demonstrates the patient's ability to localize sensation, focus on and cooperate with the examination, and communicate adequately with the care provider.

Coma Prognosis—Prognosis for patients with coma following TBI differs from that following anoxic brain injury. Following anoxic brain injury, if no improvement in the patient's neurologic status is observed after 72 hours, it is unlikely that the patient will have a significant recovery. In contrast, following TBI, treatment of concurrent injuries may delay or obscure early recovery from coma. Once the patient has been stabilized from other injuries, most neurologic recovery from TBI can be observed within 6 months with additional incremental improvements up to an year or more following the injury, especially with aggressive rehabilitation.

Sedation/Analgesia/Amnesia (See Also Chapter 16)—Trauma patients often require analgesia for soft-tissue and bony injuries. Intravenous opioids remain the standard means to control pain, either as a continuous or patient-controlled infusion. Appropriate constipation prophylaxis must be initiated. Alternatively, and especially for thoracic trauma and rib fractures, regional anesthesia, nerve blocks, and epidural catheters are effective. Nonsteroidal agents can be used with caution, especially if ongoing bleeding or renal injury is major concern. With few exceptions, a "wake-up" test, or suspension of sedation should be implemented once daily, and the opportunity taken to reassess neurologic function before restarting sedative/hypnotic agents. Utilization of benzodiazepines for amnesia or sedation is controversial. On the one hand, any recall of uncomfortable, upsetting, or delirium-induced memories has a high correlation with development of posttraumatic stress disorder (PTSD). On the other hand, benzodiazepine use is associated with delirium.

Delirium (See also Chapter 49)—Delirium is frequently observed patients following major trauma.

Its etiology is likely multifactorial. Disinhibition can occur from frontal lobe contusions in patients with TBI, systemic inflammatory response or renal failure can cause a metabolic encephalopathy, and given the prevalence of alcohol-related trauma, delirium tremens can occur from ethanol withdrawal. Treatment is largely supportive, with intravenous benzodiazepines for alcohol withdrawal and intravenous haloperidol a typical means of treatment for other causes of delirium in the acute setting. As the inflammatory response subsides, haloperidol can rapidly be tapered off within 2 or 3 days, dystonic reactions and neuroleptic malignant syndrome are rare in this setting. QT-intervals must be monitored closely. Patient recall of delirium episodes is a particularly potent risk factor for PTSD, and an amnesic agent such as a benzodiazepine may be of benefit once delirium has developed. In the absence of head injury, delirium developing in previously healthy trauma patients is temporary, and as they recover from their injuries and inflammation subsides, their mental status also normalizes.

Brain Death Determination—Brain death is the complete and irreversible cessation of all brain and brainstem function. Because cardiopulmonary function may be temporarily suspended and restarted as during cardiopulmonary bypass, even a “cardiac” death is not final until it becomes brain death. The determination of brain death in a patient whose remaining organs can retain function with support enables those organs to be procured for transplantation. The potential for organ transplantation is the only rationale for continuing cardiopulmonary support once brain death has been determined. Occasionally, family members may request continued organ support after death for cultural or religious reasons, and while efforts should be made to accommodate reasonable requests, they should not compromise the care provided to live patients in the ICU.

Specific protocols for the determination of brain death are mandated by individual jurisdictions and adapted at each hospital. In general, the process involves establishing a diagnosis, reviewing radiographs, assessing for potentially reversible causes of coma, conducting a neurologic examination of brain and brainstem function, repeating or confirming the examination, and finally performing an apnea test whereby the arterial carbon dioxide levels

are allowed to rise. The apnea test is performed as the final step because increasing CO_2 will potentially increase ICP and if the patient was not brain dead, the apnea test could theoretically complete a partial herniation, which is not the intention of the test. See [Figure 53–2](#) for a sample protocol for the determination of brain death in adults.

Pulmonary

Pulmonary contusion is a respiratory condition unique to trauma. Contusion can occur directly from blunt injury or indirectly from the blast effect and pressure wave created by a projectile passing through the tissue. The initial chest radiograph may appear normal, however after 4 to 24 hours, the contusions blossom into dense infiltrates. Oxygenation deteriorates as a consequence of shunt, and the degree of hypoxia is proportional to the degree of hypoxic pulmonary vasoconstriction impairment, usually driven by inflammation and thus worse following blunt trauma compared to penetrating. Care is supportive, and an open-lung, protective ventilation strategy should be followed similar to that used to manage acute respiratory distress syndrome (see Chapter 19).

“Flail chest” is a condition whereby 2 or more adjacent ribs are fractured in 2 or more locations following blunt trauma. Historically, mortality was quite high, and thought to be a consequence of compromised respiratory mechanics. Significant effort was directed at stabilizing rib fractures with splints and plates, with minimal outcome benefit. We have come to realize that the true insult in flail chest is the underlying pulmonary contusion, and with adequate epidural analgesia, intubation and supportive ventilator management until the contusions resolve, outcomes have improved.

Cardiovascular

Occasionally a patient’s fall or motor vehicle crash is precipitated by loss of consciousness due to another medical condition such as hypoglycemia, seizure, or pulmonary embolism. Commonly, the syncope is cardiac in origin. Myocardial infarction and arrhythmias must be considered, especially in elderly trauma patients. Cardiac monitoring must continue and evaluation undertaken concurrently with the trauma work-up.

The clinical criteria of brain death in adults

Instructions : When Steps 1, 2, and 3 are confirmed, the patient is declared brain dead (legally dead). Step 2 consists of a Firs t Exam and a Second Exam that are performed at least 6 hours apart (2 hours if a confirmatory test is performed).		Check (✓) Item of Confirmed	
<u>Step 1: Prerequisite to Exam</u> Evaluate and correct potentially reversible causes of the abnormal neurological examination. 1) Hypotension (mean arterial pressure < 60 mm Hg) 2) Hypothermia (core temperature < 32°C or < 90°F) 3) Metabolic disturbances (eg, glucose, electrolyte, acid-base, or endocrine) 4) Significant drugs or medications 5) Confounding diseases (eg, locked-in syndrome, Guillain-Barré) The cause of coma is known and sufficient to account for irreversible brain and brainstem death. Clinical history and/or neurological imaging are consistent with brain death.		<div><input type="checkbox"/></div> <div><input type="checkbox"/></div>	
<u>Step 2: Absence of Brain and Brainstem Function</u> Coma: Absent cerebral motor response in all extremities and face to noxious stimulus (applying firm pressure on the nail-beds and supraorbital ridge) Absent Brainstem Reflexes : Pupils <ul style="list-style-type: none">• Size: midposition to dilated (4 to 9 mm)• Absent response to bright light Absent corneal reflex (touch edge of cornea) Absent gag reflex (stimulate pharynx) Absent cough response (tracheobronchial suction) Ocular Movement <ul style="list-style-type: none">• Absent oculoccephalic reflex (perform this test only if cervical spine instability is excluded)• Absent deviation of eyes with cold water stimulation of the tympanic membranes	Firs t Exam	Second Exam

	<input type="checkbox"/>	<input type="checkbox"/>	
<u>Step 2a: Consider Confirmatory Test[†]</u> if Steps 1 or 2 cannot be fully performed or adequately interpreted.			
<u>Step 3: Absence of Respiratory Effort[‡]</u> Positive Apnea Test: Absent respiratory efforts when the arterial pCO ₂ increase by more than 20 mm Hg above the patient's normal baseline.		<div><input type="checkbox"/></div>	
<u>Step 3a: Consider Confirmatory Test[†]</u> if Step 3 cannot be fully performed or adequately interpreted.			
[†]Confirmatory Testing These conditions may warrant confirmatory tests: 1) significant levels of drugs, (eg, sedatives, neuromuscular blocking agents, anticholinergics, organophosphates, tricyclic antidepressants, antiepileptic drugs), 2) severe facial trauma, 3) cervical spinal cord injury, 4) preexisting pupillary abnormalities, or 5) severe pulmonary disease and chronic hypercapnia. Confirmatory test options include: cerebral angiography, brain scan with technetium-99m, electroencephalography, transcranial doppler, or somatosensory evoked potentials (See references for details). [‡]Apnea Test Prerequisites : 1) Begin test at patient's normal baseline arterial pCO ₂ (never less than 40 mm Hg), 2) T ≥ 36.5°C (97°F), systolic BP ≥ 90 mm Hg. Perform test t: 1) Preoxygenate with 100% O ₂ , 2) monitor BP and pulse oximetry, 3) deliver 100% O ₂ via cannula into the trachea to maintain oxygenation, 4) observe for respiratory movements, 5) measure arterial pO ₂ , pCO ₂ , and pH after at least 8 minutes and reconnect the ventilator. Abort test t: Draw blood gas and reconnect ventilator for: 1) spontaneous respirations or movement, 2) systolic BP ≤ 90 mm Hg, 3) oxygen desaturation, or 4) cardiac dysrhythmias.

Blunt cardiac injury (BCI) following thoracic trauma is a potentially lethal syndrome. In extreme cases, it can lead to cardiac rupture, valvular dysfunction, or coronary occlusion; however, most cases manifest as impaired ventricular function. Mortality, when it occurs, is typically from malignant arrhythmias. Consequently, when BCI is suspected, the patient must have a baseline electrocardiogram (ECG) and cardiac troponin level.

The Eastern Association for the Surgery of Trauma publishes updated guidelines¹² for the management of BCI. Among their most recent recommendations (2012):

- If the admission ECG reveals a new abnormality (arrhythmia, ST changes, ischemia, heart block, and unexplained ST changes), the patient should be admitted for continuous ECG monitoring.
- For patients with preexisting abnormalities, comparison should be made to a previous ECG to determine need for monitoring.
- For patients with a normal ECG and normal troponin level, BCI is ruled out.
- Patients with normal ECG results but an elevated troponin level should be admitted to a monitored setting.
- For patients with hemodynamic instability or persistent new arrhythmia, an echocardiogram should be obtained.

If no new arrhythmias develop in a hemodynamically stable patient for 24 to 48 hours, then continuous ECG monitoring may be discontinued.

Tachycardia—The most common cardiac abnormality in the trauma patient is sinus tachycardia. The finding is nonspecific in trauma patients, and can be a consequence of hypovolemia, anemia, pain, anxiety, inflammation, fever, or elevated catecholamines. Each patient’s ability to tolerate tachycardia must be weighed against the stress placed on the heart. Any evidence of strain or ischemia must prompt an investigation to diagnose and treat the underlying cause. If the tachycardia fails to resolve, or is attributable to elevated catecholamines, central fevers, or dysautonomia, then beta blockers should be considered for sustained heart rates more than 130 bpm so as to avoid tachycardia-induced cardiomyopathy.

Anticoagulation Management (See Also Chapters 20 and 34)—Although the early concern during resuscitation is directed at correcting coagulopathy, within hours to days, trauma patients become hypercoagulable and at significantly increased risk for deep vein thrombosis (DVT), especially if other trauma-related risk factors are present (see [Table 53–3](#)).

DVT prophylaxis should be initiated as soon as appropriate once bleeding is controlled, and the coagulopathy has been corrected. In patients with TBI, pharmacologic DVT prophylaxis with subcutaneous unfractionated or low-molecular weight heparin is safe to begin once the patient’s neurologic exam and head CT scans are stable for 24 hours. Although the combination of mechanical DVT prophylaxis with pharmacologic prophylaxis has not been shown to decrease the incidence of DVT compared to each used alone, because of the high likelihood of missed heparin doses and periods of time where sequential compression devices are removed or turned off, many adopt a “belt and suspenders” approach and implement both modalities concurrently.

General surveillance screening with Doppler evaluation for the presence of DVT in trauma patients has not been shown to be cost-effective provided appropriate DVT prophylaxis is maintained. A notable exception would be a patient at high risk for DVT, who is not a candidate for therapeutic anticoagulation in whom placement of an inferior vena cava (IVC) filter would be considered if a DVT were present.

Unfortunately, definitive data do not exist to guide the appropriate usage of IVC filters in trauma

patients.¹³ Although retrievable filters are available, for various reasons the actual retrieval rate remains low. The protective benefit of IVC filter placement for pulmonary thromboembolism is temporary, yet the potential IVC complications of erosion and embolization are long-term. On the other hand, for patients with compromised cardiopulmonary function, even a relatively small pulmonary embolus can be fatal.

Musculoskeletal

Fat Embolism Syndrome—Multiple critical care concerns arise as a consequence of bony and soft-tissue injury to the extremities. Fat embolism syndrome (FES) manifests as pulmonary, neurologic, cardiac, and renal dysfunction following pelvic and long-bone fractures.¹⁴ The injurious substances released into systemic circulation are most likely bone marrow constituents rather than purely fat. The diagnosis is one of exclusion and care is supportive. Neither corticosteroids, anticoagulation, nor IVC filter placement are recommended. Because movement of bony fragments is thought to be a contributing factor in the development of FES, the splints, traction, and external fixation devices placed during the first phase of damage control must be assiduously maintained throughout the patient’s ICU course.

Crush Injury/Rhabdomyolysis—Mechanical limb compression, prolonged ischemia, blast effect, and vascular insufficiency are all factors which can contribute to delayed myonecrosis. Typically prophylactic fasciotomies are created to prevent limb compartment syndrome. When a limb salvage approach is chosen over early amputation, the intensivist must be aware of the progressive pathophysiology which may follow. Initially the skin and soft tissue of the limb appear normal, however serum CK levels must be monitored closely. If CK levels rise, rhabdomyolysis has begun, and surgical debridement of necrotic tissue (or extension of fasciotomies) must be undertaken before renal failure progresses to multiorgan system failure or worse.¹⁵ If the patient’s systemic condition continues to deteriorate, amputation may be necessary. The Mangled Extremity Severity Score (MESS)¹⁶ can aid in anticipating the success or failure of limb salvage (see Table 53–4).

Limb salvage success is significantly diminished when the MESS is greater than 7. Intravenous hydration with close monitoring of electrolytes, directed

at maintaining renal function is the mainstay of treatment for rhabdomyolysis. Alkalinization of urine and forced diuresis may be considered.

Renal (See Also Chapters 30 and 31)

Besides the usual factors associated with renal failure in the critically ill (advanced age, hypertension, vascular disease, diabetes), trauma patients have additional risk factors contributing to a high rate of renal insufficiency and need for renal replacement

therapy. For instance, direct renal trauma leading to nephrectomy results in an immediate decrease in glomerular filtration rate by half. Multiple exposures to contrast during the radiographic work-up of injuries, or during interventional vascular procedures is common. Rhabdomyolysis, exposure to aminoglycosides, and sepsis are potential additional insults.

Except for hydration therapy for rhabdomyolysis, the evidence supporting renal protective interventions for contrast-induced nephropathy is inconsistent. The potential outcome benefit demonstrated by intravenous hydration, bicarbonate administration, urine alkalization, and oral N-acetylcysteine administration results in a lower peak creatinine level compared with placebo. Renal prophylactic therapies have neither been shown to improve survival nor to decrease the need for renal replacement therapy. However, because of the low cost, minimal risk, and potential benefit, renal prophylaxis for intravenous contrast exposure is often implemented.

Gastrointestinal Nutrition

In many trauma patients, gastrointestinal ileus develops directly as a consequence of bowel injury or indirectly from an elevated stress response or from narcotic exposure. At the same time, metabolic requirements necessary to heal wounds increase demands significantly following trauma. Interestingly, even relatively minor TBI increases metabolic demands well out of proportion to what might be anticipated from the amount of tissue damaged.

A plan for nutritional support must be established as early as possible. Often, if it can be anticipated that a patient will not be able to eat by mouth for a prolonged period, surgical feeding access may be obtained at the first take-back damage-control operation. Although there appears to be no difference in aspiration risk between nasogastric and postpyloric nasoduodenal tube feeding, a tube placed beyond the ligament of Trietz into the jejunum for feeding, with a proximal gastric port for evacuation may offer some benefit (see also Chapter 70).

Damage-control laparotomy with an open abdomen is not itself a contraindication to enteral nutrition.¹⁷ Intestinal luminal cells derive a portion of their energy from directly absorbed enteral nutrition, so providing even minimal trophic feeding could be expected to increase bowel perfusion and

motility, enhance anastomotic integrity and decrease interstitial edema. In fact, in patients without bowel injury, enteral feeding in the open abdomen is associated with increased fascial closure rates, decreased complication rates, and decreased mortality.

Traditionally, enteral feeding is suspended prior to any planned operative procedure. The severely injured trauma patient may return to the operating room almost daily for various staged repairs in a damage-control strategy. As a consequence, nutritional support can become severely compromised. A more prudent approach is to continue enteral nutrition perioperatively, provided that the airway remains protected with a cuffed endotracheal tube, and the planned surgical procedure does not involve the aerodigestive tract.

Long-Term Concerns

Social Support

Unlike the majority of critically ill patients who are admitted to an ICU after a long-term trajectory of deterioration from a chronic disease or condition, most trauma patients are relatively healthy prior to their injury. Indeed, many have never been hospitalized before. Trauma patients require a tremendous amount of social support and assistance ranging from tracking down family members to arranging for pets to be fed. A skilled and experienced trauma social worker is an invaluable member of the team.

Psychologic Issues

As the trauma patient begins to regain consciousness, they often experience retrograde amnesia even if they did not suffer a head injury. The last thing they remember might be events from the day before they were injured. They may not know what happened, where they are, how they got there, nor realize, for instance, that a loved one perished in the same vehicle crash, or that they have lost a limb. As difficult as those conversations are to have, providing truthful information to the patient is the only way to alleviate their extreme anxiety and fear of not knowing. Anticipating how best to compassionately inform a patient of the events surrounding their trauma enables the care team to enroll the expertise of psychologists, social workers, grief counselors, clergy, family members, or even former trauma patient volunteers who can be available to provide support and answer questions for patients and their families.

As gratifying as it can be to care for severely injured trauma patients and enable them to recover from their physical injuries, neglecting their psychologic well-being can undermine an otherwise successful outcome. Trauma patients are at elevated risk for PTSD, and early screening and treatment can begin during their critical care stay.¹⁸ Full-blown PTSD can be incapacitating, but even posttrauma anxiety or depression can lead to substance abuse, alcoholism, and risk-taking that partly explain how trauma can become a chronic, relapsing condition.

Rehabilitation

Early mobility and ambulation, even in the ICU, has been shown to improve outcomes for specific types of injuries, while at the same time prolonged bedrest and immobility have almost universally been associated with increased ICU complications. Physical and occupational therapy availability for trauma patients in the ICU enhances their recovery and eases the transition to their next phase of care.¹⁹

Postcardiothoracic Surgery Care

Mabel Chung, MD and Anthony Carlese, DO

KEY POINTS

- 1 Every postcardiac patient should be evaluated for fast tracking, and the decision to proceed with this strategy should be assessed on a case-by-case basis and may be modified by patient comorbidities or situational factors.
- 2 Subsequent administration of sedatives and analgesics should be done judiciously to keep the patient comfortable while intubated, but to avoid oversedation and respiratory depression that may delay extubation.
- 3 To conceptualize the hemodynamic changes in the postoperative period is to consider whether the myocardium is pressure overloaded or volume overloaded or particularly with the various valvular surgeries.
- 4 Viscoelastic whole blood tests such as the thromboelastography (TEG) may pinpoint the hemostatic defect and provide more targeted transfusion therapy.
- 5 Atrial fibrillation after cardiac surgery is a common phenomenon occurring in 10% to 65% of postoperative patients with a peak incidence occurring 2 to 3 days after surgery.
- 6 Renal dysfunction is not uncommon after surgery with an incidence of 1.4% for overt renal failure, risk factors being age, New York Heart Association (NYHA) class 3 or 4 heart failure, chronic renal disease, type I diabetes mellitus (DM), prolonged operative time, and poor cardiac performance.

INTRODUCTION

The care of patients after cardiac surgery, particularly in the immediate postoperative period, frequently involves a period of physiologic volatility as the body adapts to the cardiac intervention and recovers from the effects of cardiopulmonary bypass (CPB) and anesthesia. The successful management of this patient population can be facilitated by addressing common issues such as fast-track eligibility and extubation, hypotension and low cardiac output (CO), postoperative bleeding, dysrhythmias, renal function,

and glucose control. This chapter aims to provide an overview of these topics as well as a framework for approaching problems in these areas.

TRANSITION OF CARE

When the postcardiac surgery patient arrives in the intensive care unit (ICU), the optimal transition of care is achieved by direct communication between the ICU team and the surgeons and anesthesiologists involved in the case. If a coronary artery bypass

graft (CABG) was performed, the report from the surgeons should include the number of bypasses, the locations of the grafts, and whether the quality of the targets were good, as this has implications for the degree of protection achieved against future myocardial ischemia. Patients very commonly will have had coronary stents placed prior to their CABG. If the grafts did not bypass these stents, then antiplatelet agents such as clopidogrel may need to be reinstated as soon as hemostasis is assured. When radial artery or bilateral internal mammary grafts are utilized, some institutions utilize low-dose nitroglycerin or nicardipine to protect against vasospasm, and the need for these agents should be communicated to the ICU team. If a valvular procedure has been performed, the differentiation in the surgeon's report should include the valve of interest, whether it was repaired or replaced, and if it was replaced, the type of valve that was implanted, that is, bioprosthetic or mechanical. Mechanical valves necessitate anticoagulation once hemostasis is achieved, and a plan for implementation should be made clear. The surgeon should communicate the need for any particular blood pressure goals. A lower blood pressure may be requested in situations where the risk of bleeding is higher than usual, such as when a friable aorta was encountered during the procedure. A higher blood pressure goal may be needed in patients with chronic hypertension or in those with known vascular stenoses of the carotid or renal vasculature. Finally, a plan for devices such as intra-aortic balloon pumps should be communicated.

The transition of care should also include a thorough report from the anesthesiologist. The difficulty of mask ventilation and intubation should be communicated as this has implications for whether a patient might be safely extubated later on. If the intubation was difficult, the details on how intubation was achieved should be obtained. The report should also comment on the difficulty or ease of line placement. Information about CPB should be communicated as well, including prebypass stability, duration of bypass, duration of circulatory arrest, difficulty in arresting the heart and difficulty of weaning off bypass including the number of attempts and the vasoactive medications required for separation. Knowledge of the findings on transthoracic echocardiography are paramount for postoperative

management in the ICU including left and right ventricular functions, thickness of the ventricle, and the presence of any valvular abnormalities. Other details such as rhythm issues and the requirement for pacing as well as baseline hemodynamic measurements such as pulmonary artery pressures and cardiac index (CI) should be obtained. Finally, the number and type of blood products should be communicated to the ICU team.

FAST-TRACK CARE

Once report has been obtained from the surgical and anesthetic teams, the decision of whether to fast track the patient should be made. Fast-track care or fast tracking involves a strategy of early extubation with the aim of promoting an expedient discharge for the purpose of reducing the length of stay in the ICU and hospital and to realize cost savings. It typically starts as an anesthetic strategy of decreased opioid dosage (eg, intraoperative fentanyl usage of less than 20 micrograms/kg vs greater than 20 micrograms/kg) to promote timely awakening and return of respiratory drive, and is executed as an ICU team strategy of achieving extubation within a predetermined timeframe, often with the help of a time-directed extubation protocol, typically within 8 hours of arrival to the unit. One meta-analysis found that fast tracking resulted in a significant mean reduction in time to tracheal extubation of 8.1 hours as well as achievement of a statistically significant decrease in overall ICU length of stay of approximately 5 hours, though not in overall hospital length of stay,¹ a finding echoed by a Cochrane Review on fast-track cardiac care (decreased time to extubation 3.0 to 10.5 hours, decreased length of stay in ICU 0.4-8.7 hours).² An earlier trial by Cheng et al found that fast tracking (intraoperative fentanyl 15 g/kg vs 50 g/kg) led to a decrease in time to extubation by approximately 15 hours and a decrease in ICU length of stay of approximately 5 days; in this context, use of fewer higher cost ICU days resulted in a cost savings of per CABG of 25% as well as a decrease in the rate of case cancellations (0.3% vs 2%) due to improved ICU throughput.³ Fast tracking appears to be safe without evidence of increased mortality or postoperative complications such as myocardial infarction, reintubation, acute renal failure, major bleeding, and stroke.^{1,2}

Patient selection for fast tracking must be considered. For example, Cheng et al excluded patients who were older than 75 years of age and who experienced a recent myocardial infarction (within 3 weeks), inotropic therapy within 24 hours before the study, or had an intra-aortic balloon pump as well as patients with severe hepatic disease, significant renal insufficiency, or severe chronic obstructive pulmonary disease (COPD), among other criteria. Every postcardiac patient should be evaluated for eligibility for fast tracking, but the decision to proceed with this strategy should be assessed on a case-by-case basis and may be modified by patient comorbidities or situational factors.

Delays in extubation may be warranted with certain comorbidities. For example, the patient with a low ejection fraction (EF) due to left ventricular dysfunction should be carefully assessed for signs of low CO prior to liberation from the ventilator. CPB induces a temporary deterioration of myocardial contractility⁴⁻⁶ (see section “Hypotension and Low Cardiac Output”), which may significantly impact a patient with low myocardial reserve. Extubation during this time period, with loss of left ventricular afterload reduction due to withdrawal of positive pressure ventilation, may further compromise a tenuous state of contractility.⁷⁻⁹ Patients who maintain an adequate CO despite a starting low EF and demonstrate signs of adequate perfusion should be extubated when ready. However, those with myocardial dysfunction resulting in hemodynamic instability with a rising vasopressor requirement, especially with concurrent acidosis, low mixed venous saturation (SvO_2) and oliguria should be kept intubated until stabilized with therapies such as initiation or escalation of inotropic therapy or placement of an intra-aortic balloon pump. Another example is the patient with end-stage renal disease who is dependent on dialysis who may require renal replacement therapy in the immediate postoperative period. In this case, extubation may be better delayed after completion of a therapy that will induce fluid shifts in the early postoperative period.

Situational factors such as bleeding, hemodynamic instability, delayed emergence, difficult intubation, hypothermia, or intraoperative complications may also prevent fast tracking. The bleeding patient with copious output from chest tubes may

require a return to the operating room for achievement of surgical hemostasis. The hemodynamically unstable patient with a rising pressor requirement will require assessment for and treatment of hypovolemia or bleeding, tamponade, loss of myocardial contractility, or sepsis. Delayed emergence despite lower doses of narcotic utilization during the operation due to pharmacologic sensitivity may prevent the patient from achieving extubation criteria by 8 hours due to excessive sleepiness and apnea. Although a difficult intubation in and of itself should not be a deterrent to fast tracking as long as extubation criteria are achieved, a difficult airway resulting in trauma due to multiple intubation attempts may warrant a delay in removal of the endotracheal tube in order to institute measures to decrease airway edema (eg, elevation of the head of the bed and steroids), especially if the patient does not demonstrate an air leak with the endotracheal tube balloon deflated. In addition, the patient with the difficult airway with marginal achievement of extubation criteria may benefit from resources that may be more easily available during the daytime rather than the nighttime such as advanced airway equipment and the immediate availability of an anesthesiologist. Hypothermia (core temperature $< 36^\circ\text{C}$) promotes arrhythmias, impairs coagulation, and may cause shivering, which increases oxygen consumption and myocardial oxygen demand and should be rectified prior to extubation. Finally, intraoperative events such as a prolonged (> 2.5 hours) bypass run, bleeding requiring massive transfusion, or difficulty in repairing the aortic cannulation site may merit exemption from fast tracking. In the latter case, avoidance of hypertension both pharmacologically and by preventing rapid awakening with immediate sedation on arrival to the ICU may be requested to decrease the probability of dehiscence of the repair and resultant surgical bleeding.

In general, regardless of whether the patient qualifies for the fast-track strategy, sedatives and analgesics should be held after arrival in the ICU until the patient awakens. Documentation of emergence from the anesthetic with movement of all extremities is an important milestone in the postoperative course, as postoperative stroke may manifest as delayed emergence or hemiplegia. If the patient is to be fast tracked, subsequent administration of

sedatives and analgesics should be done judiciously to keep the patient comfortable while intubated but to avoid oversedation and respiratory depression that might delay extubation. In those patients who arrive to the ICU awake or awaken shortly thereafter, a number of agents are available for sedation and analgesia ([Table 54–1](#)).^{10,11} Dexmedetomidine, an α_2 agonist that decreases sympathetic outflow, produces sedation without respiratory depression and is useful in the patient who expected to be fast tracked. Its cost as well as the potential for inducing bradycardia and resultant hypotension are limiting factors. When dexmedetomidine is not available, propofol provides rapid onset and offset of sedation at low doses; at higher doses propofol will induce respiratory depression. Benzodiazepines such as midazolam are slower in offset and are less favored in the patient expected to be extubated. However, they may provide greater stability in the hemodynamically tenuous patient. The patient in pain may benefit from an array of available analgesics. Intravenous acetaminophen may provide pain relief without concern for inducing apnea. Fentanyl, a μ opioid agonist, provides rapid pain relief with limited duration. Longer acting analgesics such as hydromorphone and morphine should be given judiciously to prevent respiratory depression that may delay extubation. Morphine should not be dosed in patients with significant kidney dysfunction, as the active metabolite morphine-6-glucuronide has additive sedative effects. Certain patients may be candidates for IV ketorolac, a potent nonsteroidal anti-inflammatory drug (NSAID). However, this analgesic should be avoided in patients with renal insufficiency, a history of gastric ulcers, severe or aspirin-sensitive asthma, and in those in whom bleeding is a concern. Lidocaine patches may give relief to the patient who is experiencing great discomfort from chest tubes. The patient who is shivering may benefit from meperidine, although this agent should not be given to the patient on monoamine oxidase inhibitors (MAOIs) or selective serotonin-reuptake inhibitors (SSRIs). Together, these agents should keep the patient comfortable while intubated; ongoing weaning should occur concurrent to completion of an appropriate postoperative evaluation (electrocardiogram, chest X-ray, laboratory values, and continual evaluation of hemodynamics as well as chest tube and urine outputs).

EXTUBATION

In general, extubation of the postcardiac surgery patient can be considered once the patient is warm (temperature $> 36.0^\circ\text{C}$) and has demonstrated hemodynamic stability with regards to heart rate (HR), CI (ideally $> 2.2 \text{ L/min/m}^2$), and blood pressure. Inotropic and vasopressor requirements should be stable or decreasing and parameters associated with adequate perfusion such as the Svo_2 , lactate, and urine output should be acceptable. In addition, chest tube outputs should not be excessive (consider a threshold of $> 200 \text{ cc/h}$). As the postoperative evaluation is being completed, the patient should be actively weaned to a fraction of inspired oxygen (Fio_2) 40% and positive end-expiratory pressure (PEEP) 5 cm H_2O while maintaining a peripheral capillary oxygen saturation (Spo_2) greater than 92%. As the spontaneous respiratory drive returns, pressure support ventilation should be instituted and weaned to 5 cm H_2O . The final assessment of extubation should be performed on minimal ventilator settings with evaluation of the following parameters: oxygenation, ventilation and strength, and airway protection ([Table 54–2](#)).

Common issues such as atelectasis and pain control may provide barriers to timely extubation. Some patients become atelectatic during the bypass run and develop an alveolar to arterial (A-a) gradient that precludes full weaning of Fio_2 . As hemodynamics allow, recruitment maneuvers (ie, PEEP 20 cm H_2O for 20 s) can open up collapsed alveolar units and improve oxygenation. Pain control can pose a challenge, as well. Some patients find inadequate pain relief with opioids and as a result, may splint and breathe shallowly on the ventilator. Other patients demonstrate dose-limiting sleepiness and apnea only to wake up in persistent pain. To those who qualify, adjuncts such as intravenous acetaminophen or ketorolac can be beneficial.

HYPOTENSION AND LOW CARDIAC OUTPUT

The goal mean arterial pressure (MAP) is typically set as greater than 65 mm Hg. A higher goal may be needed with chronic hypertensives in whom the autoregulatory curve of the brain and kidney have shifted to accommodate long-standing elevated

TABLE 54–1 Sedatives and analgesics.

Sedatives and Analgesics	Class	Doses	Considerations
Dexmedetomidine (Precedex)	α_2 agonist	0.5 $\mu\text{g/kg}$ IV over 10 min 0.2-1.5 $\mu\text{g/kg/h}$	<ul style="list-style-type: none"> No respiratory depression Antishivering, antidelirium properties Does not accumulate with prolonged infusion Bradycardia and hypotension; may see transient initial hypertension from crossover α_1 agonism No active metabolites

Acetaminophen (Tylenol)	Centrally acting analgesic	1 g IV	<ul style="list-style-type: none"> No respiratory depression Antipyretic Do not exceed 4 g in 24 h Avoid in hepatic insufficiency
Ketorolac (Toradol)	NSAID	15-30 mg IV	<ul style="list-style-type: none"> Avoid in renal insufficiency, gastric ulceration, severe or aspirin-sensitive asthma, and bleeding Consider lower dose or avoiding in older patients due to decreased GFR
Meperidine (Demerol)	μ opioid agonist	25 mg IV	<ul style="list-style-type: none"> Antishivering Avoid with MAOIs or SSRIs Neuroexcitation w/renal insufficiency or high doses

GFR, glomerular filtration rate; MAOIs, monoamine oxidase inhibitors; NSAID, nonsteroidal anti-inflammatory drug; SSRIs, selective serotonin-reuptake inhibitors.

systemic pressures. In addition, patients with known vascular stenoses of the carotid or renal arteries, as well as those with unrepaired coronary artery disease may require a higher perfusion pressure to overcome these potentially flow-limiting lesions. A lower MAP may be required for a time

in patients with a friable aorta to decrease the risk of bleeding.

MAP is defined as $\text{MAP} = \text{CO} \times \text{SVR}$, where SVR denotes systemic vascular resistance. As CO itself is defined as HR times stroke volume (SV), the equation may be further defined as: $\text{MAP} = \text{HR} \times \text{SV} \times \text{SVR}$.

TABLE 54–2 Extubation criteria.

Patient Should Achieve	
Temperature	36.0°C
Hemodynamics	<ul style="list-style-type: none">• Heart rate: absence of excessive bradycardia or tachycardia• Cardiac output as follows:<ul style="list-style-type: none">• CI > 2.2• SvO₂ > 60%• Normal or downtrending lactate• Urine output > 0.5 cc/kg/h• Stable or decreasing inotropic and vasopressor requirements
Chest tube output	< 200 cc/h
Oxygenation	FiO ₂ 40%, PEEP 5 resulting in PaO ₂ > 60-80 mm Hg or SpO ₂ > 92%
Ventilation/strength	<p>Pressure support ventilation at 5 cm H₂O</p> <ul style="list-style-type: none">• Adequate tidal volume and respiratory rate; rapid shallow breathing index < 105• Absence of acute respiratory acidosis secondary to rapid and shallow breathing or bradypnea (should achieve pH > 7.35)• Presence of 5 s head lift or strong hand grip
Airway protection	Awake; presence of cough, gag, or swallow
Airway patency	If airway edema a concern, test for presence of air leak while endotracheal tube cuff deflated

CI, cardiac index; FiO₂, fraction of inspired oxygen; PaO₂, partial pressure arterial oxygen; PEEP, positive end-expiratory pressure; SpO₂, peripheral capillary oxygen saturation; SvO₂, mixed venous saturation.

Thus, hypotension may be conceptualized as being affected by 1 of these 3 major variables.

Heart Rate

HR may be a factor in hypotension. The process of cooling and arresting of the myocardium during cardiac surgery renders the muscle less compliant and induces diastolic dysfunction.¹² This resultant increase in the “stiffness” of the ventricles can limit the stroke volume and render the CO more dependent on HR. Thus, a HR that is too slow, even if not strictly bradycardic, may limit CO and decrease MAP. The responsivity of the blood pressure to pacing with epicardial wires to a HR of 90 to 100 beats/minute may be tested. If both atrial and ventricular wires are present, pacing can be accomplished with maintenance of atrial kick. However, if only ventricular wires are available, the hemodynamic benefit of increasing HR with ventricular pacing may be diminished by loss of contribution to stroke volume from loss of atrial kick. In fact, an increased pressor requirement may be observed in patients who lose atrioventricular (AV) synchrony and the atrial

contribution to SV due to the development of an arrhythmia such as atrial fibrillation.

Stroke Volume

SV is affected by preload, contractility, and afterload. Hypotension, especially in the patient with a labile blood pressure, may be due to decreased preload and low SV from hypovolemia. Low preload may be due to an obvious process such as chest tube drainage or to a more occult occurrence such as retroperitoneal bleeding in the patient who has undergone femoral arterial cannulation. The volume responsiveness of the patient can be tested empirically by 250 to 500 cc fluid boluses with subsequent assessment of the effect upon blood pressure. Both normal saline and lactated ringers may be used for resuscitation although 5% albumin is frequently utilized with the intention of administering an agent with a greater intravascular half-life. Transfusion with packed red blood cells may be indicated in the setting of significant anemia, especially with a concurrent vasopressor requirement. The data on hydroxyethyl starch (HES) agents discourage its use in the cardiac

surgical ICU. One study randomized 45 patients to receive either 15 mL/kg HES solution or 4% albumin after admission to the cardiac ICU and found that the HES group demonstrated thromboelastometry tracings indicative of impaired fibrin formation and clot strength.¹³ Although the 2 groups demonstrated similar chest tube outputs, a subsequent meta-analysis of 18 trials comparing HES solutions with albumin for fluid management in CPB surgery found that HES solutions increased blood loss, reoperation for bleeding, and the rate of blood transfusion.¹⁴ Given these results, it seems prudent to avoid the use of HES solutions for resuscitation in the postcardiac surgery patient. Hypotension from decreased preload and low SV may be secondary to mechanical obstructive process rather than hypovolemia. Conditions such as tamponade and tension pneumothorax prevent adequate venous return, depress SV and CO, and can result in hypotension and shock with rising pressor requirement and lactate and oliguria. Tamponade is further discussed under section “Bleeding.”

Hypotension may also be secondary to low SV from decreased contractility. A temporary decrease in myocardial function is to be expected in the postcardiac surgery patient.^{4,6} One study examining 24 patients undergoing elective coronary artery bypass surgery with serial hemodynamic measurements and radionuclide evaluation of ventricular function found that 96% experienced left- and right-sided myocardial depression postprocedure. The left-sided EF dropped from 58% preoperative to 37% with the nadir occurring 4.4 hours after coronary bypass. Recovery back to 55% occurred approximately 7.1 hours after coronary bypass.⁶ An earlier study of 22 patients undergoing coronary artery bypass surgery found that those with an EF of more than 55% recovered ventricular function within 4 hours of bypass but that those with an EF more than 45% demonstrated a more profound decrease in function and a delayed recovery to baseline even after 24 hours.⁵ Thus, the immediate postoperative cardiac patient may demonstrate a temporary inotropic or vasopressor requirement until myocardial contractility has fully recovered. However, a high index of suspicion for differentiating between this known and expected decrease in function and concurrent detrimental processes should be maintained.

Other independent causes of decreased myocardial contractility include new onset myocardial infarction from unrepaired disease or from CABG thrombosis or vasospasm. Diagnosis of a new ischemic insult may be accomplished with an electrocardiogram or with echocardiography demonstrating a new wall motion abnormality. In addition to hemodynamic instability, the onset of new arrhythmias such as ventricular tachycardia (VT) may be a manifestation of myocardial supply-demand mismatch. Troponins are of limited utility in detecting ischemia as they are typically elevated postcardiac surgery; however, some advocate trending the values. Management may include the administration of nitroglycerin to vasodilate the coronary arteries and to increase coronary perfusion pressure by decreasing preload and hence left ventricular end-diastolic pressure, cardiac catheterization to remove thrombus, or reexploration in the operating room to visually inspect the grafts.

Systemic Vascular Resistance

Hypotension may also be caused by insufficient systemic vascular resistance. Some patients arrive to the ICU hypothermic despite adequate rewarming on CPB due to a phenomenon called afterdrop—a redistribution hypothermia secondary to a cool periphery. These patients require active rewarming, which results in vasodilation of the peripheral vasculature and can uncover or worsen a vasopressor requirement. CPB causes a systemic inflammatory response that can lead to decreased SVR and a form of postbypass hypotension known as vasodilatory shock,^{15,16} generally described as a MAP less than 70 mm Hg in the setting of an adequate CI of more than 2.5 L/min/m². Increased levels of vasodilators such as nitric oxide and bradykinin have been implicated in the pathogenesis of this phenomenon. The increase in bradykinin may be related to lack of deactivation by angiotensin converting enzyme (ACE) due to decreased blood flow to the lungs during CPB.^{17,18} Vasodilatory shock may also be caused by a relative vasopressin deficiency.^{19,20} One prospective study of 145 patients measured vasopressin levels 5 minutes after weaning from CPB. Those with vasodilatory shock demonstrated lower levels of vasopressin than those with postbypass hypotension due to decreased CI, and infusion with exogenous vasopressin improved MAP.¹⁹ This study found the

incidence of vasodilatory shock to be 8%, although the incidence was higher (27%) in those with an EF of less than 35%; in addition, preoperative ACE-inhibitors, commonly part of a heart failure regimen, were found to be a risk factor for the development of vasodilatory shock. A retrospective study of 2823 patients found a 20% rate of vasoplegia; clinical risk factors included observation of a clinically significant decline in MAP at the onset of CPB, length of bypass, and preoperative use of β blockers and ACE-inhibitors among others.²¹

Another way to conceptualize the hemodynamic changes of the postoperative period, especially in patients with valvular lesions, is to consider whether the myocardium is pressure-overloaded or volume-overloaded. Lesions such as aortic stenosis give rise to pressure-overloaded ventricles. In this situation, chronic obstruction to left ventricular ejection results in concentric hypertrophy as a compensatory response to increased wall stress. The increase in ventricular wall thickness results in a ventricle with decreased diastolic compliance or greater “stiffness.” As a result, the resultant limitation in SV can result in a decrease in CO with lower HRs. Conversely, excessively high HRs may limit diastolic filling time, SV, and may also compromise CO. The stiffness of the ventricle impedes filling and makes the myocardium more dependent on atrial kick for stroke volume. Hence, the development of a nonsinus rhythm such as atrial fibrillation may result in a decrease in SV that decreases CO and MAP. The pressure-overloaded ventricle is more prone to ischemia than the normal ventricle. The increase in muscle mass increases the basal metabolic rate of the entire ventricle. In addition, the increase in stiffness of the pressure-overloaded myocardium results in an increase in the left ventricular end-diastolic pressure (LVEDP). This results in a decrease in the gradient for coronary perfusion pressure ($\text{CPP} = \text{aortic diastolic pressure [AoDP]} - \text{LVEDP}/\text{coronary vascular resistance}$) rendering the myocardium more vulnerable to ischemia with decreases in blood pressure. Tachycardia is particularly detrimental not only because it limits SV by decreasing diastolic filling time but also because it reduces the duration of diastolic coronary perfusion and increases myocardial oxygen demand. The hemodynamic considerations in the pressure-overloaded ventricle are summarized in [Table 54–3](#).

TABLE 54–3 Hemodynamic goals in the pressure-overloaded ventricle.

Rhythm	<ul style="list-style-type: none"> • Maintain sinus to preserve atrial kick
Heart rate	<ul style="list-style-type: none"> • Avoid bradycardia to avoid decreased CO ($\text{CO} = \text{HR} \times \text{SV}$) • Avoid tachycardia to avoid ischemia (increased myocardial oxygen demand, decreased duration of diastolic coronary perfusion)
Blood pressure	<ul style="list-style-type: none"> • Avoid hypotension ($\text{CPP} = \text{AoDP} - \text{LVEDP}/\text{coronary vascular resistance}$)

AoDP, aortic diastolic pressure; CO, cardiac output; CPP, coronary perfusion pressure; HR, heart rate; LVEDP, left ventricular end-diastolic pressure; SV, stroke volume.

Although hypotension is to be carefully avoided in the pressure-overloaded myocardium, patients with preserved LV function often present to the ICU hypertensive, as the left ventricle has not yet had time to adapt to the removal of the stenotic aortic lesion. In this case, institution of a vasodilator such as nifedipine can control blood pressure in the acute setting. The patient with decompensated aortic stenosis may have decreased contractility and may have presented with decompensated heart failure.

Lesions such as aortic and mitral regurgitation result in volume-overloaded ventricles. Chronic volume overload results in eccentric hypertrophy where overall muscle mass is increased but chamber enlargement is greater than the increase in ventricular wall thickness. This gradual increase in LV size and compliance usually causes little change in the LVEDP. Chronic volume overload may result in a dilated cardiomyopathy with decreased LV systolic function and may require the use of inotropes to separate from bypass and their continued use in the ICU until myocardial stunning resolves. Decreased CO after correction of mitral regurgitation may also be secondary to decreased volume loading of the left ventricle from the resolution of regurgitation. Reports of the ejection prior to and after resolution of mitral regurgitation may be somewhat misleading. For example, a preoperative EF of 55% with a postoperative EF of 30% may not reflect any actual change in the contractility. The estimated EF prior to surgery reflects a SV that includes both forward flow and retrograde flow into the left atrium, and the

effective EF taking only forward flow into account may have been 30% from the start. Because left ventricular afterload increases acutely after correction of mitral regurgitation, the left ventricle may benefit from pharmacologic afterload reduction. Chronic volume overload differs greatly from the volume overload resulting from acute aortic or mitral insufficiency where LVEDP increases dramatically and can result in sudden pulmonary edema and decreased CO prior to surgical correction.

Mitral regurgitation and stenosis may result in left atrial hypertension and dilation that can predispose to atrial fibrillation. In addition, pulmonary hypertension secondary to chronic venous congestion may be present with concomitant right ventricular dysfunction due to long-standing increases in RV afterload.

The hemodynamic problem of low CO ($CO = HR \times SV$) may be broken down by examining the HR as well as the factors affecting SV (preload, afterload, and contractility). In the situation where low CO is accompanied by bradycardia, the CO may be augmented by increasing the HR. This can be accomplished either by electrical pacing with an external epicardial wire, reprogramming the rate of an internal pacemaker, or increasing the HR chemically with an agent with chronotropic properties. If a low CO is accompanied by a low afterload state and hypotension, the blood pressure should first be supported with vasopressors until more definitive therapies can be instituted. If the patient is volume-responsive, the SV and CO may be augmented with

additional preload. If the patient does not demonstrate improvement with volume, then the depressed CO may be secondary to decreased contractility. Epinephrine, an inoconstrictor, provides inotropic support along with vasoconstriction that should increase MAP. The inodilators dobutamine and milrinone may also be used but because they vasodilate the peripheral vasculature, vasopressor initiation or increase may be necessary to counteract a further drop in blood pressure. SV and CO may also be limited due to excessive afterload. The patient with high MAP and depressed CO may benefit from afterload reduction with a systemic vasodilator.

A high CO in the presence of a low HR does not need any intervention. If accompanied by low MAP, the low SVR state may be counteracted with vasoconstrictors such as norepinephrine and vasopressin. A high CO state with high MAP should be treated, as a high MAP may increase the risk of bleeding and will increase the oxygen demand of the myocardium; a decrease in blood pressure should, however, always be made in the context of baseline blood pressure and with an evaluation of the risk of hypoperfusion to pressure-dependent organs. The various possible therapies for disordered blood pressure and CO are detailed in [Table 54–4](#).²²

The details of various vasopressors and inotropes are included in [Tables 54–5](#) and [54–6](#).²³ The vasopressors are utilized for their ability to increase MAP by increasing SVR ($MAP = CO \times SVR$). Norepinephrine, an α_1 agonist that provides β_1 inotropy is typically chosen in favor of phenylephrine, a pure

α_1 agonist that only increases afterload and does not provide inotropic assistance. Vasopressin may be useful in the vasoplegic patient with low SVR post-bypass as a supplement to norepinephrine. In addition, as it has minimal pulmonary vasoconstrictive effects at low doses (< 4 U/h), vasopressin may be useful in patients with significant pulmonary hypertension or right ventricular dysfunction. Dopamine at low doses produces renal and splanchnic vasodilation, an effect that has not been shown to impact outcomes. Dopamine is the precursor to norepinephrine; at higher doses, the effect of dopamine becomes more similar to that of norepinephrine with the addition of inotropic and then vasoconstrictive properties. Epinephrine, dobutamine, and milrinone provide inotropy with varying effects upon the blood pressure. Epinephrine, due to greater α_1 constriction than β_2 vasodilation, has the overall effect of increasing blood pressure. Dobutamine and milrinone, both inodilators, increase inotropy but at the cost of increased vasodilation and the potential need for initiation or escalation of vasopressors. Compared with dobutamine, milrinone produces a greater decrease in SVR. Dobutamine and milrinone both increase levels of cyclic adenosine monophosphate (cAMP) (and subsequently calcium and contractility) in the cardiac myocyte but by different mechanisms: through the β_1 receptor, dobutamine activates the G_s /adenylate cyclase pathway while milrinone inhibits phosphodiesterase III, an enzyme that degrades cAMP. These 2 agents, hence, are synergistic and lower levels of each medication may be coadministered with fewer side effects. Although all β_1 agonists demonstrate some degree of chronotropy, isoproterenol demonstrates a particularly strong ability to increase HR and is colloquially known as the chemical pacemaker.

In addition to chronotropy and inotropy, the different β_1 agonists also demonstrate varying degrees of bathmotropy (arrhythmogenicity) and dromotropy (increased conduction through the AV pathway). High doses of norepinephrine, dopamine, epinephrine, and dobutamine may induce tachycardia or arrhythmias such as atrial fibrillation with rapid ventricular response. Milrinone also has a proarrhythmic tendency but is less than that of dobutamine.

The half-lives of these inotropes and vasopressors, with the exception of vasopressin and milrinone, are

on the order of minutes, thus enhancing their titratability. Vasopressin has a half-life of approximately 10 to 20 minutes. Milrinone's terminal elimination half-life is approximately 2 hours, which renders it less titratable than other more rapid-offset inotropes such as dobutamine. It accumulates with prolonged infusions as well as in patients with renal insufficiency.

Epinephrine has been associated with the development of hyperglycemia and a type B lactic acidosis, that is, lactate generation in the absence of clinical evidence of tissue hypoperfusion (in contrast to type A which is associated with poor oxygen delivery). One study randomized 36 patients to receive norepinephrine or epinephrine for hypotension after CPB. They found that 6 of 19 patients who received epinephrine developed increased lactate levels peaking between 6 and 10 hours after CPB (lactate to ~ 3.8 mmol/L, pH 7.34) while 0 of 17 patients who received norepinephrine demonstrated the same phenomenon. The lactate normalized by 22 to 30 hours after bypass. There was no difference in the oxygen-delivery index calculated between the 2 groups. The authors postulated that because epinephrine inhibits the pyruvate dehydrogenase complex, the increased levels of pyruvate get shunted to generate more lactate in order to preserve the normal balance of lactate:pyruvate needed to maintain the oxidized form of nicotinamide adenine dinucleotide (NAD).²⁴ Another study conducted in a medical ICU studying patients with dopamine-resistant cardiogenic shock randomized patients to receive norepinephrine-dobutamine or epinephrine. This study found that patients in the epinephrine group demonstrated an increase in lactate that peaked at 4.9 mmol/L at 6 hours with a pH of 7.26; this finding was notably absent in the dobutamine-norepinephrine group.²⁵ Thus, lactic acidosis in the context of epinephrine therapy may not necessarily indicate hypoperfusion as it may reflect generation of endogenous lactate by another unrelated mechanism, especially if oxygen delivery is calculated to be adequate; however, use of epinephrine may obscure the utility of lactate as a marker of hypoperfusion.

The use of a vasodilator may be necessary with excessive hypertension that cannot be resolved with the usual doses of sedative and analgesics (Table 54-7). Nicardipine is a dihydropyridine calcium channel blocker whose main effect is

TABLE 54–7 Vasodilators.

	Classification	Mechanism	Dose	Considerations
Nicardipine	Arterial dilator	Calcium channel blocker	5-15 mg/h	
Nitroglycerin	Venodilator	Nitric oxide	5-400 µg/min	
Nitroprusside	Balance arterial and venodilator	Nitric oxide	0.25-4 µg/kg/min (max 10 µg/kg/min)	Cyanide toxicity, especially with doses > 8 µg/kg/min

vasodilation of the systemic, coronary, and cerebral circulations with essentially no AV nodal blocking activity or negative inotropy. Both nitroglycerin and nitroprusside release nitric oxide, a potent vasodilator that activates guanylyl cyclase, increase cyclic guanosine monophosphate (cGMP), and results in decreased intracellular calcium and vascular smooth muscle relaxation. Nitroglycerin predominantly causes venodilation, which decreases preload and the volume work of the heart. It is particularly useful when myocardial ischemia is suspected as CPP (AoDP – LVEDP/coronary vascular resistance) is improved by 2 mechanisms: by decreasing preload which decreases LVEDP and by decreasing coronary vascular resistance by promoting coronary vasodilation. Nitroprusside causes both venodilation and arterial dilation. High doses may result in cyanide toxicity.

These 3 vasodilators provide rapid onset of action within minutes. Nicardipine has an elimination half-life of approximately 45 minutes while the elimination half life of both nitroglycerin and nitroprusside is approximately 5 minutes. Vasodilators may result in a reflex tachycardia. Tachyphylaxis can be seen, as well as rebound hypertension on sudden discontinuation of the drip. All vasodilators can reverse hypoxic vasoconstriction and worsen hypoxia by increasing shunt in atelectatic areas of the lung. In addition, those with intracranial hypertension may experience an increase in intracranial pressure due to an increase in cerebral blood flow secondary to cerebral vasodilation.

POSTOPERATIVE BLEEDING

Postoperative bleeding is tracked by output from pleural and mediastinal chest tubes. A bleeding rate of 100-400 mL/h may be considered “medical” bleeding that may be successfully treated by correcting postoperative coagulopathy. Cumulative

bleeding of more than 200 mL for 2 hours usually mandates intervention for resolution of “medical bleeding.” One study of 31 patients found that exposure of blood to the CPB circuit as well as hypothermia-induced activation of platelets resulting in a transient impairment of function and an increase in bleeding time that increased with the duration of bypass. This phenomenon resolved generally within 2 to 4 hours after CPB. However, 10 patients with platelet counts greater than 100,000/µL demonstrated substantial post-CPB bleeding and were found to have persistent platelet dysfunction even to 8 hours postbypass. Platelet transfusion resolved the bleeding in 6 of 10 patients.²⁶ The patient who has been on aspirin or loaded with clopidogrel due to a recent coronary catheterization (within 5 days) would be expected to have an even more profound platelet plug defect post-CPB due to irreversible inactivation of platelet activation. Significant bleeding in these patients should improve with platelet transfusion. Packed red blood cells should be administered as needed for significant anemia. Fresh frozen plasma may be administered empirically if bleeding is unrelenting. Cryoprecipitate for hypofibrinogenemia (< 100 mg/dL) may be warranted. Desmopressin (DDAVP) may aid with bleeding in the context of uremia or in the patient suspected of having a von Willebrand factor deficiency (0.3 µg/kg IV). Recombinant factor VIIa (rFVIIa) may be used as a last resort for life-threatening and intractable bleeding. It activates factor X directly and promotes a thrombin burst that aids in the formation of clot. A phase II dose escalation study was performed in 2009 as an international randomized, double-blind, placebo-controlled study of 172 patients testing placebo against 40 and 80 µg/kg of rFVIIa. The rFVIIa groups experienced a lower rate of reoperation for bleeding (40 µg/kg: 14%, 80 µg/kg: 12% vs

placebo: 25%) and a decreased rate of transfusion (40 µg/kg: 640 mL, 80 µg/kg: 500 mL vs placebo: 825 mL). The rate of critical serious adverse events was not statistically significant between the groups, but study was underpowered to assess this outcome; the authors emphasized the trend toward increased serious adverse events in the rFVIIa group and the need for further investigation.²⁷ Viscoelastic whole blood tests such as thromboelastography (TEG) may pinpoint the hemostatic defect (ie, coagulation factor deficiency, quantitative or qualitative platelet disorders, excessive fibrinolysis) and provide the ability to provide more targeted transfusion therapy.

Bleeding of more than 200 mL for 4 hours or more than 4 to 500 mL in 1 hour that does not respond to blood-product administration is typically designated “surgical bleeding” and may warrant a return to the operating room. Sources of surgical bleeding may include cannulation sites, graft suture lines, vein graft side branches, and small chest wall arterial bleeders.

Copious bleeding increases the risk of tamponade, especially if sudden cessation of chest tube output occurs due to a clot. Tamponade can also occur with removal of pacing wires several days after the procedure or weeks later with the start of anticoagulation for mechanical valves or atrial fibrillation. Cardiac tamponade reduces stroke volume due to restricted diastolic filling and decreased preload ultimately resulting in equalization of filling pressures between the right heart and left heart (including the central venous pressure [CVP], pulmonary artery diastolic pressure, and pulmonary artery wedge pressure). Tamponade should be suspected in the setting of a rising CVP, worsening pressor requirement, oliguria, and acidosis. The likelihood of other similarly presenting clinical entities such as right heart failure, pulmonary embolism, tension pneumothorax, and left heart failure should be assessed. Transthoracic or transesophageal echo may aid greatly in establishing the diagnosis. However, difficulties may be encountered with clotted blood, which is echo-dense and appears similar to myocardium or with effusions localized to a particular area not easily accessible by surface ultrasonography.²⁸ Ultimately, the patient with suspected tamponade will require a return to the operating room for exploration. Until that occurs, the compensatory tachycardia (increasing the CO due to limited SV)

should not be treated and a high afterload should be maintained. To that end, fluid and inoconstrictors such as epinephrine and norepinephrine may be able to temporize the patient’s hemodynamics until the mechanical obstruction can be relieved.

DYSRHYTHMIAS

Atrial fibrillation after cardiac surgery is a common phenomenon, occurring in 10% to 65% of patients.²⁹ It occurs more frequently in older patients and those undergoing valvular surgery. Those with mitral pathology tend to be at risk for atrial fibrillation due to atrial distension. Agents such as β_1 agonists (dopamine, norepinephrine, epinephrine, dobutamine) as well as milrinone increase the arrhythmogenic potential of the myocardium and may precipitate the onset of atrial fibrillation. The peak incidence of atrial fibrillation is in the second and third postoperative days. Its occurrence increases morbidity, as the rate of stroke is higher, as well as 30-day mortality. In addition, the occurrence of atrial fibrillation increases the length of stay both in the ICU and the hospital.²⁹ In hemodynamically stable patient who has been weaned-off of inotropes and vasopressors, β -blockade with intravenous or oral (PO) metoprolol is frequently initiated to decrease adrenergic tone that may precipitate atrial fibrillation.

When atrial fibrillation occurs, the stability of the patient should immediately be assessed. If the patient is unstable and is hypotensive or symptomatic (mental status changes, chest pain, or shortness of breath), the patient should be emergently cardioverted. If the patient is stable, the decision with how to proceed often differs based on institution and surgeon. The Atrial Fibrillation Follow-up Investigation of Rhythm Management (AFFIRM) trial³⁰ showed that there is no mortality benefit to pursuing rhythm control (ie, attempting to convert the patient back to sinus) over HR control. In addition, the natural history of postoperative atrial fibrillation appears to be that of spontaneously converting back to sinus rhythm within 6 weeks. Many take the approach of pursuing rate control and attempting only pharmacologic cardioversion. However, some choose to treat atrial fibrillation aggressively with electrical cardioversion to avoid the need for anticoagulation and to potentially to decrease the risk of stroke, although the risk

of stroke does persist for a time after sinus rhythm is achieved (whether via electrical, pharmacologic, or spontaneous cardioversion) due to atrial stunning; more than 80% of thromboembolic events occur during the first 3 days after cardioversion.³¹

Once electrolyte repletion of inadequate potassium and magnesium levels are addressed, first-line medical therapy with hemodynamically stable atrial fibrillation should be β -blockade with an agent such as metoprolol in an attempt to achieve a HR of less than 120. As a class II antiarrhythmic, β -blockade may achieve conversion back to sinus rhythm. Diltiazem, a benzothiazine calcium channel blocker with AV nodal blocking properties, is frequently used in the general hospital setting to control atrial fibrillation with rapid ventricular response; however, its negative inotropic property may induce unwanted hypotension, especially in the immediate postoperative period where postcardiac patients are still recovering from postbypass myocardial stunning, and is not utilized with great frequency in the cardiac ICU. Amiodarone may achieve rate control in the patient with a tenuous blood pressure or who is on vasopressors or inotropes or has a low EF and may achieve chemical cardioversion, as well. It has a long terminal elimination half-life of about 58 days. The patient with a difficult to control HR or with recurrent bouts of atrial fibrillation may benefit from multiple doses of β -blocker or an additional load of amiodarone. Digoxin, an inhibitor of the Na-K ATPase pump, decreases conduction velocity through the AV node and may aid in attaining rate control. In addition, digoxin increases inotropy and may be useful in the patient with a low EF or still on vasopressors. However, its onset of action is slow and requires loading over 1 day. In addition, lower doses must be used in those with renal insufficiency.

The side effects of these aforementioned therapies for atrial fibrillation with rapid ventricular response are hypotension and bradycardia. Thus, those being treated for atrial fibrillation should not have their epicardial pacing wires removed until the therapeutic response is established. Should bradycardia occur, pacing may be required and the therapeutic approach should be reevaluated. Postoperative new onset atrial fibrillation with a slow ventricular response often precludes use of rate-lowering agents. Amiodarone, while ubiquitously used, may with long-term use induce

hepatotoxicity, pulmonary disease, and thyroid dysfunction (hyperthyroidism and hypothyroidism). Thus avoidance in patients with liver dysfunction or pulmonary insufficiency may be merited.

Anticoagulation should be considered in those with more than 48 hours of atrial fibrillation to decrease the risk of the development of cardiac thrombus that may embolize to cause stroke. Characteristics that increase the risk of stroke include hypertension, an EF less than 35%, diabetes mellitus (DM), and age 75 years and older. The benefit of anticoagulation must be weighed against the risk of inducing bleeding in the postoperative patient. If the risk is deemed too high, anticoagulation should be held until the risk of bleeding diminishes.

VT is also seen commonly in the postcardiac surgical population. VT may be an expression of myocardial ischemia and its onset should spur an investigation into the presence of a potential myocardial supply-demand imbalance. As with atrial fibrillation, cardiotonic medications such as the β_1 agonists and milrinone may precipitate VT. Prior myocardial infarction and the presence of scar frequently act as anatomic foci of arrhythmogenicity. Finally, VT may manifest in the setting of an unfavorable milieu such as hypoxia, electrolyte imbalances, and acidosis. As with atrial fibrillation, an unstable VT should be electrically cardioverted immediately.

The actual diagnosis of VT may be difficult in the patient with a preexisting bundle branch block. In this situation, a supra-VT (SVT) with aberrancy may be indistinguishable from VT. Provided that the rhythm is regular, adenosine may be utilized to assess whether the tachycardia breaks, in which case the arrhythmia may be diagnosed as SVT.³² The diagnostic distinction is important as it may have consequences for whether the patient may need invasive therapies such as ablation and an implantable cardioverter defibrillator (ICD). Adenosine should not be given to patients with an irregular wide-complex tachycardia because such arrhythmias may become unstable after administration.

The patient with nonsustained VT (NSVT) or stable VT should be evaluated for the presence of correctable conditions such as hypokalemia and hypomagnesemia, hypoxia, and acidosis. Amiodarone may be administered in an attempt to suppress the arrhythmia. Lidocaine may be used as an

antiarrhythmic adjunct. If ischemia is a component of the onset of VT, a trial of a short acting β_1 blocker such as esmolol may be worthwhile to decrease myocardial oxygen demand. Esmolol is degraded by red cell esterases and has a short elimination half-life of 6 minutes. Overdrive pacing may be used in an attempt to suppress reentry circuits at work in the pathogenesis of VT. The patient in VT may ultimately need electrical cardioversion to get back into their native rhythm. Finally, consultation from electrophysiological experts should be obtained as the patient may be a candidate for ablation or may need placement of an ICD. The medications used in the management of dysrhythmias are detailed in [Table 54–8](#).³³

RENAL FUNCTION

Renal dysfunction is not uncommon after cardiac surgery. Mangano et al conducted a prospective observational study of 2222 patients undergoing CABG and found that the rate of renal dysfunction,

defined as a postoperative creatinine of 2.0 mg/dL or more or an increase in creatinine of 0.7 mg/dL or more was about 7.7%. The incidence of oliguric renal failure requiring dialysis was 1.4%. Preoperative risk factor for renal dysfunction included age 70 years or more, New York Heart Association (NYHA) class 3 or 4 heart failure, previous CABG, chronic kidney disease with creatinine 1.4 to 2.0, type I diabetes, and glucose more than 300. Intraoperative and postoperative factors include CPB lasting 3 hours or more, and a low output state with a CI of less than 1.5 or requiring insertion of an intra-aortic balloon pump.³⁴ Other additional risk factors include preoperative cardiac angiography or angiotensin-converting enzyme inhibitors, angiotensin receptor blockade or diuretic therapy, and perioperative red blood cell transfusion. Additional intraoperative factors include the number of red blood cell units administered, low MAP during CPB, perioperative hemodilution, and postoperative use of norepinephrine.³⁵

TABLE 54–8 Agents for rate and rhythm control.

Agents	Mechanism	Dose	Considerations
Diltiazem	Calcium channel blocker	Bolus: 0.25 mg/kg IV over 2 min Continuous: 5-15 mg/h IV PO: 120-360 mg/d in divided doses	<ul style="list-style-type: none"> Afib with RVR Negative inotropic effect may be detrimental in the postcardiac surgical patient and patient with low EF
Metoprolol	β_1 -selective blocker	Bolus: 2.5-5 mg IV \times 3 Standing: 5 mg IV q4h PO: 12.5-100 mg q12h	<ul style="list-style-type: none"> Afib with RVR
Amiodarone	Na^+ , K^+ , Ca^{2+} and β -blockade	Bolus: 150 mg IV over 10 min \times 2 Continuous: 1 mg/min \times 6 h then 0.5 mg/min \times 18 h PO: 400 mg q12h \times 1 wk, then 600 mg daily \times 1 wk, then 400 mg daily \times 4-6 wk	<ul style="list-style-type: none"> Useful in patients on vasopressors, inotropes, or with low EF Avoid in patients with liver, pulmonary, or thyroid dysfunction
Digoxin	Inhibits Na-K ATPase	Load: 0.25 mg IV then 0.125 \times 2 q8h Maintenance: 0.125-0.25 daily or every other day PO: 0.5 mg daily \times 2 d, then 0.125-0.375 PO daily or every other day	<ul style="list-style-type: none"> Dose cautiously in patients with renal insufficiency Avoid hypokalemia Digoxin-specific antibody fragments available for digoxin toxicity
Lidocaine	Na channel blocker	Load: 1 mg/kg Maintenance: 1 mg/h	
Esmolol	β_1 -selective blockade	500 μ g/kg IV over 1 min 60-200 μ g/kg/min	<ul style="list-style-type: none"> Short half-life

Afib, atrial fibrillation; EF, ejection fraction; IV, intravenous; PO, oral; RVR, rapid ventricular response.

With regards to outcomes, Mangano et al found that compared with those without renal dysfunction, those with renal dysfunction and failure experienced increased length of stay in the critical care unit (3.1 vs 6.5 and 15.4 days) and the hospital (7.4 vs 11.4 and 14.9 days). In addition, those with renal dysfunction experienced greater mortality (0.9% vs 19% and 63%).

Preventative strategies to decrease the risk of renal dysfunction after cardiac surgery are limited and include minimizing exposure to radiocontrast dyes, delaying the surgery to allow for renal recovery if preoperative renal injury was sustained, and avoidance of intraoperative anemia. Other protective strategies such as urinary alkalinization, glucose control, early continuous renal replacement therapy, statins, and fenoldopam still as of yet need more evidence to elucidate their role in renal protection.³⁵

Oliguria, defined as urine output < 0.5 mL/kg/h, as well as increases in creatinine reflective of a decrease glomerular filtration rate occur frequently in the cardiac ICU. Table 54–9 outlines the risk, injury, failure, loss, and end-stage renal disease (RIFLE) criteria and Table 54–10 presents the Acute Kidney Injury Network (AKIN) modifications. The AKIN classification, in particular, highlights how even small increases in creatinine of 0.3 mg/dL indicate some degree of renal injury.

TABLE 54–9 RIFLE classification of acute kidney injury (within 7 days).

Class	GFR	UOP
Risk	↑Cr × 1.5 or ↓GFR by 25%	<0.5 mL/kg/h for > 6 h
Injury	↑Cr × 2 or ↓GFR by 50%	<0.5 mL/kg/h for > 12 h
Failure	↑Cr × 3 or ↓GFR by 75% or Cr > 4 mg/dL or acute ↑> 0.5 mg/dL	<0.3 mL/kg/h for > 24 h or anuria > 12 h
Loss	Persistent acute renal failure with complete loss of renal function > 4 wk	
ESRD	Complete loss of renal function without recovery	

Cr, creatinine; ESRD, end-stage renal disease; GFR, glomerular filtration rate; RIFLE, risk, injury, failure, loss, and end-stage renal disease; UOP, urine output.

TABLE 54–10 AKIN classification of acute kidney injury (within 48 hours).

Class	GFR	UOP
Stage 1	↑Cr × 1.5 or ↑Cr by 0.3 mg/dL	< 0.5 mL/kg/h for > 6 h
Stage 2	↑Cr × 2	< 0.5 mL/kg/h for > 12 h
Stage 3	↑Cr × 3 or Cr > 4 mg/dL or acute ↑> 0.5 mg/dL	< 0.3 mL/kg/h for > 24 h or anuria > 12 h
Loss	Persistent acute renal failure with complete loss of renal function > 4 wk	
ESRD	Complete loss of renal function without recovery	

AKIN, Acute Kidney Injury Network; Cr, creatinine; ESRD, end-stage renal disease.

The approach to the patient with oliguria and/or rising creatinine may be categorized as postrenal, prerenal, and renal processes.

Postrenal

In the immediate postoperative period, postrenal obstruction may occur if a clogged Foley is preventing the egress of urine. Ultrasonic visualization of a full bladder in the setting of lack of urine output confirms postrenal obstruction. Flushing or changing of the Foley should rectify the problem. Less likely forms of postrenal obstruction such as nephrolithiasis may be formally evaluated by looking for hydronephrosis on a renal ultrasound.

Prerenal

Prerenal causes of oliguria and rising creatinine are secondary to insufficient perfusion pressure or hypovolemia or both. An insufficient MAP may cause oliguria, especially in the patient with chronic uncontrolled hypertension or a renal vascular stenosis and may be caused purely by a vasodilated state with decreased ability of the smooth muscle to constrict or be due to decreased CO due to hypovolemia and insufficient SV. MAP may be supported pharmacologically with vasopressors with concurrent volume loading to address any contribution of hypovolemia. The patient with an adequate MAP may still

be hypovolemia. In general, aside from the patient with tenuous pulmonary or right heart function, small boluses of 250 to 500 mL generally incur little harm and can interrogate the volume responsiveness of the patient. Aside from history and calculation of fluid balance, the prerenal state of the patient may be interrogated with the fractional excretion of sodium (FENa) or fractional excretion of urea (FEUrea) if the patient has recently received furosemide.

Renal

Prerenal acute kidney injury, when prolonged, can result in acute tubular necrosis (ATN). Some patients, such as those who underwent cardiac arrest or precipitous operating room courses may have sustained prolonged periods of hypotension and hypovolemia, and will have progressed into ATN. At this point, the patient should be assessed as to whether they are nonoliguric or oliguric. If the patient demonstrates a rising creatinine indicative of ongoing loss of kidney function but are able to generate urine, then not much intervention may be needed except monitoring of volume and electrolyte status and for plateauing of the creatinine level. If the patient has oliguric kidney injury with a poor urine output, they should be assessed for diuretic responsivity. A trial of a loop diuretic such as furosemide (40-100 mg IV) or bumetanide (1-2 mg IV) with or without augmentation with a thiazide diuretic such as metolazone (5-10 mg PO) may be made. If the patient is diuretic responsive, then medical management may be sufficient to manage the volume and electrolyte status of the patient. If the loss of kidney function can be managed pharmacologically, the patient might be able to be maintained only diuretics for management of volume and electrolytes. If the patient is not diuretic-responsive, then renal replacement might be indicated, especially if the patient demonstrates hyperkalemia with peaked T waves on the electrocardiogram, acidosis with pH less than 7.2, blood urea nitrogen (BUN) more than 80 with clinical signs of uremia (bleeding, encephalopathy, pericardial rub or effusion), or volume overload resulting in pulmonary edema and dyspnea/hypoxia.

As mentioned earlier, length of CPB is an intraoperative risk for acute kidney injury. Most patients sustain a small amount of injury from what might

be delineated postbypass ATN. The injury incurred is typically small although not infrequently achieves at least stage I by AKIN criteria. However, especially with prolonged bypass runs, the injury to the kidney can be significant. After ruling out prerenal causes of kidney dysfunction, evaluation and treatment of the patient should include an assessment of concurrent oliguria or nonoliguria, diuretic responsiveness, and whether renal replacement therapy is indicated. ATN may be more formally assessed by FENa/FEUrea as well as urine microscopy showing muddy brown casts.

If the patient has not sustained a prerenal injury by history and if MAP and volume status have been deemed to be adequately addressed, oliguria and a rising creatinine be secondary to diuretic dependence. Some patients with preoperative chronic kidney disease with diminished renal function at baseline may be dependent on diuretics for generation of adequate urine. As long as the patient is not suffering from low MAP (absolute or relative) or hypovolemia, reinstating these medications may restore urine production and by providing excretion of creatinine, restore plasma creatinine levels back to baseline.

Other causes of renal injury include toxins (exogenous and endogenous) and sepsis. Exogenous toxins include contrast dye, antibiotics such as the aminoglycosides, and NSAIDs such as ketorolac and ibuprofen. Endogenous toxins include myoglobin from rhabdomyolysis. The septic patient may demonstrate a septic nephropathy that resolves only with source control and antibiotics.

GLUCOSE CONTROL

One landmark single center study of 1548 surgical ICU patients (63% of whom were postcardiac surgical patients) suggested that intense glucose control between 80 and 110 mg/dL versus 180 and 215 mg/dL resulted in a relative reduction in mortality (8% to 4.6%).³⁶ However, the results of this study could not be replicated in multiple subsequent investigations. In particular, the Normoglycemia in Intensive Care Evaluation and Surviving Using Glucose Algorithm Regulation (NICE-SUGAR) study, a multicenter trial of 6104 medical and surgical patients, randomized the patients to 81 to 108 mg/dL versus 144 to

180 mg/dL and not only found increased mortality with intensive glucose therapy with a 90-day mortality of 27.5% in the treatment group and 24.9% in the control group but also an unacceptably high incidence of severe hypoglycemia (blood glucose \leq 40 mg/dL) with 6.8% in the intensive group and 0.5% in the conventional group.³⁷ The optimum level of glucose control, thus, is as yet to be defined, and may be better elucidated with the development of technology that may be able to allow for the safer administration of continuous insulin regimens.

SUMMARY

Multiple issues arise in the care of the immediate postoperative cardiac patient. A decision must be made as to the appropriate timing of extubation. In addition, knowledge of normal physiology as well as the pathophysiology resulting from CPB informs the understanding of hypotension and low CO, bleeding, and renal dysfunction in the postcardiac patient. Management of these common postsurgical problems also requires a thorough understanding of the characteristics of the pharmacological tools available to us. This knowledge, as well as good communication with the surgical team, allows for successful management of the postcardiac surgical patient.

Postoperative Management After Specialty Surgery

Nagendra Y. Madisi, MD and John M. Oropello, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 The success of a free-flap transfer is inversely proportional to flap ischemic time and the time to recognition of complications.
- 2 Dextran infusion syndrome should be suspected in patients on low-molecular-weight dextran that develop noncardiogenic pulmonary edema.
- 3 The classic triad of fat embolism syndrome is hypoxemia, neurological abnormalities, and petechiae.
- 4 Bone cement implantation syndrome is a life-threatening complication of orthopedic surgery characterized by hypoxia, hypotension, pulmonary hypertension, arrhythmias, loss of consciousness, and potentially cardiac arrest.
- 5 Cystectomy is an independent risk factor for venous thromboembolism.

INTRODUCTION

This chapter discusses specific postoperative complications and management in the intensive care unit (ICU) after ENT, orthopedic, and urology surgery. Radical head and neck surgery with free-flap reconstruction, total hip replacement (THR) and total knee replacement (TKR), radical nephrectomy, and radical cystectomy are discussed.

ENT SURGERY

Radical Head and Neck Surgery with Free-Flap Reconstruction

An estimated 55,000 Americans develop head and neck cancer mainly of the pharynx, larynx, and tongue annually and 12,000 die from the disease.¹ Radical head and neck dissection with free-flap reconstruction has evolved over the past 4 decades with free-flap success rates in the 90% to 99% range.

Otolaryngology patients with tumors of the head and neck undergo radical dissection and free-flap microsurgery. These patients are admitted postoperatively to the ICU for neurologic, free flap, and airway monitoring. Complications include flap failure, infections, postoperative bleeding, acute lung injury (noncardiogenic pulmonary edema), and venous thromboembolism (VTE). In addition to comorbid conditions such as chronic obstructive pulmonary disease (COPD) and diabetes, these patients often have a history of alcohol dependence and smoking, hence close monitoring for encephalopathy and alcohol withdrawal syndrome is warranted.

Surgical Factors

Radical head and neck dissection involves en bloc removal of all nodal groups between the mandible and the clavicle with removal of the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve.

The free-flap transfer, also called a free tissue transfer, is an autologous transplantation of vascularized tissues that incorporate a direct cutaneous artery and vein in the base. The free flap may contain skin, muscle, bone, or fascia. Free flaps have a higher complication rate than skin grafts. Indications for free flaps include complex defects of the head and neck regions following tumor resection or chemoradiation, reconstruction in patients failing local or regional flaps, or failure of a prior free flap. Common sites of harvest include the anterolateral thigh, fibula, and iliac crest. Fascio-cutaneous flaps are used to repair superficial lesions; and muscle and myocutaneous flaps are used to repair deeper lesions. To reconstruct mandible and floor of the mouth defects, fibular free flaps with overlying skin, or iliac crest bone flaps are usually used.

Patient Risk Factors

Diabetics are at increased risk of flap failure secondary to microangiopathy, increased risk of thrombosis and wound infection. Increasing age is an independent risk factor and smoking is associated with injury to flap vessels causing intimal fibrosis and potentially poorer outcomes.

Postoperative Management

Airway Monitoring

Anatomical changes occur in head and neck cancers that may create a difficult airway. Close monitoring for postoperative airway compromise after head and neck surgery in the ICU is warranted due to complications including soft-tissue edema, bleeding, hematoma, and bilateral laryngeal nerve damage. Securing the airway in head and neck reconstructions may be difficult hence caution should be exercised before extubation. Postoperative soft-tissue edema peaks around the second or third postoperative day.

Once the patient tolerates a spontaneous breathing trial, a cuff-leak test should be considered before extubation. Two cuff-leak methods exist. The qualitative method is listening for air movement with a stethoscope after deflating the endotracheal tube balloon. In the quantitative method the endotracheal balloon is deflated while on volume control ventilation and the difference between the inspired versus expired tidal volume is measured. An at least

110 mL difference or a decrease of 12% to 24% in the expired versus inspired tidal volume supports adequate leakage around the tube and hence less airway edema.² However, none of these tests are highly predictive of extubation success or failure and are only adjuncts to the overall clinical assessment.

In the event of respiratory distress or lack of an air-leak, extubation should be deferred for the next 24 hours. Inspection via laryngoscope may be performed to assess airway edema while the patient is still intubated. Steroids may be used in some cases for soft-tissue edema to facilitate extubation.

Intensivists should be prepared for emergent endotracheal intubation or an emergent surgical airway. Anesthesiologists and ENT surgeons should be present at bedside or in close proximity during extubation. Emergent airway equipment should remain at bedside with ENT surgeons on standby to perform emergent bedside tracheostomy if necessary.

In patients with extensive head and neck reconstructions a concomitant tracheostomy is usually done at the time of surgery to overcome airway compromise. Elective tracheostomy is recommended for patients with a high risk of airway obstruction. Multiple scoring systems for elective tracheostomy in head and neck cancer patients have been developed based on various parameters that include tumor size, tumor localization (involving larynx, base of the tongue, pharynx) TNM (tumor, nodes, metastases) staging, mandibulectomy, neck dissection, pathological chest X-ray findings, multiple comorbidities (mostly cardiopulmonary), and chronic alcohol dependence.^{3,4} However, there is no gold standard scoring system for determining elective tracheostomy and so clinical judgment is required.

Respiratory Failure

Comorbid conditions such as underlying lung disease, cardiovascular disease, renal disease, alcohol abuse, and malnutrition are significant risk factors for failure to wean from mechanical ventilation.

Fluid Resuscitation

Free-flap tissues can become ischemic and can be sensitive to ischemia/reperfusion injury with different responses to hypotension or vasopressors. Balanced volume resuscitation is very important in microsurgery, because volume overload is

associated with flap edema and compromising flap microcirculation. Given the small caliber of blood vessels, hypotension should be avoided because even minimal vasoconstriction in the flap microcirculation leads to decreased blood flow. Low-molecular-weight (LMW) dextran (eg, Dextran 40) is used at some centers because of its rheological properties in reducing viscosity and providing antithrombotic effects thus potentially improving blood flow in the free flap. Increased risk of flap edema and acute lung injury/noncardiogenic pulmonary edema may occur more often in patients receiving higher volume crystalloid administration, for example, more than 130 mL/kg in 24 hours or more than 7 liters intraoperatively as reported in 1 study.⁵

Vasopressors

Vasopressors have been used in clinical practice to increase the mean arterial pressure (MAP) and improve perfusion pressure across the free flap. In a recent study of patients undergoing free flaps receiving mainly phenylephrine or ephedrine, there was no significant relationship between intraoperative vasopressor and major free-flap complications.⁶ Prospective studies on the postoperative use of vasopressors have shown that norepinephrine and dobutamine can improve free-flap skin blood flow, with the greatest benefit from norepinephrine. Other pressors such as dopamine and epinephrine decreased flap flow.⁶⁻⁸ The use of albumin over synthetic colloids to replace intraoperative blood loss has not proven to be beneficial to date. However, the judicious use of pressors in an adequately volume resuscitated patient using norepinephrine is advised; there is no added benefit to use dobutamine which may lead to tachycardia, tachyarrhythmias, and hypotension.

Myocardial Infarction

Coronary ischemia and hemodynamic instability play an important role in flap outcomes. Long-term smoking and tobacco abuse not only increase the risk for cancer but also increase the risk of coronary artery disease (CAD) and myocardial infarction (MI). The risk of MI in the perioperative period is low, but associated with high mortality. High-risk patients with preexisting renal insufficiency, CAD, peripheral vascular disease (PVD), congestive heart

failure (CHF), age of above 74, hypertension and prior chemoradiation are at increased risk for troponin elevation in the first 24 hours. Monitoring of troponin levels and the EKG is important in the immediate postoperative period. Elevated troponins post-ENT cancer surgery are associated with an 8 fold increased risk of death.⁹

Harvest Sites

Harvest sites need to be monitored frequently for signs of bleeding, hematoma, ischemia, or infection.

Microvascular Thrombosis

The reexploration rate after free-flap surgery due to circulatory compromise is about 5% to 25%. The success of the flap transfer is inversely proportional to its ischemic time and time to recognition of complications. Venous compromise occurs more often than arterial compromise and is usually seen in the first 2 or 3 postoperative days, while arterial compromise usually occurs later.^{10,11} Flaps complicated by postoperative hematomas require early evacuation to avoid vascular pedicle compression and flap engorgement. Good surgical technique, close flap monitoring, and early recognition of flap compromise are the keys to free-flap transfer success.

Data on the success rate of free-flap salvage within the first 1 to 4 hours following vascular compromise are close to 100%, but the success rate drops to 70% to 80% for ischemia times of more than 4 to 8 hours. If circulatory compromise is not addressed within 8 to 12 hours there may be development of no-reflow phenomenon¹² where restoration of blood flow results in initial hyperemia with free-oxygen radicals and complement system activation followed by reperfusion injury, a gradual decline in perfusion and cell death.

Flap Monitoring

Flap color, temperature monitoring, color duplex, Doppler ultrasound, and pin-prick testing are a few of the monitoring modalities,¹³ but no ideal or gold standard exists. Clinical evaluation and color duplex Doppler has been proven to be more accurate in diagnosing vascular compromise of free-flap transfers.¹⁴ In the first 24 hours, patients are closely monitored in the ICU, kept nil per os (NPO) and are on strict bed rest to prevent potential complications in the

event that reexploration is required. Flap checks are initially done half-hourly or hourly to assess flap viability. Avoidance of hypotension, hypoxia, and hypothermia are important. Venous congestion and necrosis in the skin paddle of a free flap might result in loss of the flap. Venous flow can be preserved by using systemic heparin therapy, LMW dextran or medicinal leech therapy.

Clinical observation of flap color, swelling, temperature, and capillary refill remains a vital mode of monitoring. A healthy and a well-perfused flap appears pink, minimally swollen, and warm to touch; a congested flap appears bluish in color, swollen, warm to touch with a short capillary refill time of less than 2 seconds. If the flap is ischemic it appears pale, cold to touch with a delayed capillary refill time of more than 3 seconds. Upon puncturing a viable free flap with a small gauge needle (pin-prick test) bright red blood flows immediately, whereas in a congested flap the blood flow is dark suggesting compromise. This test is usually performed on flaps where clinical monitoring by visualization is difficult. In pharyngoesophageal reconstruction using small intestine, the sentinel loop that is left outside the neck is used to monitor the viability. A healthy intestinal graft is pink and warm with minimal swelling and visible peristalsis; loss of peristalsis suggests graft compromise.

Compression of the artery will lead to loss of the Doppler signal within the flap, whereas venous compression will lead to augmentation of the venous signal due to increased venous return. Implantable Doppler probes may be used to monitor the flow in buried flaps. A decrease in tissue oxygen partial pressure (ptiO₂) monitoring via an implantable oxygen-monitoring probe (eg, Licox) may suggest free-flap compromise. A pitfall of these monitors is that the probes are localized and do not assess viability outside the small sample volume that is monitored.

Microvascular Flap Anticoagulation

Aspirin and LMW heparin alone or in combination are commonly used for postoperative anticoagulation after free tissue transfer. Other strategies to prevent thrombosis include decreasing blood viscosity by LMW dextran infusions and/or hemodilution with IV fluids and avoiding blood-product transfusions unless absolutely necessary. LMW dextran antithrombotic properties are not fully understood

but are thought to be secondary to platelet function impairment, destabilizing fibrin, and prolonging bleeding time. Studies report variable efficacy of these anticoagulants in preventing free-flap thrombosis.

Complications of LMW Dextran—Dextran has significant dose-dependent adverse effects. These include anaphylaxis, a rare but potentially life-threatening complication,^{15,16} noncardiogenic pulmonary edema, renal insufficiency, and rarely cardiac arrest.

Dextran infusion syndrome should be suspected in patients on LMW dextran that develop noncardiogenic pulmonary edema. They may also develop hypotension, bronchospasm, or coagulopathy. The incidence increases with higher infusion rates and the longer the infusion continues. The treatment is prompt discontinuation of the dextran infusion and initiating symptomatic treatment.

Hirudotherapy—Medicinal leech therapy, called hirudotherapy is commonly used in the setting of free-flap venous congestion or thrombosis to temporarily establish venous outflow until neovascularization of the graft is established. Leeches produce an anticoagulant called hirudin that is a selective thrombin inhibitor; it also secretes vasodilators and hyaluronidase that allow the leech to ingest blood. The regimen is to use about 2 to 4 leeches depending on the size of the flap, attached to the tissue for approximately 20 minutes. Following the leech therapy, blood oozes for the next 24 hours. Complications from this therapy include bleeding, anemia, leech migration to a different body location, and rarely local or systemic infection with the gram-negative bacillus *Aeromonas hydrophila*.¹⁷

Blood Transfusion

There are no clear transfusion thresholds in free-flap surgery; however, it appears that a restrictive transfusion strategy using a postoperative transfusion trigger of hematocrit of less than 25 is not inferior to a higher transfusion threshold of hematocrit of less than 30 in patients undergoing free-flap surgery, with no increase in flap-related complications in the lower transfusion trigger group.¹⁸

Wound Infection

Wound infection is not uncommon in tissue transfer surgery involving head and neck tumors. Risk

factors for infection include preoperative radiotherapy, blood transfusion, smoking, and the duration of surgery.

Alcohol Withdrawal

The overall flap survival rate with alcohol withdrawal syndrome (AWS) is about 83%. Patients with postoperative AWS have a higher chance of developing non-flap-related complications, especially respiratory problems (prolonged ventilator dependency), encephalopathy, seizures, and hemodynamic instability. The onset of alcohol withdrawal symptoms is usually 1 to 2 days after abstinence (delirium tremens may occur at 2-5 days). Once AWS signs are recognized, prompt treatment should commence with an initial regimen of parenteral thiamine, multivitamins, and folic acid supplements. Effective treatment for AWS involves treatment with benzodiazepines and occasionally antipsychotics.¹⁹ As more data become available, dexmedetomidine appears promising in the treatment of AWS.

ORTHOPEDIC SURGERY

This section reviews critical-care management after THR and TKR.

Admission rates of orthopedic patients to the ICU are rising due to an increasingly elderly population. Approximately 1 of 30 patients undergoing total joint arthroplasty will require critical-care monitoring. Identifying high-risk patients undergoing joint replacement for adverse events and monitoring in ICU can optimize outcome and reduce morbidity and mortality.

Risk factors for requiring critical-care services include advanced age, hip versus knee surgery, general anesthesia, multiple comorbidities, intraoperative or postoperative complications, and surgical indications other than osteoarthritis and rheumatoid arthritis. Smoking is associated with significantly higher perioperative complications and mortality following total hip arthroplasty and total knee arthroplasty.

Surgical Factors

In THR and TKR, the damaged articular cartilage over the bone surfaces is replaced. The bone is cut based on preoperative radiographs and anatomic measurements. These cut bony surfaces are covered

by metal, ceramic, or polyethylene components that are sized appropriately to match the alignment, leg length, and range of motion. If all compartments and surfaces of the joint are replaced, the procedure is referred to as a total joint arthroplasty/replacement. If only 1 surface or compartment of the joint is replaced, it is referred to as hemiarthroplasty. In total hip arthroplasty both the femoral head and neck are replaced. In total knee arthroplasty the distal femur, tibia, and patella are resurfaced after any remaining articular cartilage and a layer of subchondral bone are resected.

Blood Transfusion Criteria

Total hip and total knee arthroplasty frequently require blood transfusion with transfusion rates ranging from 18% to 68%. The Function and Overall Cognition in Ultra-High Risk States (FOCUS), largest trial, to address blood transfusion threshold in hip fracture patients suggests that mortality, length of stay, are no different from the general population with a restrictive transfusion threshold of hemoglobin 8 g/dL.²⁰

Cardiopulmonary Complications

Risk factors for developing postoperative cardiac complications include age of 80 years or above, hypertension requiring medication and history of cardiac disease. The cardiac complication rate is approximately 0.33% after total knee arthroplasty or total hip arthroplasty. Serious complications such as MI and cardiac arrest constitute 7% to 20% of all major complications. Patients with underlying cardiac disease who receive large volume resuscitation and blood products are at increased risk of noncardiogenic pulmonary edema and supraventricular arrhythmias such as atrial fibrillation and atrial flutter. Risk factors for perioperative development of supraventricular arrhythmias include a history of atrial fibrillation, increasing age, left anterior hemiblock, and atrial premature depolarizations on the preoperative electrocardiogram. In patients aged above 60 years with any one of the above risk factors, the risk of arrhythmia is as high as 18%.²¹ Electrolyte abnormalities, hypoxia, and acidosis should be corrected.

Respiratory Failure

Occurrence of postoperative pneumonia is high in elderly patients; atelectasis and secretions, intubation,

reintubation, prolonged ventilator support, and use of preoperative proton pump inhibitor use are risk factors for developing pneumonia. The rate of serious pulmonary complications has been reported to be 2.6%, with a 30-day mortality of 17%. Risk factors for developing acute respiratory distress syndrome (ARDS) include aspiration, blood-product administration (including transfusion-related acute lung injury [TRALI]), and lung injury from fat embolism or bone cement, surgical site infection, and sepsis. The mortality rate is approximately 60% in elderly patients above 85 years. Treatment includes supportive care and lung-protective ventilation strategies.

Fat Embolism Syndrome

Fat embolism is defined as occlusion of the micro-circulation by presence of fat globules. Common causes of fat embolism syndrome (FES) include orthopedic trauma, particularly involving long-bone fractures in the lower extremity and orthopedic surgeries involving the lower extremity. The incidence of asymptomatic fat embolism in THR and TKR is approximately 46% to 65%.

The development of FES may be secondary to extravasation of fat globules from the bone marrow during the surgical procedure secondary to increased intramedullary pressure. Clinically, the classic triad of FES is hypoxemia, neurological abnormalities (eg, agitated or hypoactive delirium), and petechiae. Occasionally severe cases of FES can be complicated by disseminated intravascular coagulation, right ventricular dysfunction, biventricular failure, ARDS, shock, and death. No gold standard criteria exist to diagnose fat embolism. The incidence of FES thus varies widely. The most frequently used diagnostic criteria are Gurd’s criteria (Table 55–1).

Given the systemic complications, high-risk patients need close monitoring. No clear treatment guidelines exist; supportive care with fluid resuscitation and mechanical ventilation are the main stays. Heparin and corticosteroids have not been found to improve morbidity or mortality.^{21,22}

Bone Cement Implantation Syndrome

Bone cement implantation syndrome (BCIS) is a life-threatening complication of orthopedic surgery characterized by hypoxia, hypotension, pulmonary

TABLE 55–1 Gurd’s criteria for diagnosis of fat embolism syndrome.^{21,22}

Major Criteria	Minor Criteria
Axillary or subconjunctival petechiae	Tachycardia < 110 beats/min
Hypoxemia PaO ₂ < 60 mm Hg; FIO ₂ = 0.4	Pyrexia < 38.5°C
Central nervous system depression disproportionate to hypoxemia	Emboli present in the retina on fundoscopy
Pulmonary edema	Fat present in urine, a sudden inexplicable drop in hematocrit or platelet values Increasing ESR Fat globules present in the sputum

ESR, erythrocyte sedimentation rate; FIO₂, fraction of inspired oxygen; PaO₂, partial pressure arterial oxygen.

hypertension, arrhythmias, loss of consciousness, and potentially cardiac arrest occurring around the time of bone cementation.²³ Complications from acrylic bone cement polymethylmethacrylate (PMMA) have been recognized as early as the 1970s, but recently have been more frequently reported. The majority of complications develop soon after the application of cement or in the immediate postoperative period. Patient risk factors include advanced age, malignancy, osteoporotic bones, renal failure, congestive heart failure, chronic obstructive lung disease, use of diuretics, and angiotensin converting enzyme medications. BCIS increases the 30-day mortality rate by 16 fold.

The pathophysiology is not fully understood but may be secondary to the release of inflammatory markers, anaphylaxis and complement activation leading to increased pulmonary vascular resistance causing ventilation/perfusion disturbances and right ventricular failure. Recently, BCIS has been classified into 3 grades depending on the severity (Table 55–2).²⁴

The incidence of BCIS may be reduced by use of noncemented joints, high-volume medullary lavage, intraoperative canal suctioning during cementation, low-viscosity PMMA, and slow controlled insertion of the prosthesis. Use of tobramycin-impregnated

TABLE 55–2 BCIS classification.

BCIS grade I	Moderate hypoxia, (SpO ₂ < 94%) or hypotension [a decrease in systolic arterial pressure (SAP) > 20%]
BCIS grade II	Severe hypoxia (SpO ₂ < 88%) or hypotension (a decrease in SAP > 40%) or unexpected loss of consciousness
BCIS grade III	Cardiovascular collapse requiring cardiopulmonary resuscitation

BCIS, bone cement implantation syndrome; SpO₂, peripheral capillary oxygen saturation.

Data from Donaldson AJ, Thomson HE, Harper NJ, Kenny NW. Bone cement implantation syndrome, *Br J Anaesth* 2009 Jan;102(1):12-22.

bone cement decreases the incidence of BCIS but is associated with acute kidney injury (AKI) in patients with underlying renal disease.

ICU admission is warranted in patients with hypotension, hypoxemia, anaphylactic reactions, and right heart failure after undergoing cement joint replacement. Transthoracic echocardiography should be considered in these patients to assess cardiac activity especially, right ventricular function. In patients with hemodynamic instability, fluid resuscitation and vasopressor support should be provided. Patients with symptomatic hypoxia or ARDS should be supported by lung protective mechanical ventilation.

Venous Thromboembolism

The rate of pulmonary embolism (PE) in the nonorthopedic population aged above 65 years is approximately 0.03%, but patients undergoing THR or TKR have a 10 fold or 0.3% increase in PE. Risk factors for VTE are increasing age, immobilization, presence of varicose veins, previous deep vein thrombosis

(DVT), smoking, hormonal therapy, location of surgery (knee > hip) malignancy, type of anesthesia, indwelling venous catheters or pacemaker, surgical time, and joint replacement itself. High-risk patients with evidence of right ventricular dysfunction clinically or echocardiographically are at risk of shock or death and need close ICU monitoring (Table 55–3).

The latest (9th) American College of Chest Physician (ACCP) guidelines from 2012 suggest initiating VTE prophylaxis 12 or more hours preoperatively or postoperatively rather than 4 hours or less preoperatively or postoperatively. LMW heparin is preferred prophylaxis for a minimum of 10 to 14 days along with intermittent pneumatic compression devices. Patients with active signs of bleeding are recommended to receive mechanical VTE prophylaxis. Current evidence does not provide clear guidance about inserting prophylactic inferior vena cava (IVC) filters in patients undergoing elective hip and knee arthroplasty with contraindications to chemoprophylaxis or residual venous thromboembolic disease. Orthopedic surgeons should be consulted prior to initiation of VTE prophylaxis in these patients at all times, especially in patients with acute blood loss anemia requiring ICU admission. Formal discussion with the primary team regarding VTE prophylaxis should be incorporated into team rounds.

UROLOGICAL SURGERY

Most patients undergoing radical nephrectomy and cystectomy do not require intensive care monitoring unless they develop perioperative complications such as hemodynamic instability (from acute blood loss, splenic injury, MI, adrenal insufficiency (AI), hypovolemia, pulmonary embolism) and respiratory failure.

TABLE 55–3 Incidence of VTE in patients with and without VTE prophylaxis after major orthopedic surgery.

	Initial Prophylaxis, Postoperative Days (0-14)	Extended Prophylaxis, Postoperative Days (15-35)	Cumulative, Postoperative Days (0-35)
No prophylaxis	VTE 2.80% (PE 1.00%, DVT 1.80%)	VTE 1.50% (PE 0.50%, DVT 1.00%)	VTE 4.3% (PE 1.50%, DVT 2.80%)
LMWH	VTE 1.15% (PE 0.35%, DVT 0.80%)	VTE 0.65% (PE 0.20%, DVT 0.45%)	VTE 1.8% (PE 0.55%, DVT 1.25%)

DVT, deep vein thrombosis; LMWH, low-molecular-weight heparin; PE, pulmonary embolism; VTE, venous thromboembolism.

Prevention of VTE in orthopedic surgery patients: Antithrombotic Therapy and Prevention of Thrombosis, 9th ed: American College of Chest Physicians Evidence-Based Clinical Practice Guidelines, *Chest* 2012 Feb;141(2 Suppl):e278S-325S.

Radical Nephrectomy

Renal cell carcinoma (RCC) is the third most common cancer of urinary tract and accounts for 80% to 85% of all primary renal neoplasms, with an annual incidence of over 60,000 in the United States. One third of newly diagnosed patients with RCC present with advanced stage (III/IV) tumors.

Surgical Factors

Radical nephrectomy includes removal of the kidney and Gerota's fascia, ligation of the renal artery and vein, and occasionally removal of the ipsilateral adrenal gland. This procedure is usually done laparoscopically for renal masses smaller than 4 cm, whereas open radical nephrectomy is reserved for large, locally advanced tumors, caval extension, or enlarged lymph nodes.

Complications

In a retrospective analysis from the National Surgical Quality Improvement Program (NSQIP), cystectomy had the highest morbidity (3.2% mortality), followed by nephrectomy, retroperitoneal lymph node dissection, and radical retropubic prostatectomy. Postoperative complications following radical nephrectomy include postoperative bleeding, pneumothorax (PTX), MI, liver injury, pancreatic and splenic injury.

Hypotension is not uncommon in the postoperative period from blood loss, dehydration, and sedation. Prompt recognition of bleeding, achieving hemostasis, fluid resuscitation to maintain intravascular volume and tissue perfusion, MAP greater than 65 and avoidance of fluid overload are the mainstays of treatment.

PTX may occur with surgeries involving the flank; rib resection is not always necessary to cause PTX. In the event of postoperative respiratory or hemodynamic instability, the diagnosis of PTX must be considered. Physical examination, ultrasound, and chest radiography are methods to determine the diagnosis.

The adrenal gland is a highly vascular structure and is occasionally removed during radical nephrectomy. There is no difference in the survival of patients undergoing radical nephrectomy with or without adrenalectomy, whereas in metastatic disease the survival is poor, independent of adrenalectomy.

Monitoring for signs and symptoms of acute Addisonian crisis is important. AI is characterized by hypotension, fever, hyperkalemia, hypoglycemia, weakness, and nausea or vomiting. However, signs of AI may not always be seen in ICU patients who usually present with refractive hypotension with or without hypoglycemia; therefore, a low threshold for the diagnosis of AI is warranted. This is a medical emergency and needs to be treated promptly with corticosteroids without waiting for cortisol levels or an adrenocorticotrophic hormone (ACTH) stimulation test.

Left radical nephrectomy is the second most common cause of splenic injury. The incidence is approximately 4.3% to 13.2% and is higher during transperitoneal approach compared to retroperitoneal approach. Common signs and symptoms in an awake patient are abdominal pain, hematocrit drop, hypotension, and Kehr sign (referred pain at left shoulder tip), but these signs may not be recognized in less responsive patients. Splenic injury should be considered in the event of unexplained hypotension or hematocrit drop postnephrectomy. Bedside, ultrasonography can be utilized to quickly diagnose splenic injury in hemodynamically unstable patients (perisplenic fluid or intraperitoneal fluid seen in Morrison's pouch). Splenic injury can be also diagnosed by computed tomography. Nonoperative management of splenic injury includes aggressive volume and blood-product resuscitation and supportive care to keep the hemoglobin greater than 7.0 g/dL. Surgical treatment includes angiography and embolization or emergency splenectomy. Other important differentials for postoperative hemodynamic instability include hypovolemia, acute blood loss, sepsis, acute coronary syndrome, and pulmonary embolism.

Left radical nephrectomy can result in pancreatic injury and bleeding, hence follow up with lipase; amylase and abdominal imaging should be considered in suspected patients. The risk factors for VTE include poor functional status, age of above 60 years, anesthesia time more than 2 hours, steroid usage, metastatic disease, and congestive heart failure.

Patients with underlying chronic kidney disease (CKD) are at increased risk of developing AKI. The overall incidence of AKI in patients undergoing radical or partial nephrectomy is approximately 7%.

Sepsis, urinary obstruction, and bleeding are leading causes of AKI in these patients. The overall mortality increases with severity of AKI (4.8% in stage 1, 9.1% in stage 2, 14.9% in stage 3).

Radical Cystectomy and Urinary Diversion

Open radical cystectomy (ORC) remains the standard treatment for high-grade nonmetastatic invasive bladder cancer. Multiple centers have adopted new operative techniques such as robotic assisted radical cystectomy (RARC) that has increased from 0.6% of all cystectomies in 2004 to 12.8% in 2010.²⁵

Surgical Factors

Radical cystectomy involves removal of the bladder, adjacent organs, and regional lymph nodes. In males, radical cystectomy includes removal of the prostate, seminal vesicles, along with the urinary bladder. Advances such as laparoscopic cystectomy and RARC have resulted in technical improvements resulting in less blood loss, fewer blood transfusions, reduced risk of complications and shorter hospital stay, as compared with open surgery.

Using the NSQIP database, the rates of DVT and PE (4.0% and 2.9%) were found to be the highest after cystectomy and urinary diversion^{26,27} followed by nephrectomy and prostatectomy. Cystectomy is an independent risk factor for VTE; other risk factors include increased body mass index (BMI), positive surgical margins, older age, and increased length of stay. ACCP guidelines, suggest 4 weeks of low-molecular-weight heparin for VTE prophylaxis in patients at high risk who undergo abdominal and pelvic surgeries.

Gastrointestinal events represent the majority of complications following radical cystectomy with ileal conduit. Intestinal obstruction is most common (23%), followed by ileus (18%) and intestinal anastomotic leakage (3%) in a recent series.²⁸ Special monitoring is necessary to detect signs and symptoms of urosepsis, urinary leak, and pyelonephritis following urinary diversion surgery.

The use of balanced crystalloid solutions (Plas-malyte, Lactated Ringer's) in patients undergoing radical cystectomy with ileal conduit is preferred over normal saline because 0.9% sodium chloride solution is associated with hyperchloremic metabolic

acidosis. Hypervolemia can result in interstitial edema causing deleterious effects on bowel function. One recent report suggested that restrictive fluid administration and preemptive use of norepinephrine to correct hypotension might be beneficial in decreasing postoperative complications.

Infectious events constitute about 25% and are the second most common complications of radical cystectomy according to a recent investigation.²⁸ Antibiotic prophylaxis (eg, ampicillin) is given for radical cystectomy. Major infections that are encountered following radical cystectomy are urinary tract infection, urosepsis, pyelonephritis, and sepsis. Wound-related complications in the early postoperative period include primary dehiscence and infection.²⁹

Urinary diversion is a surgical procedure in which the urinary flow is rerouted from the bladder.³⁰ Different types of diversion include ileal conduit, continent cutaneous diversion, and orthotopic neobladder (the urine is eliminated by the urethra). Potential complications following urinary diversion include AKI, hydronephrosis, urinary tract infection, nephrolithiasis, and metabolic disturbances. Mucus is often produced by urinary reservoirs and bladder substitutes; hence frequent irrigation of mucus is necessary to avoid mucus accumulation and infection.³¹ Orthotopic diversion is a significant predictor of VTE compared to nonorthotopic diversion.

Radical cystectomy often leads to considerable blood loss with an average blood loss of 560 to 3000 mL.

Postoperative Vascular Surgery Care

Charanya Sivaramakrishnan, MD and Rami Tadros, MD

“The tragedies of life are largely arterial”—Sir William Osler

KEY POINTS

- 1 Permissive hypotension while ensuring adequate organ perfusion is recommended in ruptured abdominal aortic aneurysm (AAA).
- 2 Acute spinal cord ischemia post-thoraco-AAA repair mandates emergent lumbar CSF catheter placement and monitored drainage in an intensive care unit.
- 3 High index of suspicion for postoperative ischemic colitis—abdominal pain, rising lactate, fever, and leukocytosis.
- 4 Management of acute aortic dissections with impulse control by intravenous beta blockers followed by nitroprusside.
- 5 Early recognition of malperfusion syndromes in type B aortic dissection.

INTRODUCTION

Care of the vascular surgery patient postoperatively presents a challenging clinical scenario to the intensivist. These patients are at a high risk for perioperative complications whether undergoing open or endovascular surgery. Advanced age, comorbidities such as coronary artery disease, congestive heart failure, chronic kidney disease, advanced diabetes, peripheral vascular disease in addition to the insult of major vascular surgery places these patients at a high-risk category and potentially requiring intensive care unit (ICU). Major vascular surgery exposes the patient to extensive tissue damage, elicits a robust inflammatory response and can predispose to profound hemodynamic changes.

This chapter will review the commonly encountered vascular procedures most likely to require subsequent ICU care.

ABDOMINAL AORTIC ANEURYSM

An abdominal aortic aneurysm (AAA) is defined as a pathologic focal dilation of the aorta that is more than 30 mm or 1.5 times the adjacent diameter of the normal aorta. Male aortas tend to be larger than female, and there is a generalized growth of the aortic diameter with each decade of life. Ninety percent of the AAA are infrarenal in location and fusiform in morphology.¹

Most AAAs are asymptomatic and are found incidentally during workup for chronic back pain or kidney stones. The indications for surgery are any patient who is symptomatic with back pain and/or abdominal pain with a tender pulsatile mass or any asymptomatic aneurysm that is greater than or equal to 5 to 5.5 cm or increases by greater than 0.5 cm/year.

There are 2 approaches to AAA repair—the open surgical approach and endovascular aneurysm repair (EVAR).² The majority of AAAs today are managed using EVAR. Therefore, the number of patients requiring ICU care after aneurysm repair has decreased. Currently, those with AAA not treatable with EVAR often have pararenal or juxta-renal morphology increasing the risk of open repair. These aneurysms increase the challenge of repair and often require supraceliac aortic clamping. The physiologic disturbance in this cohort is much greater.

The advantage of open repair (Figure 56–1) is that the AAA is permanently eliminated because it is entirely replaced by a prosthetic graft and risk of recurrence or delayed rupture is less. Consequently, long-term imaging surveillance is not needed in most patients. However, several prospective clinical trials across devices and databases have demonstrated a significantly decreased operative time, blood loss, hospital length of stay, and overall perioperative morbidity and mortality of endovascular repair as compared to open surgical repair.

Endovascular procedures aim to reduce the morbidity and mortality of treating arterial disease in a patient population that is increasingly older and less fit than when major open repairs were developed and

FIGURE 56–1 Large abdominal aortic aneurysm seen in the operating room.

popularized. Studies that assign aneurysm patients to treatment with EVAR or traditional open surgery have demonstrated fewer early complications with the minimally invasive approach. Some studies have also observed a lower mortality rate with EVAR. Hence endovascular AAA repair (EVAR) is currently the treatment of choice for repair of uncomplicated infrarenal AAAs. EVAR is also used for ruptured AAA with 1 meta-analysis of 3 recent trials demonstrating a mortality rate of 38.6% with EVAR vs 42.8% in open repair.³ However, the IMPROVE trial demonstrates no survival benefit, although there is a significant improvement in speed of discharge, quality of life, and cost-effectiveness with EVAR.⁴

There have been advances in the techniques of EVAR allowing treatment of patients with atypical vascular anatomy.

Fenestrated EVAR—When the aneurysm begins close to the renal arteries, standard EVAR may be contraindicated because there will be an inadequate length of suitable aorta for the endograft attachment. In these cases a fenestrated endograft may be useful, where the attachment of the endograft to the aorta may be placed above the renal arteries with each fenestration opposite a renal artery so that blood flow to the kidneys is maintained.⁵

Branched EVAR—A branched endograft has graft limbs that branch off of the main portion of the device to directly provide blood flow to the kidneys or the visceral arteries.⁶

RUPTURED ABDOMINAL AORTIC ANEURYSM

Emergent surgical intervention is indicated for a rupture but despite improvements in perioperative care the mortality rate remains high (approximately 50%) after conventional open repair. Emergency endovascular aneurysm repair (eEVAR) has been used successfully to treat ruptured AAA (RAAA), proving that it is feasible in selected patients.

Management of RAAA discussed as follows:

1. Patients should be resuscitated with fluids (crystalloids, colloids, or blood) to maintain adequate organ perfusion and mentation.

Aggressive resuscitation to a normotensive state is not advised until the aneurysm is repaired. Permissive hypotension is ideal prior to controlling hemorrhage.

2. Hypertension should be avoided to lessen further bleeding.
3. Patients who are relatively stable, with an intact mental status should undergo emergent CT scanning to confirm the diagnosis and to consider EVAR if available.
4. However, those who are persistently unstable should immediately be transferred to the OR for exploration or to a center that can offer the best treatment.

THORACIC AORTIC ANEURYSM

Ascending aortic aneurysms are the most common (~60%) thoracic aortic aneurysm (TAA) followed by aneurysms of the descending aorta (~35%) and of the transverse aortic arch (< 10%). Most descending TAAs begin just distal to the orifice of left subclavian artery.⁷

Most TAA are clinically silent; with nontraumatic TAAs detected as incidental findings on chest imaging obtained for other purposes. A minority of patients may present with chest discomfort or pain that intensifies with aneurysm expansion or rupture, aortic valvular regurgitation, congestive heart failure, compression of adjacent structures (recurrent laryngeal nerve, left main-stem bronchus, esophagus, superior vena cava), erosion into adjacent structures (esophagus, lung, airway), or distal embolization.

Chest X-ray reveals widened mediastinum or an enlarged calcific aortic shadow. Traumatic aneurysms may be associated with skeletal fractures. MR or CT imaging with intravenous (IV) contrast provides precise estimation of the size and extent of aneurysms and facilitates surgical planning (refer to [Figure 56–2](#) for CT evidence of a contained TAAA rupture). Echocardiography may be useful in evaluating aneurysms involving the aortic arch.

Options include open repair and thoracic endovascular aneurysm repair (TEVAR). Surgical management varies based on type and location of TAA. Repair of proximal arch aneurysms requires cardiopulmonary bypass and circulatory arrest. Ascending and transverse arches are repaired through a median

FIGURE 56–2 Contained thoracoabdominal aortic aneurysm rupture.

sternotomy incision. Descending and thoraco-AAAs (TAAAs) are approached through a left posterolateral thoracotomy or thoracoabdominal incision.

Endovascular management of descending TAA: Because of the considerable morbidity and mortality associated with surgical repair of descending thoracic aneurysms, the endovascular approach to aneurysm exclusion is preferred for isolated descending thoracic aneurysms. Newer technologies are being developed for management of TAAA.

Complications

Both open surgical repairs and EVAR are associated with a wide variety of complications ranging from major organ system dysfunction to procedure specific localized complications carrying significant morbidity and mortality.

Cardiac derangements manifest as fatal arrhythmias and myocardial infarction. Myocardial infarction is the most common cause of death following major vascular surgery. Troponin I is a consistent predictor of increased cardiac events and increased mortality following vascular surgery.

Respiratory compromise requiring mechanical ventilation might be needed as a complication secondary to cases with significant intraoperative hemorrhage with ensuing fluid shifts and noncardiogenic pulmonary edema. Respiratory complications are

also common due to a history of smoking, COPD, and heart failure.

Acute renal insufficiency negatively impacts hospital length of stay and mortality, with an incidence of 1% to 23% post-EVAR (lower compared to that of open repair).⁸ The likely pathophysiology of AKI in EVAR is complex with multiple probable implicated mechanisms—contrast-induced nephropathy, renal microembolization, and acute tubular necrosis. Among the several preventive strategies for AKI, hydration is the mainstay of prevention as it ameliorates the effect of contrast and oxidative stress and increases renal perfusion. Hydration is of crucial importance in ruptured EVAR to correct the associated hypovolemia and decrease the effect of the pronounced oxidative stress onto the kidney. One may also consider the use of NAC or bicarbonate (there is a need for further rigorous clinical trials and studies to validate these 2 measures). Again, these are very relevant in ruptured AAAs where oxidative stress is more significant.

Abdominal compartment syndrome (ACS) is defined by the World Society of Abdominal Compartment Syndrome as intra-abdominal pressure greater than 20 mm Hg with new organ dysfunction. Intra-abdominal hypertension (IAH) is defined as intra-abdominal pressure greater than 12 mm Hg. ACS results in significant cardiac, renal, and respiratory compromise. It is suggested that large retroperitoneal hematoma and diffuse visceral edema postoperatively contribute to the development of IAH/ACS. Intra-abdominal hypertension is noted to be an important risk factor for colonic hypoperfusion and ensuing ischemic colitis after ruptured AAA repair.⁹ Monitoring of IAP may be associated with improved mortality postruptured AAA repair treated with open surgery or EVAR.¹⁰

Intra-abdominal pressures are measured by intermittent or continuous bladder pressure measurement with urethral catheterization. The definitions of the WSACS are used as the diagnostic criteria for both IAH and ACS.

The major pathophysiologic consequences of ACS are listed as follows:

- Decreased preload—compression of IVC
- Increased afterload—aortic impedance, decreased stroke volume

- Decreased extra thoracic compliance—increased shunt fraction, dead space, transalveolar pressures
- Hypoperfusion—hepatic, splanchnic dysfunction
- Increased transmitted intracerebral pressure
- Cessation of renal filtration gradient

Successful outcomes depend on early recognition and management to reduce IAH. Decompressive laparotomy should be used if conservative treatments fail or if the clinical picture warrants decompression (see [Table 56–1](#) for medical management of IAH).

Hypertension—Even brief episodes of hypertension can disrupt suture lines in open surgery and can precipitate bleeding or pseudoaneurysm formation. At the same time, hypotension, after TAA repair, can lead to spinal cord ischemia. Hence it is a delicate, fine balancing act in these cases to maintain mean arterial blood pressure between 80 and 100 mm Hg. Use of IV nitroprusside, IV beta blockers, or IV calcium

TABLE 56–1 Medical management of intra-abdominal hypertension.

Conservative Medical Management of Elevated Intra-abdominal Hypertension Include
Insertion of gastric and rectal decompressive tubes
Administration of promotilic/kinetic GI agents
Percutaneous drainage of fluid collections
Optimize sedation and analgesia
Consider neuromuscular blockade
Consider using reverse Trendelenburg position
Remove abdominal constrictive bandages/dressings
Prevention of positive fluid balance after initial resuscitation
Diuresis or ultrafiltration
Use of hypertonic crystalloids or colloids to expand intravascular compartment
Goal directed resuscitation
Successful outcome depends on early recognition, early conservative treatment to reduce IAH and decompression laparotomy if ACS develops.

channel blockers in cases of hypertension in the first 24 to 48 hours may be needed.

Spinal cord ischemia (SCI)—Surgical and endovascular repair of thoracoabdominal aneurysm is associated with a significant risk of spinal cord ischemia at the rate of 5% to 21%.¹¹ More common with TAAA and TAA than with AAA, but can occasionally be seen with high AAA or AAA in the setting of prior TAA. The etiology is likely multifactorial involving interference with cord blood supply, prolonged intraoperative hypotension, extended aortic cross-clamping time and aortic embolization. None of these are, however, solely responsible for SCI. The spinal cord depends on more than the artery of Adamkiewicz for perfusion; it relies on a complex network of flow from the vertebral arteries, intercostal arteries, lumbar arteries, and hypogastric arteries. Classical symptoms are lower extremity sensory and motor deficits with bowel/bladder incontinence with conservation of vibration and proprioception sense. SCI can also be seen after TEVAR. The subset of this population that remain at a higher risk are as follows: prior history of aortic surgery, a previous stent graft placement, aortic graft covering more than 20 cm, aortic graft covering the subclavian artery without revascularization, and graft placement in the high-risk zone between T8 and T12.

All patients at a high risk for spinal cord ischemia should be strongly considered for prophylactic CSF drainage with a CSF lumbar catheter placed in the preoperative period to optimize spinal cord perfusion.¹² CSF is drained to achieve target pressures of 10 to 12 mm Hg. The MAP is maintained between 80 and 100 mm Hg to optimize the spinal cord perfusion pressure¹³ ($\text{MAP} - \text{CSF pressure} = \text{spinal cord perfusion pressure}$).

However, patients who develop clinical features suggestive of cord ischemia should have prompt elevation of the blood pressure to maintain mean arterial pressures between 80 and 100 mm Hg using crystalloids, colloids or even vasopressors such as phenylephrine. These patients should then have an emergent CSF drain placed if a preoperative drain is not in place.

Acutely, an initial 20 cc of CSF is drained and opening pressure should be checked. Subsequently 10 cc of CSF is drained every 1 hour to achieve a target spinal fluid pressure of 10 to 12 mm Hg. Careful monitoring of the CSF pressures with intermittent drainage should be done in the ICU to minimize the

TABLE 56–2 Management of spinal cord ischemia.

Management of Spinal Cord Ischemia
Symptoms of acute spinal cord ischemia (lower extremity sensory/motor deficits or bowel/bladder incontinence)
Maintain MAP between 80-100 mm Hg (with crystalloids/colloids/pressures)
Place emergent lumbar CSF catheter
Drain 20 cc CSF and check opening pressure
Subsequently drain 10 cc/h until you achieve opening pressure of 10-12 mm Hg

risk of subdural hematoma. Overaggressive drainage can result in intracranial hemorrhage and/or herniation (see Table 56–2 for management of spinal cord ischemia).

Optimizing spinal cord perfusion has been shown to result in marked clinical improvement if implemented early.

ISCHEMIC COLITIS

Ischemic colitis is a well-described complication following open and endovascular aortic aneurysm repair; however, it is also noted to occur after aortoiliac revascularization and repair of aortic dissection.¹⁴ Ligation of inferior mesenteric artery and subsequent interruption to flow is the commonly implicated etiology of colitis following major aortic surgery.

Following open repair, larger perioperative fluid shifts, longer aortic cross-clamping time, compressive retroperitoneal hematoma and prolonged hypotension; all of which lead to a state of hypoperfusion seems to be the underlying etiology of the ensuing bowel ischemia and subsequent necrosis. However, the implicated pathogenesis following endovascular procedure also includes embolization of the cholesterol plaque. This is suspected to occur after placement of the stent graft or following manipulation of the aortic aneurysmal sac with catheters and guide wires. The inflammatory response is more pronounced following cholesterol embolization and tends to portend a poorer outcome. Peri-EVAR hypogastric occlusion for complex aneurysm morphologies is also a risk factor.

The presentation of ischemic colitis includes fever, abdominal pain, and distension, increased peristalsis with often, but not always, bloody diarrhea in the immediate postoperative phase. Abdominal examination might vary from localized tenderness to diffuse peritonitis. Laboratory values range from leukocytosis with left shift, lactic acidosis (a useful early and consistent marker of bowel ischemia) with metabolic acidosis, significant electrolyte abnormalities, and eventual hemodynamic instability if abdominal sepsis ensues.

Early recognition is vital and the diagnosis requires a high index of suspicion as the initial picture might sometimes only reveal vague abdominal pain and a gradually rising lactate in the setting of fever and leukocytosis. When the diagnosis is suspected, fluid resuscitation and broad spectrum antibiotics aimed at colonic flora should be started.

The diagnostic test of choice is sigmoidoscopy or colonoscopy (done as routine postoperative screening in some centers) with findings ranging from superficial ulcerations, mucosal erythema to mucosal sloughing and full thickness necrosis. CT imaging with contrast is also recommended which might reveal wall thickening, mesenteric fat stranding, mucosal enhancement, intramural air, colonic dilation and in advanced cases portal venous air. CT or endoscopy findings suggestive of mucosal or full thickness transmural involvement, in addition to the patients' hemodynamic status will determine need for surgical intervention versus supportive measures alone, with the unstable patient showing evidence of transmural necrosis necessitating immediate colon resection.

Supportive measures include adequate fluid resuscitation and blood pressure support. Use of vasopressors in the setting of bowel ischemia though controversial is necessary in the background of requiring an adequate blood pressure. If vasopressors are needed then beta adrenergic agonists that improve cardiac output are recommended over alpha agonists. Broad spectrum antibiotics should be initiated empirically covering gram negative and anaerobic organisms, after blood cultures are drawn. There is a high degree of risk of bacterial translocation with a breach in bowel wall mucosa.

In most cases of ischemic colitis, surgical intervention leading to a left colectomy with colostomy is required. Ischemic colitis should be differentiated

from acute mesenteric ischemia (AMI). The clinical deterioration in AMI is much more profound and the lactic acidosis is more pronounced. With colitis, the pain may be localized to the LLQ. With AMI, the pain is usually generalized and out of proportion to the physical exam. Eventually frank generalized peritonitis ensues.

AORTIC DISSECTION

Aortic dissection occurs secondary to a tear within the aortic wall that is propagated by the aortic pulse wave.¹⁵ Studies indicate an incidence of 3 cases per 100,000 in a year.

A preceding history of strenuous exercise or drug use (cocaine, amphetamine) is highly suggestive of acute aortic dissection. The presentation is sometimes complicated by malperfusion syndromes, aortic rupture, acute valvular insufficiency, and cardiac tamponade. Malperfusion can manifest in a wide range of organ dysfunctions based on the branch vessel that is obstructed. Malperfusion syndrome is defined as the loss of blood supply to a vital organ caused by a branch arterial obstruction secondary to the dissection. This obstruction can be fixed or dynamic.¹⁶ Fixed obstruction is less common and results in a nonreversible branch vessel occlusion. Commonly, the branch vessel obstruction is dynamic. In this form of obstruction, the branch is compressed with each cardiac pulsation. The result of both forms of obstruction is end-organ ischemia, with possible malfunction and infarction if not corrected in a timely fashion. Reducing the heart rate is first priority. A reduced number of pulsations results in less dynamic compression and reduces the likelihood of propagation. Once the heart rate is controlled then, the blood pressure should be reduced.

Types of Dissections

The classification of aortic dissection is based on anatomic location of entry tear and/or the extent of the dissection flap. This information is crucial to the management of the dissection. It drives the decision to proceed with surgical or medical management. The commonly used classifications are the Stanford¹⁶ and DeBakey¹⁷ systems, as listed in [Table 56–3](#) (see [Figure 56–3](#) for diaphragmatic representation of the above classifications).

TABLE 56–3 DeBakey and Stanford classification.**DeBakey**

- Category I: Dissection tear in the ascending aorta propagating distally to include at least the aortic arch and typically the descending aorta
- Category II: Dissection tear only in the ascending aorta
- Category III: Dissection tear in the descending aorta propagating most often distally
- Category IIIa: Dissection tear only in the descending thoracic aorta
- Category IIIb: Tear extending below the diaphragm

Stanford

- Type A: All dissections involving the ascending aorta irrespective of the site of tear
- Type B: All dissections that do not involve the ascending aorta; note that involvement of the aortic arch without involvement of the ascending aorta in the Stanford classification is labelled as type B

Proximal
DeBakey I and II
Stanford A

Dis tal

FIGURE 56–3 Stanford and DeBakey classification. (Reproduced with permission from Nienaber CA, Clough RE: Management of acute aortic dissection, Lancet. 2015 Feb 28;385(9970):800-811.)

The highest mortality is in the first 48 hours, hence early recognition is very important. It becomes especially critical in younger patients, those with connective tissues diseases and in women who can present with atypical symptoms and signs.

Diagnostic Evaluation

Chest X ray: Demonstrates widened mediastinum, double or irregular aortic contour. It may also be normal.

EKG: May show signs of coronary malperfusion.

Labs: Elevated cardiac enzymes, LFT, lactate.

CT angiography (CTA) is the investigation of choice.¹⁸ It is widely available, fast, and noninvasive. It helps to diagnose and classify dissection and also enables early identification of distal complications with detailed views of cardiac, thoracic, and vascular anatomy (see [Figure 56–4](#) for axial and [Figure 56–5](#) for coronal CT scan view of type B dissection).

Transthoracic ECHO (TTE)—In a hemodynamically unstable patient, focused cardiac ultrasound by a trained intensivist can help with time sensitive assessment and evaluation of aortic root size, valvular function and the presence of dissection.

Transesophageal ECHO (TEE)—Offers much better imaging and spatial resolution for evaluation of primary tear, secondary communication and true lumen compression.

FIGURE 56–4 Type Baortic dissection.

FIGURE 56–5 Type Baortic dissection.

Management of Acute Aortic Dissection

Type A dissection—Patients with acute type A dissection who do not receive treatment die at a rate of 1% to 2% per hour during the first day and almost half die by 1 week. Therefore, emergent surgical repair is an absolute indication for acute ascending aortic dissection as there is a high risk of mortality given the imminent danger of retrograde dissection and all the previously discussed cardiac complications.

Type B dissection—Patients with uncomplicated descending thoracic aortic dissection are traditionally treated with medical therapy. In addition to medical management, complicated dissections (malperfusion, aneurysm, and refractory pain) require early TEVAR ± adjunctive procedures as needed vs open surgical repair. Open surgical repair has a high perioperative morbidity and mortality and is rarely a treatment of choice. More recently, the trend is toward endovascular management of high-risk type B dissections, even if uncomplicated.

High-risk patients include those with patent and large false lumens (> 22 mm) and those with aortas measuring more than 4 cm at initial presentation. Ideally, this treatment should be offered to those with a life expectancy of approximately 5 years. Endovascular treatment of high-risk uncomplicated type B dissections should be performed during the subacute phase (2–6 weeks) if possible.¹⁹

ICU Management

Patients with profound hemodynamic instability need to be intubated and ventilated without delay.

Medical therapy is imperative in the management of Stanford type A and type B dissections. Medical management hinges on limiting propagation of the intimal tear and reducing blood pressure over time (dP/dT). Close monitoring in an ICU with an aim to achieve rapid reduction in heart rate and normalization of blood pressure is critical. Importantly, ensuring adequate analgesia to prevent a pain induced catecholamine response, which will cause increased shear stress on the intimal wall, is imperative. Constant vigilance for any evidence of organ or limb malperfusion is also fundamental in the management of these tenuous patients.

Impulse Control

The goal is to reduce left ventricular contractility, prevent and avoid tachycardia to decrease the shear force and hence minimize propagation of the intimal tear. The aim is to achieve a target systolic blood pressure of 100 to 120 mm Hg and a heart rate of 60 to 75. This is best achieved by IV beta blockade such as labetalol and esmolol. Esmolol has the advantage of a shorter half-life and thus potentially less risky to use in patients with intolerance to beta blockade such as those with asthma and heart failure.

If after beta blockade, the blood pressure still remains elevated, then an IV nitroprusside drip or IV calcium channel blockers can be added. Nitroprusside should not be used without prior beta blockade, as the vasodilation alone can cause reflex tachycardia and increased left ventricular contractility and worsening wall shear stress. Hydralazine is generally avoided because it increases aortic wall shear stress. All these patients should be monitored

in an ICU setting with an arterial catheter preferably in the arm with the higher blood pressure.

Pain control—In most cases pain is an indication of persistent dissection and resolution of the pain can be a marker of halting dissection. Persistent pain evokes a strong catecholamine response and can aggravate the tachycardia causing an increase in the shear stress. Hence good pain control with narcotics such as morphine or hydromorphone should be given with close monitoring of respiratory status and hemodynamic parameters in an ICU.

Recognition of malperfusion—As previously stated the need for early recognition and high clinical index of suspicion for organ and limb malperfusion is imperative for appropriate management of type B dissection. Always look for evidence of organ malperfusion with laboratory evidence of lactic acidosis, metabolic acidosis, probable rhabdomyolysis (in cases of limb ischemia, abdominal ischemia) such as CPK elevation, urine myoglobin, and organ-specific enzyme elevation. In a system-based approach watching for clinical exam findings as listed in Table 56–4 is necessary.

TABLE 56–4 Malperfusion syndromes.

Anatomic Complications	Symptoms and Signs
Carotid malperfusion	Syncope, focal neurologic deficits
Spinal malperfusion	Paraparesis and paraplegia
Aortic valvular insufficiency	Early diastolic murmur, dyspnea
Coronary malperfusion with myocardial ischemia	Anginal chest pain, dyspnea, ischemic changes in EKG
Pericardial tamponade	Dyspnea, pulsus paradoxus, jugular venous distension, muffled heart sounds
Subclavian or iliofemoral artery malperfusion	Pulse deficit, cold, painful extremity, sensory, motor deficit, syncope
Mesenteric malperfusion	Nausea, vomiting, abdominal pain
Renal malperfusion	Oliguria, anuria, hematuria, AKI

CAROTID ARTERY STENOSIS

The location most frequently affected by carotid atherosclerosis is the carotid bifurcation, often with extension into the proximal internal carotid artery (ie, the origin). Progression of atheromatous plaque at the carotid bifurcation results in luminal narrowing, often accompanied by ulceration. This process can lead to ischemic stroke or transient ischemic attack (TIA) from embolization, thrombosis, or hemodynamic compromise (see [Figure 56–6](#) for CT imaging of severe carotid disease).

Carotid artery stenting is a less invasive alternative to endarterectomy. There is a higher risk of periprocedural stroke with angioplasty and stenting limited to patients who are older than 70 years. There is, however, a greater risk of myocardial infarction (nonfatal), cranial nerve palsy (usually transient), and surgical-site hematoma with endarterectomy.²⁰

Postoperatively most of these patients might require closer monitoring and care in an intermediate care unit such as a step down unit.

Carotid surgery is unique in that 1 of the principal components of the physiologic control mechanism of arterial pressure, the baroreceptors in the carotid sinus, are involved in the disease process

itself, and may be affected by the surgical procedure, concurrent therapy, and by anesthesia.

Postcarotid endarterectomy—Carotid baroreceptor denervation causes increased arterial pressure variability.²¹

Bradycardia can be seen perioperatively and intraoperatively. Hypotension or hypertension can be seen. It is imperative to aggressively treat postoperative hypertension in these patients, as it can predispose to cerebral edema, cerebral hyperperfusion syndrome and intracerebral hemorrhage. Elevations in blood pressure with SBP more than 160 mm Hg can be controlled by nitroglycerine drip or nicardipine drip. Low blood pressure with SBP less than 90 mm Hg can be treated with phenylephrine drip.

Postcarotid artery stenting—Stretching of the vessel by the balloon or the stent and stimulation of the carotid baroreceptors can lead to a fall in the vascular tone leading to transient hypotension or bradycardia. Most often the hypotension is transient and resolves in time. Acutely, bradycardia can be managed with atropine or glycopyrrolate. If persistent, a phenylephrine drip may be needed until spontaneous hemodynamic stability is achieved. The baroreceptor may take hours to days to regulate. Early ambulation and activity help achieve a new steady state.

Bradycardia can often be observed in a cardiac monitoring unit, however, in rare cases of symptomatic bradycardia with rates below 40, we recommend atropine at doses of 0.5 mg IV push up to a total of 3 mg. Pacing is rarely needed.

FIGURE 56–6 Severe carotid disease.

ACUTE LIMB ISCHEMIA

Acute arterial insufficiency of the lower extremity presents abruptly with the classical features of ischemia—pain, pallor, pulselessness, paresthesias, and paralysis.

Traditionally, the most common cause was arterial embolization from cardiac sources. With improved anticoagulation and arrhythmia management, arterial thrombosis in the setting of known arterial disease is now the most common cause of arterial ischemia. Other causes include direct arterial trauma, aortic dissection, venous outflow obstruction or low-flow states.

TABLE 56–5 Rutherford classification of acute limb ischemia.

Category	Description/Prognosis	Findings		Doppler Signals	
		Sensory loss	Muscle weakness	Arterial	Venous
I. Viable	Not immediately threatened	None	None	Audible	Audible
II. Threatened					
a. Marginally	Salvageable if promptly treated	Minimal (toes) or none	None	Inaudible	Audible
b. Immediately	Salvageable with immediate revascularization	More than toes associated with rest pain	Mild/moderate	Inaudible	Audible
III. Irreversible	Major tissue loss or permanent nerve damage inevitable	Profound anesthetic	Profound paralysis (rigor)	Inaudible	Inaudible

The Rutherford classification of acute limb ischemia is used to correlate the clinical findings and site of arterial occlusion (refer [Table 56–5](#)). If history and physical examination are clearly demonstrative of acute limb ischemia there should not be any delay in initiating definitive treatment.

Management is primarily divided into surgical or endovascular revascularization. There are many possible surgical options. Endovascular treatments often include thrombolysis. All patients treated with continuous thrombolytic infusions should be admitted to an ICU or step-down unit bed for closer monitoring.

Continuous thrombolytic therapy is used as an alternative to open surgical procedures or to treat residual clot after percutaneous thrombectomy. Lytic therapy is instilled through an infusion catheter positioned in the thrombus. Despite its association with a higher frequency of hemorrhagic complications, intra-arterial infusion of urokinase reduced the need for open surgical procedures, with no significantly increased risk of amputation or death.²² Currently used agents are alteplase, reteplase, and urokinase. Doses are as follows:

Alteplase: continuous, 0.5 to 1.0 mg/kg/h (40 mg maximum); bolus, 2 to 5 mg bolus, then continuous infusion; pulse spray, 0.5 mg/mL at 0.2 mL every 30 to 60 seconds.

Reteplase: continuous, 0.25 to 0.5 U/h (20 units maximum); bolus, 2 to 5 U bolus, then continuous infusion.²³

Based on the TOPAS trial it is now recommended to start the patient on a concurrent subtherapeutic dose of heparin which is given through the arterial sheath to prevent pericatheter arterial thrombosis. Heparin is administered at a subtherapeutic dose to avoid the risk of major intracranial hemorrhage. Heparin is infused at a rate of 200 to 500 units/h when given with intra-arterial TPA with a goal PTT 1.25 to 1.5 times control.

Twenty four hours after initiation of the thrombolytic agents patients are taken back to the angiography suite for reassessment of vessel patency.

In the ICU monitor the following:

1. Blood loss—Assessed by clinical exam and laboratory findings on complete blood count, coagulation parameters (PT, aPTT, fibrinogen, fibrin degradation products). If there is access site bleeding, turn off the thrombolytic agent for 1 hour, and reassess the patient's clinical exam and laboratory parameters. If normal, then restart at the same initial dose or reduced. Any evidence of severe blood loss requires prompt reevaluation by the vascular surgery team, resuscitation, and an early CT scan to assess for retroperitoneal bleeding.
2. Fibrinogen level and coagulation parameters every 6 hours—The risk of major bleeding increases when the fibrinogen level drops to less than 100 mg/dL or the PTT increases to 3 to 5 times the normal. If the fibrinogen

level is less than 100 turn off the thrombolytic infusion and reassess the fibrinogen level in 6 hours. Once normalized then restart the infusion at half the initial dose.

3. Stroke—Neurochecks every hour is needed to assess for hemorrhagic stroke. If a neurologic deficit becomes obvious, all thrombolytics and anticoagulants must be held. Emergency neurology consultation and head CT are needed.

Complications

Rhabdomyolysis secondary to acute reperfusion injury is manifested by markedly elevated CPK levels, lactic acidosis, myoglobinuria, hyperkalemia, and acute kidney injury. All these laboratory parameters should be frequently monitored in an ICU. It is essentially treated with aggressive hydration and if necessary with urinary alkalinization.

Compartment syndrome is a dreaded complication sometimes requiring a 4 compartment fasciotomy. Compartment syndrome can be diagnosed clinically or by finding compartment pressures greater than 30 mm Hg. In the ICU, the diagnosis can be occult and a high index of suspicion is needed. Prophylactic fasciotomy should be done in anyone with more than 6 hours of ischemia or anyone with an unreliable exam.

Smoke Exposure Models in COPD

Patrick Gerahty, PhD and Robert Foronjy, MD

KEY POINTS

- 1 COPD is a leading cause of death worldwide and the lack of effective therapies and continued smoking prevalence indicate that this will be a major public health challenge confronting physicians for years to come.
- 2 COPD is a frequent cause of ICU admission and the diagnosis of COPD in ICU patients increases the risk of ICU delirium, ARDS, and in-hospital and postdischarge mortality.
- 3 Our limited understanding of the pathogenesis of COPD has hindered advancements in treatment of this disease highlighting the need for more basic and clinical research.
- 4 Animal models of COPD, particularly the cigarette smoke exposure model, reproduce key features of the disease providing the opportunity to gain key disease insights within a relatively short time frame.
- 5 Findings from animal models have identified the importance of inflammation, proteases, oxidants, and apoptosis in the pathophysiology of this disease. Furthermore, these studies have established key injury repair mechanisms that are activated in the lung in COPD.
- 6 The findings from these studies could lead to targeted strategies that block damaging injury responses and enhance protective lung repair responses in this disease.

THE SIGNIFICANCE OF CHRONIC OBSTRUCTIVE PULMONARY DISEASE

Chronic obstructive pulmonary disease (COPD) is defined as a disease state characterized by airflow limitation that is not fully reversible.¹ The limitation in airflow is caused by airway inflammation,² loss of lung elasticity,³ lung tissue destruction,⁴ and the closure of small airways.^{5,6} The airflow obstruction progresses over time and loss of lung function impairs the ability of individuals to carry out routine daily activities and greatly increases their risk of death. Indeed, COPD is now the third leading

cause of death in the United States and is projected to become the third leading cause worldwide within the next 20 years.^{7,8} While the age-adjusted mortality for cardiovascular diseases had decreased significantly over the past 3 decades, the age-adjusted mortality for COPD has increased over this time period⁹ highlighting the need for better therapies^{10,11} and increased COPD research. It is well known that exposure to cigarette smoke, both first and second hand, is the primary etiologic factor associated with this disease. Although great strides have been made in reducing smoking prevalence in the United States, 43.8 millions people or 19.0% of the United States population (age 18 or older) continue to smoke.¹²

Moreover, smoking remains a major public health issue for adolescents with the latest surveys showing that 16% of all eighth graders had tried smoking and 17% of high school students continue smoking beyond graduation.¹³ Internationally, the picture is even bleaker with a smoking prevalence of 28% in China,¹⁴ 27% in Germany, and 36% in Russia.^{15,16} These figures ensure that this disease will be a major public health issue for the foreseeable future.

While cigarette consumption is the main risk factor for COPD, 10% to 15% of COPD cases are not related to cigarette smoke exposure.¹⁷ In the developing world, it is estimated that air pollution from biomass smoke accounts for 2.2 to 2.5 million deaths annually.¹⁸ Epidemiologic studies have implicated biomass use in the development of chronic obstructive pulmonary disease (COPD) in adults and acute lower respiratory infection in children.^{19,20} Women are particularly affected given their daily usage of these fuel sources for cooking. Moreover, exposure in women begins early in life and continues for decades.²¹ Indeed, several studies have found increased markers of inflammation and oxidative stress in premenopausal women exposed to biomass smoke.²²⁻²⁴ Worldwide, it is estimated that 3 billion people utilize biomass as their primary source of domestic energy.²⁵ Though plans are underway to distribute improved cook stoves that emit less harmful particulates, these efforts will take time and a continued commitment on the part of public health authorities to impact on the development of COPD in these impoverished communities. Data obtained from cigarette smoking studies suggest that despite discontinuing smoking the rate of progression of COPD does reduce, but it does not prevent persistent airway inflammation and significant progression of COPD observed by CT scan.² Therefore, a large percentage of the current 3 billion people utilizing biomass sources may already have irreversible inflammation and COPD.

THE IMPACT OF COPD ON CRITICAL CARE

Acute episodes of respiratory distress in patients with COPD account for up to 5% to 10% of all emergency medical admissions²⁶ and almost 10%

of these patients are referred to the ICU for further management.²⁷ Hospital mortality for those admitted with COPD is 5.6% and approximately 18% of COPD subjects will die within 180 days posthospital discharge. Historically, COPD patients that develop respiratory failure without a precipitating cause (pneumonia, pneumothorax, pulmonary embolism) have been perceived to have very poor outcomes. Indeed, in the United Kingdom, patients with COPD exacerbation were infrequently admitted to the ICU and withdrawal of treatment was the most common cause of death in these individuals after admission.²⁸ However, the data shows that survival following mechanical ventilation is actually better when no causative factor is identified for an exacerbation.²⁹ Thus, a COPD patient who presents with isolated respiratory failure cannot be “written off” as a lost cause. Short-term survival following an episode of mechanical ventilation for COPD ranges from 63% to 86%.³⁰⁻³² In contrast, long-range survival rates are worse—52%, 42%, and 37% at 1, 2, and 3 years.²⁸ Determining who will benefit from critical care utilization is difficult. Though medical comorbidities, prolonged (> 72 hours) mechanical ventilation and failure postextubation predict poor outcome,³¹ national guidelines do not currently support the use of clinical scoring systems for management of COPD exacerbations.³³ Thus, physicians have little to guide them when judging the appropriateness of critical care intervention in this population.

While many patients make excellent recoveries, others that survive COPD exacerbations suffer with chronic critical illness that impairs their quality of life and causes tremendous financial hardships for their families. Overall, it is estimated that between 5% and 10% of patients requiring mechanical ventilation for acute respiratory failure will develop chronic critical illness.³⁴⁻³⁶ The cost of caring for these patients is estimated to be over 20 billion in the United States and will likely rise as the population continues to age.³⁷ Delirium is a serious adverse event that complicates the management of ICU patients and increases their morbidity and mortality.³⁸ The diagnosis of COPD has been identified as an independent risk factor for delirium in cardiothoracic ICU patients.³⁹ In addition, COPD has been reported to increase the risk of developing ARDS in ICU patients.^{40,41} The specific mechanisms

responsible for this increased susceptibility have yet to be determined. Clearly, an enhanced understanding of the underlying disease pathogenesis is needed for improved prognostication and to develop better means of treating this disease and preventing its associated complications in the ICU.

COPD research funding has been disproportionately low given its impact on public health.⁴² This is undoubtedly due to the fact that this is perceived as a “self-inflicted” disease. For the most part, if people did not smoke they would not develop the disease and if they stopped smoking the disease, if present, would not progress as quickly. This naturally raises the question why should scarce public research dollars be used to investigate a disease that has such a clear-cut solution? However, this perspective clearly ignores the history of this product over the past century. Cigarettes are not marketed toward 20, 30, or 40 years olds.⁴³ Rather, cigarettes, whether in print, sporting events or the movies are aggressively pitched towards adolescents.⁴⁴ This is a group that is more susceptible to peer pressure and influence and less able to gauge the true risks of this habit. In fact, billions of dollars are spent annually marketing this product to young people worldwide.⁴⁵ Unfortunately, adolescents and the public as a whole have a very poor understanding of the addictive potential of this product. Cigarettes are not ground up tobacco leaves wrapped in paper. They are a carefully engineered product laced with chemicals, such as ammonia that speed the absorption of nicotine in the body.⁴⁶ Nicotine reaches the brain within seconds of a puff on a cigarette creating a sensation of euphoria.⁴⁷ These rapid effects are powerfully reinforcing psychologically and help to explain why smoking cessation success rates are so poor.⁴⁸ There are 17 nicotinic acetylcholine receptor subunits in humans that trigger multiple responses.⁴⁹ Cigarettes are a legal product and tobacco companies are permitted to spend billions of dollars to get people to try their product despite the potential of addiction and reliance on this product. Given this current state of affairs, those who suffer from COPD are as deserving of effective treatments as those who suffer from other lifestyle influenced conditions such as diabetes, hypertension, and heart disease. Equally, there are numerous clinical manifestations that occur with second hand smoking, with individuals

who involuntarily undergoing smoke exposure. Thus, there is an urgent need to better understand the pathogenic processes that cause this disease so that more effective therapies can be developed.

THE DEVELOPMENT OF ANIMAL MODELS OF COPD

While we know that cigarette smoke exposure will induce pathologic effects in the lungs of smokers, the mechanisms by which cigarette smoke mediates these changes remain incompletely understood. Studies in humans frequently utilize biological materials from patients who are already in the advanced stages of the disease. Although helpful, these studies may not provide insights into the processes by which cigarette smoke promotes the development of the disease state in the lung. Performing prospective studies in humans could address these limitations; however, such studies would be time-consuming and expensive as COPD is an insidious disease that evolves over many years.⁵⁰ Over the long term, it would be difficult to perform these analyses in a rigorous scientific manner that would limit the confounding effects of other dietary, genetic and environmental variables. Moreover, obtaining biological specimens over this length of time would be costly and require years to answer scientific questions. For this reason, animal models of COPD are needed to better understand the underlying disease mechanisms. After Laurell and Erickson's observation that A1AT (alpha-1-anti-trypsin) deficiency resulted in the premature development of emphysema,^{51,52} the role of elastase in this disease became center focus. A1AT protein is an abundant circulating anti-protease that binds and neutralizes neutrophil elastase within the lung.⁵³ Thus, it was postulated that the unopposed action of elastase would degrade elastin, which is abundant in the alveolar wall, thereby causing the destruction of lung tissue.⁵⁴ This theory was further supported by the finding that intratracheal elastase induced the development of emphysema in rats.⁵⁵ This was one of the first animal models of the disease and it had a tremendous influence on the research direction of the pulmonary field for the subsequent 30 years. After this discovery, emphysema was primarily regarded as a disease of elastin degradation that resulted from an elastase/anti-elastase

imbalance in the lung. Although this model provided important insights into the disease, it had numerous shortcomings that limited its applicability to the human disease. For one, emphysema in this animal model develops within 3 weeks of exposure.⁵⁶ The rapid onset of development does not mimic the human disease, which often takes decades to develop. Thus, it is likely that distinct biological processes are responsible for the pathologic changes that are required for disease initiation and progression to occur. Secondly, by its design, the elastase animal model cannot address the impact of cigarette smoke exposure on the lung. Although cigarette smoke induces expression, release and activation of lung elastases,^{57,58} it also triggers a myriad of other effects that will not be replicated by an elastase disease model. Thirdly, the elastase model reproduces the alveolar destruction that occurs in emphysema but it does not replicate other disease features such as mucus plugging, bronchiolitis and altered lung inflammation.⁵⁹ Indeed, the hallmark features of human COPD such as chronic lung inflammation, impaired lung function, emphysema, mucus hypersecretion, vascular injury, and small airway remodeling are not well represented in this model. Thus, researchers have sought to utilize smoke exposure models to gain more relevant insights into the disease.

Developing a smoke exposure model that would generate emphysematous changes was a laborious process. The early attempts to develop smoke exposure models were complicated by the long exposure time required to develop the disease and the variable effects of cigarette smoke in the exposed animals. Indeed, some of the first studies reported cellular proliferation and mucus metaplasia but not the classical alveolar destruction seen in the human disease.⁶⁰⁻⁶² Hautamaki et al were the first group to successfully overcome these challenges in a mouse exposure model.⁶³ In their model, they used a pump to circulate the cigarette smoke generated by the burning of 2 cigarettes to a Plexiglas chamber containing the mice. Carbon monoxide (CO) measurements showed that the mice had CO levels that were comparable to human smokers. By exposing mice in this manner daily for several months they successfully generated alveolar destruction within the lungs of the exposed mice. Moreover, they demonstrated

that this destruction was dependent on the expression of an elastase, matrix metalloproteinase-12 (MMP-12). Establishing an emphysema model that successfully generated alveolar destruction was one of the most important accomplishments in the pulmonary field in the past 2 decades. Today, investigators are actively using variations of this model to obtain important new insights into the mechanisms of this disease.

The 2 most common smoke exposure models that have been utilized are the nose only and the whole body exposure apparatus.

The nose only system requires restraining the mouse so that their nose is inserted into a cone where they inhale the cigarette smoke.⁶⁴ This generates a uniform exposure that produces emphysematous changes. However, the prolonged periods of restraint are stressful for the mice and the machine can usually accommodate only a limited number of mice (eg, the Jaeger system has 18 ports which is depicted in [Figure 57A-1A](#)). In contrast, whole body exposure systems expose mice to a mixture of both passive and mainstream smoke released from a burning cigarette and mainstream smoke, which is actually smoke aspirated through the cigarette using a pump.⁶⁵ The passive and mainstream smoke streams are mixed and then propelled by a fan to a chamber containing the mice that are housed within their cages. The advantage of this system is that the mice freely move about and have access to food and water ([Figure 57A-1B](#)). Thus, mice in this system can be exposed for longer periods of time. In addition, the whole body exposure system allows for the exposure of large groups of mice. Some systems allow the exposure of up to 120 mice at a time enabling researchers to use large numbers of mice and to perform multiple experiments simultaneously. An important note about whole body exposure systems is that the exposure intensity needs to be monitored very carefully. Cigarette smoke is removed from cages via exhaust valves that are typically maintained with a small aperture in order to allow smoke levels to build up within the chambers. Cigarette smoke releases a large amount of tar that can clog these valves and minimize the flow of cigarette smoke, which can allow for smoke levels to build up to toxic levels. If the tar obstruction of the valve becomes too great, all smoke/air flow stops

FIGURE 57A-1 Typical mouse models for smoke exposure. (A) A nose only cigarette smoke exposure system requires animals to be restrained while they inhale the cigarette smoke. (B) The passive and mainstream smoke streams cigarette smoke exposure system allows animals access to food and water without restraint.

and the mice receive no smoke exposure. Both of these outcomes can ruin a carefully planned experiment. Thus, the mice have to be closely monitored to ensure that airflow is circulating properly and that toxic levels of cigarette smoke are not building up.

This is accomplished by measuring total particulate matter (TPM) concentration within the chamber and carbon monoxide levels in the mice. Typically, the TPM is maintained at 80 to 100 mg/m³, which will produce CO levels in the mice of 10% to 12%.⁶⁵ These levels are well tolerated by the mice and produce the alveolar lung tissue destruction.^{63,65} TPM can be monitored using a filter sample unit fitted with a diaphragm pump and a timer. Utilizing sampling air to measure particulate matter in a specific volume sampled over time allows accurate TPM measurements and consistent exposure to animals.

Although many animals have been used in COPD studies, mice offer very clear advantages, which have led to their becoming the dominant animal model for this disease. For one, mice are small in size and the costs of feeding and housing these animals are far less than dogs, sheep, and large rodents. Also, the mouse genome has been extensively characterized and there is a plethora of antibody, molecular probes and equipment modified for mouse anatomy available for studies in these animals. Likewise, it is far more cost-effective

to generate genetically manipulated mice than it is to do so in other species. The gestational period for a mouse is 21 days compared to a time period of up to 74 days in guinea pigs. This allows investigators to generate large numbers of genetically altered mice in a relatively short period of time. Exposing mice to smoke for 1 year represents approximately 50% of the animal's lifetime, thereby allowing a better representation of lifetime smoke exposure. These cost advantages allow for large numbers of animals to be utilized for smoke exposure studies. This is extremely important when studying this disease, as the effect of cigarette smoke on the lung is highly variable. In humans, some estimates state that only 15% of smokers will develop emphysematous changes in the lung⁶⁶ and the susceptibility of mice to cigarette smoke is also quite variable.^{65,67} Thus, exposing large numbers of mice increases the power of a study to detect significant differences in emphysema between control and genetically altered mice. The typical enlargement of airways observed after 6 months of smoke exposure is depicted in [Figure 57A-2](#).

Mice provide the best opportunity to investigate the mechanisms of this disease. However, as noted previously, not all strains of mice are equally responsive to cigarette smoke.^{65,67} Some strains of mice, such as C57Bl/6J, are relatively resistant to cigarette

FIGURE 57A–2 Histologic comparison of mouse lung after smoke exposure. H&E-stained lung sections from age-matched room air littermates (C57BL/6J strain) and mice exposed to cigarette smoke for 6 months. Images are at 10× magnification.

smoke and develop increases in their mean linear intercept (MLI), a parameter of airspace enlargement, which range from 15% to 20% after 6 to 12 months of exposure.⁶⁷ Because of this, smoke exposure studies using C57BL/6J mice require large numbers of mice to be exposed for long periods of time. This greatly increases the time and expense needed to carry out these exposure studies. In addition, the C57BL/6J mice do not develop increased lung compliance following chronic cigarette smoke exposure.⁶⁵ Numerous mouse strains have been utilized for smoke exposure studies. However, A/J mice are the most sensitive to cigarette smoke and develop increases in their MLI in the range of 20% to 30%

after only 2 months of exposure,⁶⁵ as depicted in [Figure 57A–3](#).

Because of this, the A/J mouse is becoming the preferred strain for smoke exposure studies in mice.⁶⁸ Unfortunately, many genetic mouse models are developed in a C57BL/6J background.

Crossing these mice into a more sensitive A/J background requires several generations of backcrossing. This is a costly and time-consuming endeavor. If the primary endpoint of one's research is emphysema, it may be worthwhile to cross into an A/J background. These mice need less smoke exposure time and develop greater emphysema potentially making it easier to detect changes between

FIGURE 57A–3 Demonstrating the typical MLI observed in age-matched C57BL/6J and A/J mice after 6 months of cigarette smoke exposure or their room air controls.

groups. On the other hand, if one's focus is on inflammation, apoptosis, and protease expression then there is no evidence that A/J mice are superior to C57Bl/6J for examining these parameters.

MECHANISTIC INSIGHTS FROM THE SMOKE EXPOSURE MODEL

Inflammation

The smoke exposure model has provided important new insights into the role of inflammation in the development of emphysema. As observed in humans, cigarette smoke induces a pronounced airway and lung parenchymal inflammatory response, particularly in dendritic cells.^{65,69} Indeed, smoke studies in mice demonstrated that monocyte chemoattractants, such as granulocyte monocyte chemoattractant factor (GM-CSF), endothelial cell monocyte activating protein (EMAPII) and monocyte chemoattractant protein (MCP-1) play a pivotal role in the development of smoke-induced inflammation and emphysema.^{63,70,71} In fact, smoke mediates this inflammatory response by stimulating receptors for advanced glycation end-products (RAGE) on the surface of alveolar macrophages.⁷² The importance of this cell type was underscored by the fact that deficiencies in macrophage number or function ameliorated the inflammatory and destructive changes to smoke exposure in mice.^{63,73}

In addition to macrophages, the murine smoke exposure model has also established that cigarette smoke stimulates the infiltration of CD4+ and CD8+ cells in the lung tissue.⁷⁴ This is significant, as T cells have been linked to emphysema development in the human disease.⁷⁵⁻⁷⁷ In fact, chronic smoke exposure in mice generates an oligoclonal expansion of pathogenic CD4+ and CD8+ cells in a mouse model of COPD.⁷⁸ Furthermore, smoke exposure in mice induced IFN- γ expression by NK cells in the lung.⁷⁹ By stimulating IFN- γ , these cells promote a Th1 inflammatory response that causes lung remodeling and tissue destruction.⁸⁰ More recently, the smoke exposure model identified that IL-17 production by Th17 cells plays an important role in the pathogenesis of this disease.^{81,82} These Th17 cells from smoke exposed mice were capable of generating emphysematous changes when transferred into normal

recipient mice.⁸³ While T cells play a central role in the disease pathogenesis, studies in humans show that lymphoid follicles containing B cells are associated with emphysema.^{84,85} However, the role of B cells in the development of the disease has been controversial.⁸⁶ The smoke exposure model, however, has provided key new insights into the role of these cells in this disease. In mice, the smoke-mediated increase in B-lymphocytes correlated with the development of air space enlargement⁸⁷ and neutralizing the B-cell attracting chemokine CXCL13 prevented smoke-induced emphysema.⁸⁸ Thus, data from the mouse smoke exposure model suggests that both B and T cells are participating in the evolution of this disease.

While the smoke exposure model has identified new roles for T and B cells in COPD, it has confirmed and expanded our understanding of the effect of neutrophils in this disease. Smoke exposure studies in mice affirmed that proteases released from neutrophils break down matrix elements in the lung^{89,90} and inhibiting these proteases exerts a protective effect in this disease.⁹¹ In addition, they demonstrated that cigarette smoke and nicotine sustain inflammatory responses by blocking the spontaneous death of lung neutrophils.⁹² Furthermore, the smoke exposure model showed that IL-1 α is central to the initiation of smoke-induced neutrophilia.⁹³ However, though blocking IL-1R1 prior to smoke exposure prevents the influx of neutrophils and the development of emphysema,⁹⁴ blocking IL-1 late in the disease course could exacerbate lung injury by preventing the resolution of lung neutrophilia. Stimulation of IL-1R1 induces miR135b, which, in turn, suppresses lung inflammation by down regulating IL-1R1 expression in the lung.⁹⁵ Thus, the use of IL-1 antagonists as a treatment for COPD will have to be approached with caution as inhibiting IL-1 in the late stages of the disease may accentuate lung tissue injury by heightening and sustaining the influx of neutrophils in the lung.

PROTEASES IN COPD PROGRESSION

Animal models have shown that cigarette smoke triggers the production of damaging proteases in the lung.^{96,97} These proteases augment lung

inflammation by degrading key structural elements that release chemotactic peptides in lung.⁹⁸ Studies in mice show that anti-proteases, such as alpha one antitrypsin, antagonize these effects to prevent the development of smoke-induced emphysema.^{99,100} Specifically, A1AT blocks the production of MMP-12 and TNF- α in alveolar macrophages from mice¹⁰¹ and prevents caspase-3 activity and apoptosis in lung endothelial cells.¹⁰² Animal studies from the mouse smoke exposure model show that both MMP-12 and TNF- α play a central role in the development of smoke-induced emphysema.^{63,103} Likewise, endothelial cell death is a key process in the onset and progression of COPD.^{104,105} Thus, A1AT, by inhibiting these responses, counteracted key processes responsible for this disease. Alteration on lung signaling can have a profound effect on the protease/antiprotease balance in the lung. Studies in mice show that cigarette smoke inactivates the histone deacetylase SIRT1 leading to the up regulation of MMP-9 and downregulation of TIMP-1.¹⁰⁶ This proteolytic imbalance resulted in the development of smoke-induced emphysema in mice.¹⁰⁷ Furthermore activation of the tyrosine kinase c-Src induced the expression of MMP-9 and MMP-12 both in lung epithelial cells and the lungs from smoke exposed mice.¹⁰⁸ These findings indicate that targeting c-Src may counter the proteolytic process that lead to lung inflammation and tissue destruction in this disease.

Oxidants

The use of animal models has greatly enhanced our understanding of the role of oxidants in the development of emphysema. Chronic smoke exposure studies document the accumulation of oxidative injury in the lungs of exposed mice.^{109,110} Importantly, oxidants can inactivate A1AT thereby negating a key protective mechanism in the lung.¹¹¹ In fact, oxidized A1AT actually enhances the release of MCP-1 from lung epithelial cells. Although cigarette smoke exposure is associated with oxidative stress and the induction of injury lung responses,¹¹² direct evidence of the role of smoke-derived oxidants in the pathogenesis of the disease had been lacking. Studies in nuclear factor (erythroid-derived 2)-like 2 (Nrf2) deficient mice demonstrated that lung antioxidant expression was a key determinant of smoke-induced inflammation and tissue destruction. Nrf2

is a transcription factor that is normally bound to its inhibitor Keap1 in the cytosol. In response to oxidative stress, Keap1 dissociates from Nrf2 allowing it to translocate to the nucleus where it turns on the expression of lung antioxidant genes. Thus, Nrf2 knockout mice had deficient antioxidant responses and this resulted in greater oxidative stress, lung inflammation and airspace enlargement.¹¹³ In contrast, Keap1 knockout mice had decreased inflammation and oxidative injury in response to acute smoke exposure.¹¹⁴ Furthermore, it was demonstrated in mice that enhancing lung antioxidant expression effectively counteracts the inflammation and proteolytic responses to acute and chronic cigarette smoke exposure. Indeed, mice with the transgenic expression of the antioxidant superoxide dismutase-1 (SOD1) were completely protected against smoke-induced inflammation, protease expression, oxidative injury and lung tissue destruction.⁵⁶ This was the first direct demonstration that countering smoke-induced oxidants could have a beneficial impact in this disease. Subsequently, it has been shown the extracellular SOD (EC-SOD) similarly protects against smoke-induced emphysema in mice by preventing the oxidative fragmentation of the extracellular matrix.¹¹⁵ In addition, the antioxidants glutathione peroxidase-1^{116,117} and thioredoxin exert similar protective effects in smoke exposed mice.^{118,119} These studies offer hope that enhancing the antioxidant defenses of the lung can prevent the damaging effects of chronic smoke exposure in the lung. Current antioxidant approaches in humans are limited by pharmacokinetic factors that restrict the lung bioavailability of exogenously administered antioxidants.¹²⁰ Indeed, the n-acetyl cysteine dose used in the BRONCUS study¹²¹ was shown not to significantly enhance lung antioxidant defenses in humans.¹²² This may explain the disappointing results from this clinical trial. Lastly, though these studies indicate that oxidants are contributing to the injurious effects of cigarette smoke exposure, the genetic ablation of the NADPH oxidase actually enhances airspace enlargement and inflammation in smoke exposed mice.¹²³ Free radicals are key mediators of intracellular signaling events. Thus, the complete absence of lung oxidases may alter the ability to the cell to respond to the damaging effects of cigarette smoke exposure in the lung. Rather than an

indiscriminate antioxidant approach it may be more effective to identify redox-regulated processes that could be targeted with specific pharmacotherapies.

Apoptosis

Apoptosis is a critical event in the development of lung tissue destruction and remodeling in COPD.¹²⁴ However, it is difficult to determine how cigarette smoke induces lung apoptosis using only clinical specimens. Thus, the animal exposure model provides a powerful tool for better understanding the apoptotic mechanisms that are triggered by cigarette smoke. Studies in mice showed that apoptotic responses occur in the lung even after short-term cigarette smoke exposure.¹²⁵ Furthermore, these studies show that antioxidant supplementation blocks apoptosis in response to cigarette smoke in these mice. The importance of redox factors on lung apoptosis was further demonstrated in Nrf2 knockout mice. The loss of antioxidant induction in Nrf2 knockouts accentuated the development of apoptosis in both lung epithelial and endothelial cells.¹¹³ Thus, these smoke exposure studies have helped to identify how redox biology influences cell fate in resident lung cells exposed to cigarette smoke.

As observed with oxidants, studies in mice have shown that cytokines, such as IFN- γ , also play a critical role in smoke-induced apoptosis in the lung. Indeed, cigarette smoke up regulates IFN- γ , which then acts through its receptor CCR5 to trigger apoptosis and lung tissue remodeling.⁸⁰ Similarly, TNF signaling has been shown to play an important role in the induction of apoptosis in mouse smoke exposure models. Mice that lacked expression of TNF-receptor I or TNF-receptor II (TNFR1 or TNFR2) were protected against the development of smoke-induced apoptosis, particularly within type II pneumocytes.¹²⁶ This protection was associated with decreased lung inflammation and the preservation of normal lung architecture. Cigarette smoke also induces IL-6 and this cytokine-triggered alveolar apoptosis and emphysema in smoke exposed mice.¹²⁷ In addition to epithelial cells, smoke studies in mice found that IL-18 and the chemokine receptor CXCR3 were important mediators of endothelial cell apoptosis and lung injury.^{128,129} Over the past 10 years, there has been an increasing awareness of the role of the lung endothelium

in the pathogenesis of COPD.⁵⁹ Vascular endothelial growth factor (VEGF) maintains endothelial integrity and prevents cell death.¹³⁰ Impairing VEGF signaling by inhibiting its receptor VEGFR2 augmented inflammation and endothelial dysfunction in smoke exposed mice.¹³¹ This is important as cigarette smoke induces oxidative stress that blocks VEGFR2 activation and impairs VEGF signaling within the endothelium.¹³² Studies in both mice and humans show decreased expression of VEGF within the airways in response to cigarette smoke exposure.¹³³ Moreover, studies in mice show that endothelial VEGF expression is similarly decreased in response to cigarette smoke exposure.¹³⁴ Together, these findings establish that altered VEGF signaling within the lung endothelium causes endothelial cell death and tissue destruction in this disease. Future studies are ongoing to determine whether antagonizing these effects can preserve endothelial integrity and ameliorate the inflammatory and destructive changes that occur in this disease.

RECOVERY MECHANISMS IN COPD

As noted in the prior section, the cigarette smoke exposure model has provided key insights into the mechanisms by which cigarette triggers lung inflammation, protease expression, apoptosis, and tissue destruction. These studies have enabled us to better understand why cigarette smoke causes lung disease. Much less attention, however, has been paid to determining how the lung recovers from the damaging effects of cigarette smoke. This is an important question as enhancing recovery mechanisms may be a means of countering or reversing the harmful biological responses that occur in this disease. Several recent reports have begun to address this issue and have laid the groundwork for future study.^{135,136}

It is well established that FoxP3⁺ T regulatory cells mediate the resolution of inflammatory responses in the lung. In an LPS lung injury model, depletion of these cells exacerbated lung inflammation while adoptive transfer of these cells, even 24 hours after LPS challenge, accelerated lung recovery.¹³⁷ In smoke exposed mice, there is an accumulation of T regulatory cells in the lung.¹³⁸ This suggests that these cells are functioning to limit

the inflammatory responses to this stimulus in the lung. Unfortunately, with chronic exposure T cells were skewed to a T 17 phenotype and away from the development of T regulatory cells.¹³⁹ While these studies point to a protective role for T regulatory cells in COPD, a recent study in mice found that in utero smoke exposure increased T regulatory activity, which impaired tumor clearance later in life by impeding the function of cytotoxic T cells.¹⁴⁰ Given these conflicting findings, further studies are needed to determine whether augmenting T regulatory cell activity will have a beneficial or adverse effect in this disease.

The clearance of inflammation is not a passive process but rather involves innate resolution mechanisms that are activated at the initiation of injury. In the lung and other organs, a class of natural lipid-derived mediators (lipoxins, resolvins, protectins, maresins) is produced to resolve inflammation in a manner that does not suppress the immune system. Lipoxins are derived from cell membrane arachidonic acid and suppress inflammation in asthma¹⁴¹ and lung injury models.¹⁴² Serum amyloid A (SAA) protein, which blocks the effects of lipoxins, is increased in COPD and administering SAA enhances neutrophilic responses in mice.¹⁴³ Thus, the loss of lipoxin activity may contribute to neutrophilic inflammation in this disease. Resolvins, protectins, and maresins are derivatives of omega-3 polyunsaturated fatty acids (ω -3-PUFA). Eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA) are 2 essential ω -3-PUFAs that are converted into these bioactive lipid mediators in order to regulate the local resolution of inflammation.¹⁴⁴ Animal models have demonstrated that resolvins promote the resolution of lung inflammation due to bacterial pneumonia,¹⁴⁵ LPS,¹⁴⁶ or asthma.¹⁴⁷ Resolvins exerted these effects by blocking mast cell degranulation,¹⁴⁸ promoting neutrophil clearance¹⁴⁹ and suppressing NF- κ B activation.¹⁴⁶ Using the mouse smoke exposure model it was shown that resolvin D1 decreases neutrophilic inflammation and up regulates the anti-inflammatory cytokine IL-10.¹³⁵ Given these effects, further studies in this model are needed to determine whether resolvins prevent inflammation and tissue destruction in response to chronic smoke exposure.

The cell contains a tightly coordinated network of kinases and phosphatases that switch proteins from

the phosphorylated to the dephosphorylated state in order to cope with various physiologic challenges.¹⁵⁰ Cigarette smoke activates kinases that promote lung disease by stimulating inflammation,^{108,151} up regulating proteases¹⁵² and inducing apoptosis.¹⁵³ While a significant body of research has elucidated the role that protein kinases exert in these processes,¹⁵⁴ much less is known about the effects of protein phosphatases. Protein phosphatase 2A is the primary serine threonine phosphatase of eukaryotic cells. Cigarette smoke activates PP2A both in human lung epithelial cells and mouse lung.¹⁵⁵ This activation occurs rapidly and limits the intensity and duration of smoke induced inflammation. Indeed, inhibiting PP2A in mice sustained and exacerbated the effects of acute smoke exposure.¹⁵⁵ Though acute smoke exposure activates PP2A, this response is lost with chronic smoke exposure potentially rendering the lung more susceptible to smoke-induced injury.¹⁵⁵ It is important to note that studies from the mouse smoke exposure model showed that PP2A protects against smoke-induced emphysema. In fact, the antioxidant glutathione peroxidase-1 (GPx-1) acted via PP2A to prevent smoke-induced inflammation and lung tissue destruction¹¹⁷ in mice. PP2A plays a pivotal role in preventing and resolving smoke-induced lung inflammation and injury. Thus, targeting PP2A activity in the lung may be an effective means of preventing the onset and progression of COPD.

FINAL THOUGHTS ON THE SMOKE EXPOSURE MODEL

As noted previously, COPD is a leading cause of death worldwide. Despite its importance, there are few specific therapies for this disease and only oxygen has been shown to impact on disease mortality. The lack of effective treatments is due in large measure to the limited knowledge of the underlying disease mechanisms. Over the past 20 years, the cigarette smoke exposure model in mice has provided valuable insights into the biological processes responsible for the disease pathogenesis. Today, the role of proteases, inflammation and apoptosis in the disease development is much better understood. In addition, researchers have identified key counter inflammatory mechanisms that serve to protect the lung against the damaging effects of cigarette smoke

exposure. The knowledge gained from these studies has the potential to translate into effective treatments to prevent or reverse the course of this disease. Additionally, well-established smoke exposure models are now available to test potential new therapies prior to human clinical trials. However, the translational impact of these studies has yet to be realized for a multitude of reasons. For one, COPD is a complex disease that develops over years. Interventions administered during the early or pre stage of disease may not be effective when given to late stage patients. This is a daunting problem for COPD as this is a woefully under diagnosed disease and most cases are not detected till the disease is well established.¹⁵⁶ Unfortunately, most studies that utilize the mouse smoke exposure model administer the intervention before smoke exposure begins or before lung damage is established.¹⁵⁷ This is obviously not what happens with a patient who is newly diagnosed with the disease. Moreover, inhibiting some processes during the early period of exposure may prevent disease but blocking the same pathway in late stage disease may hinder needed compensatory responses. Therefore, the scientific community may be studying the prevention of disease initiation rather than recovery. This may be the case with TNF- α antagonists, which prevented COPD in animal models^{158,159} but were ineffective and potentially harmful in clinical studies in humans.^{160,161} In the future, animal exposure studies will need to be conducted after the disease is already established. The A/J strain of mice will be well suited for these studies because they develop significant emphysema after only 2 months of smoke exposure. Thus, the intervention could be begun at this time point to assess the potential benefit of an intervention. Though changes in study design will help, the limitations of the murine smoke exposure model have to be recognized. Most obviously, mice are not humans. They have shorter lifespans, less submucosal glands and more airway macrophages than their human counterparts.^{162,163} Given these and other biological differences, the mouse model may not fully replicate what occurs in the human lung. Carefully conducted correlative studies in humans are, therefore, needed to confirm promising results obtained with this model. The statistician George E.P. Box once wrote, “All models are wrong, but some models are useful.”¹⁶⁴ The smoke exposure

model, by definition, is an approximation of what occurs in the human lung. It can provide useful insights, but if used without discretion it can obfuscate the truth. The challenge for researchers moving forward will be to conduct exposure studies that integrate physiologic, biologic, and architectural endpoints and then to validate these findings with research using complementary in vitro and in vivo models and studies using human samples. Rushing to drug development or testing based on the results from the smoke exposure model alone is short-sighted especially considering the model’s limitations. Nevertheless, if used wisely, this model can be an important component of a multifaceted research approach for this disease.

Toxic Pulmonary Inhalation

Jennifer Wang, DO and
John M. Oropello, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 Accidental and intentional airway inhalation injuries are a major cause of death in the United States.
- 2 Toxic inhalants include asphyxiants, irritants and systemic toxins that result in airway damage, hypoxia and respiratory failure.
- 3 Tests and imaging should include arterial blood gas, carboxyhemoglobin level, chest radiograph, electrocardiogram (EKG), and may include bronchoscopy.
- 4 Attention should be focused on securing the airway, insuring adequate oxygenation, treating shock, correcting acidemia, cardiac monitoring, and administering available antidotes.

INTRODUCTION

Fires kill more than 3200 and injure approximately 16,000 civilians annually in the United States^{1,2} via thermal, chemical and systemic injury to the airway caused by toxic inhalation of carbon monoxide (CO), cyanide (CN), and other toxins. Toxic inhalation is the major cause of death from fires with 80% of cases related to CO poisoning.³ Complications of toxic inhalation include airway damage, pneumonia, and acute respiratory distress syndrome (ARDS).⁴ More than 50,000 patients a year visit the emergency department with CO poisoning in the United States.⁵

PATHOPHYSIOLOGY

Particles greater than 5 μm in diameter are cleared by the nasopharynx,⁶ but in smoke inhalation, larger particles may lodge deeper in the airway as patients breathe through the mouth.⁴ Thermal injuries from fires primarily affect the upper airways, as air cools as it travels to the carina. Combustion results in decreased oxygen in ambient air and asphyxiation.

Damage to the airway and lung parenchyma result in free radical formation, inflammation, increased capillary permeability, and capillary leakage. Alveoli are filled with fluid and blood. Polymorphonuclear macrophages, IL-1, IL6, IL-8, and tumor necrosis factor- α activation result in atelectasis, bronchospasm, impaired mucociliary function, and in some cases, ARDS. ARDS results from alveolar and lung endothelium capillary injury. Initially inflammation leads to increased capillary endothelial permeability resulting in accumulation of fluid in the alveoli and pulmonary edema. This leads to intrapulmonary shunting as fluid-filled alveoli are perfused but not ventilated, resulting in hypoxemia.

Toxic inhalants can be divided into asphyxiants, irritants and systemic toxins. Asphyxiants induce hypoxia, which can result in headache, dizziness, nausea, dyspnea, altered mental status, cardiac ischemia, respiratory failure, syncope, coma, and seizures. Simple asphyxiants such as helium, argon, carbon dioxide, chlorofluorocarbon refrigerants, methane, and propane displace oxygen and result

in oxygen deprivation. Systemic asphyxiants such as CO, CNs, and sulfides impair oxygen transport resulting in tissue hypoxia and reduced oxidative phosphorylation and hence ATP synthesis. Irritants such as ammonia, chlorine, nitrogen oxides, and sulfur dioxide, and systemic toxins such as hydrocarbons, organophosphates, and metal fumes can cause upper and lower airway burns and destruction resulting in respiratory distress and failure.

DIAGNOSIS AND TREATMENT

In all cases of toxic inhalation (Table 57B–1) priorities include securing the airway and insuring adequate oxygenation, treating shock with crystalloids and vasopressors, correcting acidemia, cardiac

monitoring and administering antidotes if available.⁷ Tests and imaging should include complete blood count, complete metabolic panel, arterial blood gases (ABG), carboxyhemoglobin to rule out CO poisoning, chest radiograph and an ECG to look for arrhythmias and myocardial ischemia.

Any patient that has the potential to become hemodynamically unstable or have airway compromise should be monitored in the ICU. Patients who appear ill or those with serious comorbidities, other injuries such as hypoxia from smoke inhalation, airway compromise requiring mechanical intubation or burns should be admitted to the ICU. All toxic inhalation victims should receive high (FiO₂ 100%) supplemental oxygen, decontamination, airway protection, bronchodilators if necessary and close monitoring.^{8,9}

TABLE 57B–1 Potential toxins in inhalational injury.

Category	Substance	Source	Mechanism of Injury	Specific Treatment Considerations
Asphyxiants	Carbon monoxide (CO)	Motor vehicle exhaust fumes, heaters, smoke, gas	Competes for hemoglobin binding sites, impairs oxygen delivery and usage	100% oxygen, hyperbaric oxygen
	Cyanide (CN)	Paint, nylon, silk, wool combustion, smoke	Inhibits cytochrome oxidase	Hydroxycobalamin, thiosulfate; amyl nitrite, sodium nitrite → methemoglobinemia
	Hydrogen sulfide	Sewer, farm manure, natural hot springs	Inhibits cytochrome oxidase	Amyl nitrite, sodium nitrite → methemoglobinemia (not as clearly effective as in CN poisoning)
Irritants	Ammonia	Nylon, refrigerant, plastic, fertilizer	Upper airway damage	
	Chlorine	Bleach, germicide	Lower airway damage	
	Nitrogen oxides	Wall paper, lacquered wood, dye, diesel combustion	Lower airway damage	Methylene blue
	Sulfur dioxide	Coal, oil, cooking fuel combustion	Upper airway damage	
Systemic toxins	Hydrocarbons	Glue, paint remover, solvents	CNS depression, bronchospasm, coma	
	Organophosphates	Insecticides, nerve agents	Blocks acetylcholinesterase	Atropine ± pralidoxime
	Metal fumes	Welding	Flu-like symptoms, throat irritation, chest tightness	

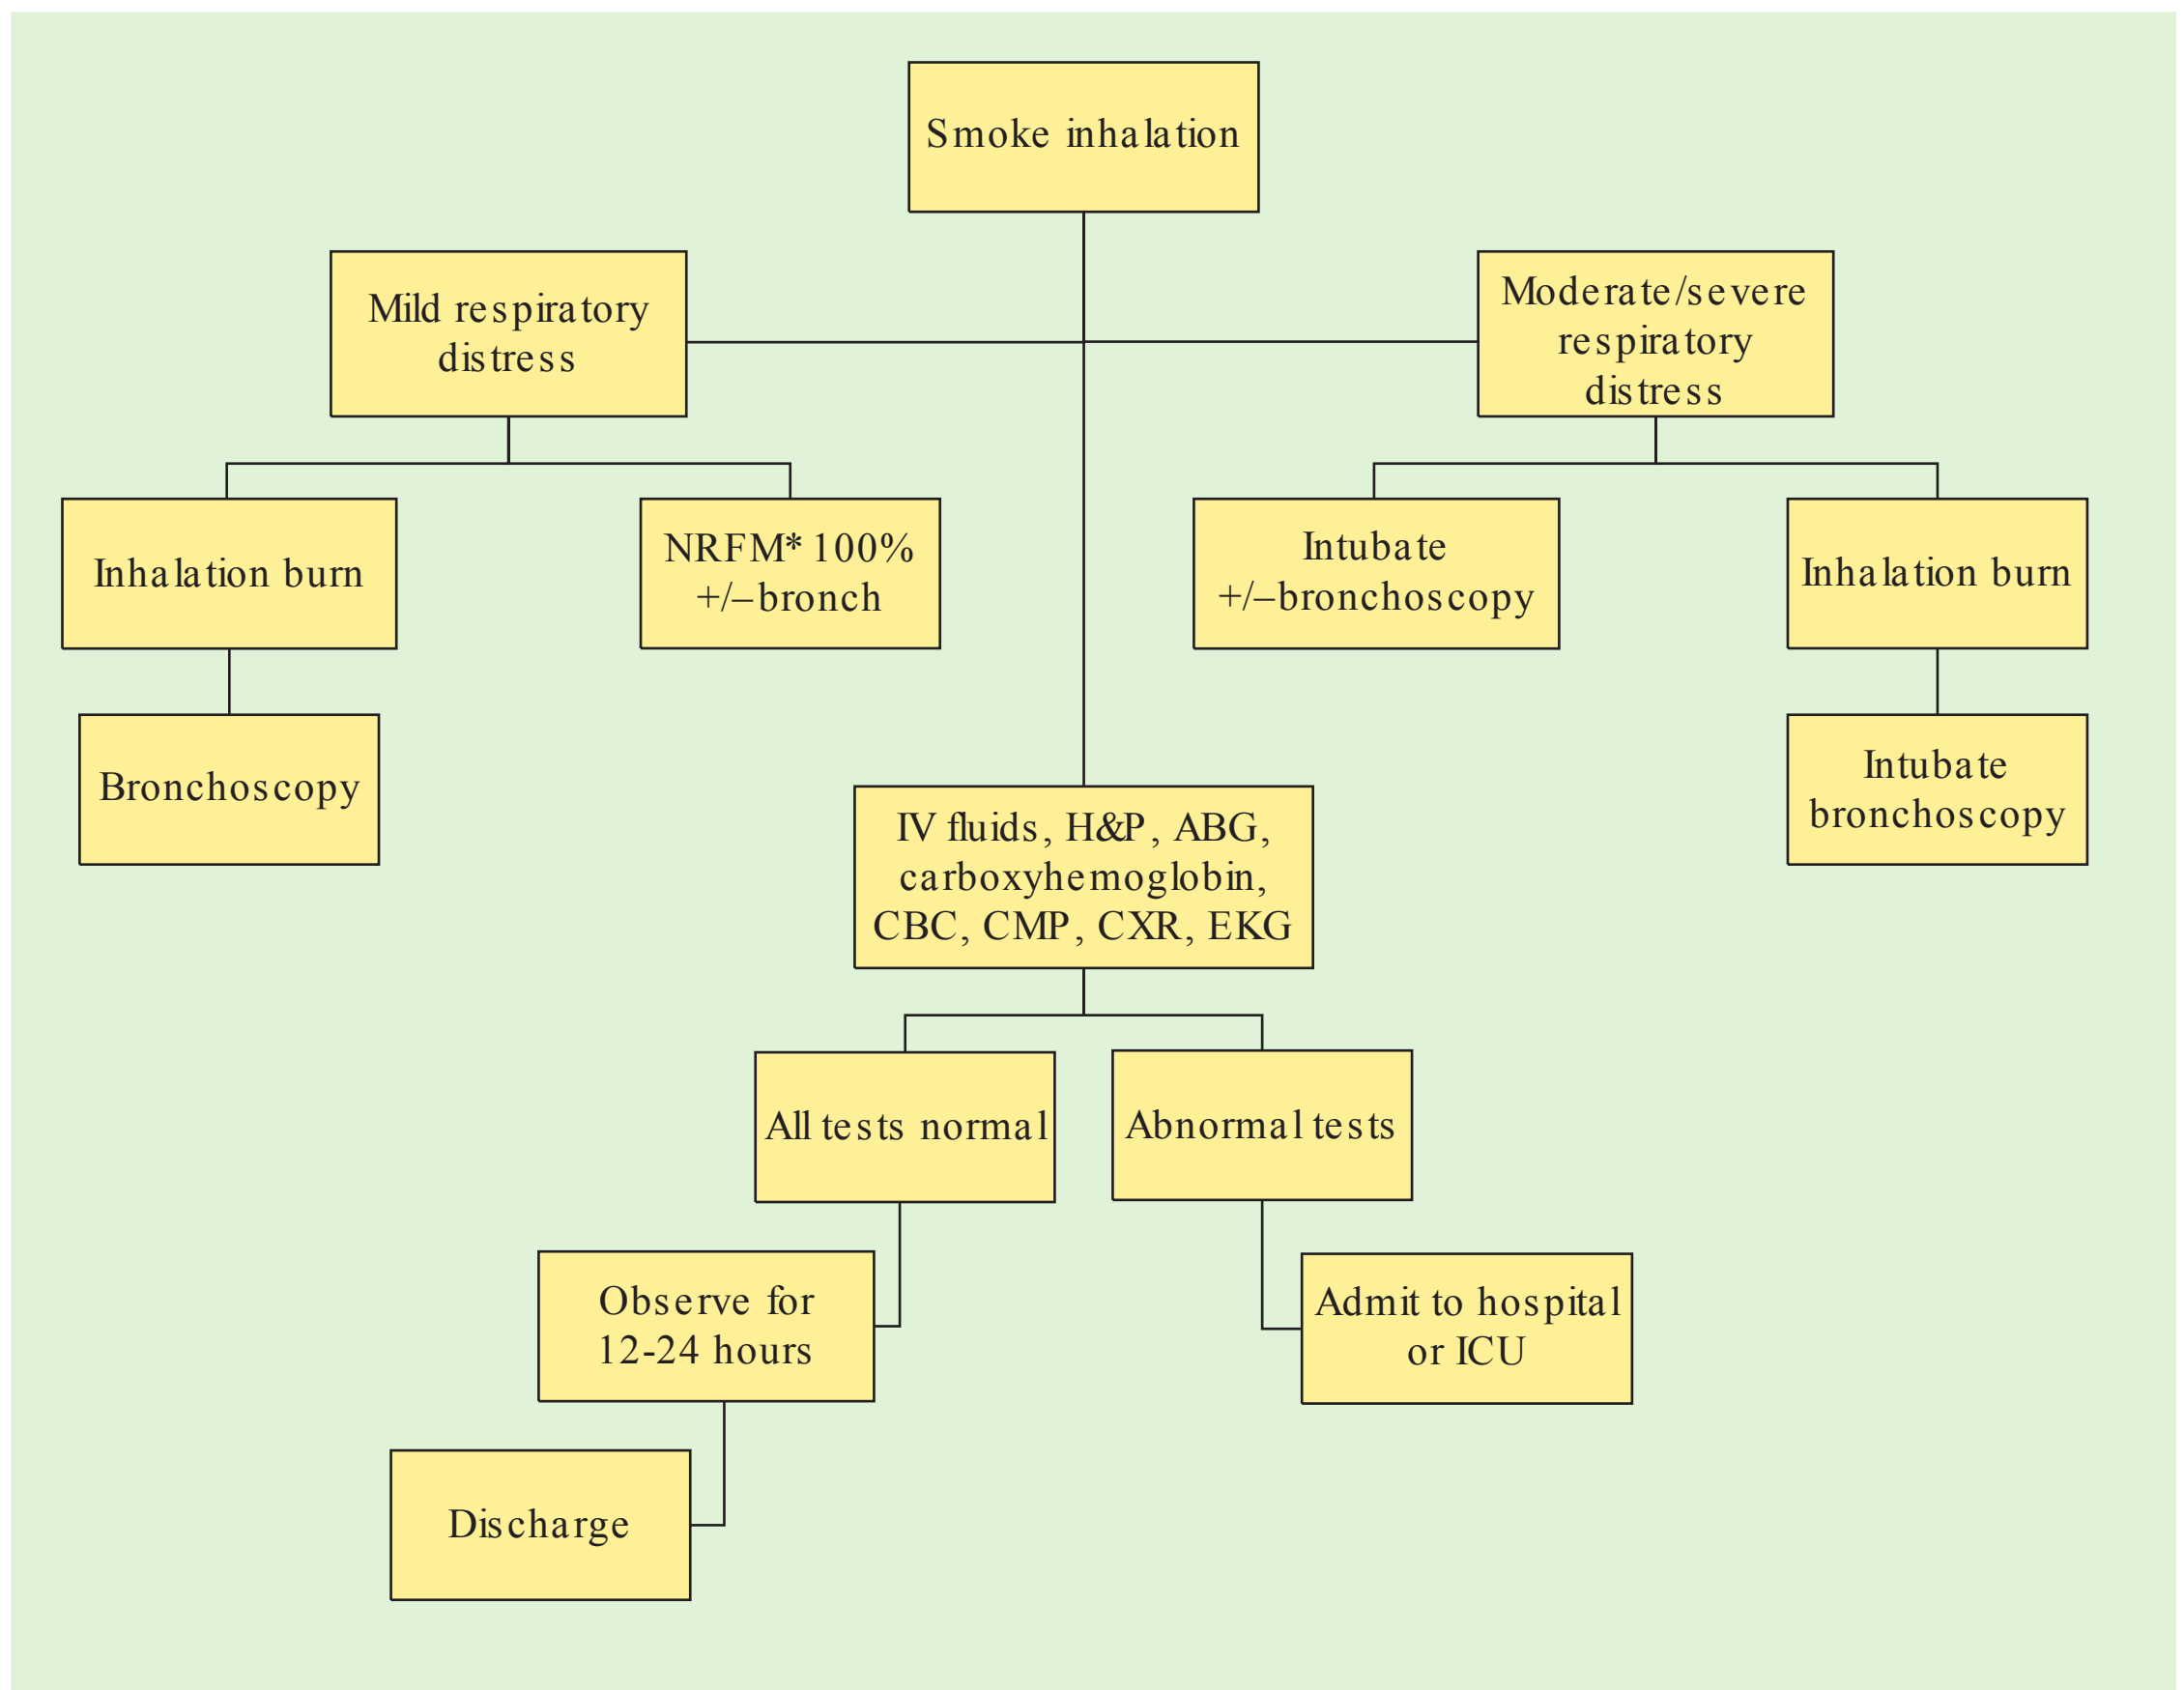

FIGURE 57B–1 Algorithm: Patients with burns in the mouth or difficulty speaking should be evaluated for early intubation. In these patients, laryngoscopy or bronchoscopy can be used to evaluate the extent of airway swelling, ulceration, and structural damage.

Hyperbaric oxygen is useful for CO, CN, and hydrogen sulfide toxicity as it increases the amount of dissolved oxygen in the blood and increases delivery of nonhemoglobin bound oxygen to tissues. Its use is limited by availability. The benefits of hyperbaric oxygen on noncomatose patients are inconclusive.¹⁰ Patients with burns in the mouth or difficulty speaking should be evaluated for early intubation. In these patients, laryngoscopy or bronchoscopy can be used to evaluate the extent of airway swelling, ulceration, and structural damage (Figure 57B–1).

Asphyxiants

CO is the most frequent cause of toxic inhalation in the United States. It is an odorless, colorless gas

produced by incomplete combustion of hydrocarbons. Hypoxia results from hemoglobin having a 200-fold greater binding affinity to CO than to oxygen, causing decreased oxygen transport and unloading. Important sources of CO include motor vehicle exhaust, metal and chemical manufacturing, fires, stoves, cigarette smoke, and unvented space heaters. Elevated carboxyhemoglobin levels confirm the diagnosis. However, low carboxyhemoglobin levels do not exclude CO toxic exposure if there is a delay between exposure and testing; oxygen therapy lowers CO levels more rapidly. Severe CO toxicity causes lactic acidosis. The SaO_2 reported from standard ABG (SaO_2 value is calculated from the dissolved oxygen [PaO_2]) will be normal in the presence

of CO toxicity; direct measurement of oxyhemoglobin with co-oximetry is needed to accurately detect the SaO_2 , which will be lowered by carboxyhemoglobin. It is also important to note that most bedside pulse oximeters cannot differentiate carboxyhemoglobin from oxyhemoglobin and will display a normal SpO_2 (SpO_2 = pulse oximeter measurement of SaO_2) in the presence of low oxyhemoglobin.^{11,12} Of note, the ABG findings seen with CO poisoning also occur with methemoglobinemia.

CN toxicity often occurs with CO poisoning and should be suspected in any smoke inhalation patient with elevated carboxyhemoglobin levels and severe lactic acidosis or with persistent neurologic symptoms despite low carboxyhemoglobin levels, for example, less than 30%.

CN is a colorless gas with a bitter almond smell. It is found in plastics, paints, lacquer, polyurethane, nylon, and rubber. It is also found in cigarette smoke. CN binds to ferric iron in cytochrome a_3 , arresting cellular respiration. CN toxicity causes persistent hypotension and severe lactic acidemia. There is no specific test to diagnose CN toxicity and suspicion is based on the smoke inhalation history and clinical findings as noted above under CO. Hydroxocobalamin, thiosulfate, and sodium nitrite are treatments for CN toxicity. Hydroxocobalamin directly binds CN, thiosulfate increases the detoxification of CN, and sodium nitrite results in methemoglobin formation increasing the affinity of CN away from the cytochromes and toward hemoglobin. Methemoglobin levels must be checked in these patients. In an event, nitrites should not be administered in patients with significant hypoxemia (eg, as a result of high carboxyhemoglobin levels) that cannot tolerate any further reductions in oxygen delivery (oxyhemoglobin) caused by methemoglobin generation.

Hydrogen sulfide is a colorless, flammable gas that is irritating to eyes and mucous membranes and has a rotten egg odor. It is formed from the decomposition of organic material including crude oil, petroleum, sewers, compost piles, cleaners, sulfur springs, and underground fields of natural gas. Toxicity causes central nervous system (CNS) and respiratory depression. There are no specific tests to diagnose hydrogen sulfide poisoning; suspicion is based on the exposure history and clinical findings. There is no specific antidote for hydrogen sulfide

toxicity. Patients should be monitored for ocular inflammation and scarring, and pulmonary edema. Any patient with significant exposure should be monitored for 24 hours for signs of CNS depression and respiratory distress. If these symptoms are present, the patient should be admitted to the intensive care unit. Supportive respiratory and cardiovascular management are primary. Sodium nitrite may have a benefit if administered early in patients without severe hypoxemia by inducing methemoglobin formation to attract hydrogen sulfide away from cytochromes to hemoglobin. Methemoglobin levels must be followed.

Irritants

Irritant inhalation is often a result of manufacturing accidents. Examples include ammonia, chlorine, nitrogen oxide, and sulfur dioxide. Symptoms depend on exposure and solubility. Highly soluble irritants cause upper airway burns whereas low soluble irritants cause lower airway destruction. No specific tests are available to detect irritant toxicity. Ammonia and chlorine have pungent odors, are highly corrosive and cause extensive airway damage, bronchoconstriction and pulmonary edema. Both are used in household cleaners. Ammonia is used in fertilizer and manufacturing. Chlorine is used as a bleach and in manufacturing paper, cloth, and pesticides.¹³

Nitrogen oxides are nonflammable and colorless gases that are found in vehicle exhaust, coal, oil, natural gas combustion, and in manufacturing. Exposure primarily causes lower respiratory tract damage and results in free radical generation, reduced immune function, methemoglobinemia, pulmonary edema, and bronchospasm.

There are no antidotes for ammonia, chlorine, nitrogen oxide, and sulfur dioxide exposure, although methylene blue is used to treat nitrous oxide-induced methemoglobinemia.

Methemoglobin and Treatment of Methemoglobinemia

Methemoglobin is an altered form of hemoglobin where iron is oxidized from ferrous to a ferric state, rendering it unable to bind oxygen. It results in decreased oxygen carrying capacity of blood.

Normal methemoglobin levels are 1% to 3%. Methemoglobinemia results in cyanosis which does not improve with oxygenation and ventilation. Levels above 15% cause cardiac, respiratory, and neurologic symptoms, and levels more than 70% are usually fatal. Sources of methemoglobin include nitrates, exhaust, cocaine, dapsone, metoclopramide, primaquine, rasburicase, and sulfonamides.

Pulse oximeters estimate oxygen saturation by comparing the absorbance of light at 2 wavelengths; oxyhemoglobin absorbs infrared light and deoxyhemoglobin absorbs red light. Methemoglobin and oxyhemoglobin absorbance characteristics are similar, thereby, falsely elevating pulse oximeter readings. Specialized pulse oximeters with co-oximetry measure light absorbance at 4 or more wavelengths enabling accurate measurements of oxyhemoglobin, methemoglobin, and carboxyhemoglobin.

The treatment for methemoglobinemia is methylene blue which rapidly reduces methemoglobin to hemoglobin. In high doses, methylene blue can actually induce methemoglobinemia. Methylene blue is contraindicated in patients with glucose-6-phosphate dehydrogenase deficiency because it is ineffective and can cause severe hemolysis.

Systemic Toxins

Hydrocarbons are organic substances that have the potential to be inhaled as recreational drugs or in workplace accidents. Examples include: gasoline, motor oil, paint, glue, and solvents. Inhalation toxicity of them results in pneumonitis. Organophosphates are found in insecticides, herbicides, nerve agents, fertilizers, and solvents. Organophosphates inhibit acetylcholinesterase, resulting in cholinergic overstimulation. Toxicity is a clinical diagnosis. Symptoms include sweating, lacrimation, rhinorrhea, salivation, bronchorrhea, miosis, weakness, fasciculations, paralysis, tachycardia, hypertension, and respiratory failure. Metal fumes released by welding cause flu-like illness. Symptoms are often transient and self-limited, and are more likely and severe after a period away from work.

Hydrocarbons and metal fume toxicities are treated with supportive care including supplemental oxygen, decontamination, airway protection and bronchodilators if necessary. Organophosphate antidotes include atropine and pralidoxime.

It is essential to remove any contaminated clothing. Healthcare workers must also take precautions while decontaminating victims.

Overdose, Poisoning, and Withdrawal

Edward Mossop, MD and Fred DiBlasio, MD

KEY POINTS

- 1 Supportive care is most important. “Treat the patient not the poison.”
- 2 Always check for the common and treatable coingestants: alcohol, acetaminophen, and salicylates.
- 3 Consider decontamination and the use of antidotes.
- 4 Empiric treatment with glucose, naloxone and thiamine is generally safe in the comatose patient.
- 5 Always seek help from your regional poison control center.

GENERAL PRINCIPLES OF OVERDOSE AND POISONING

Introduction

Exposures to toxic substances, whether accidental or intentional, remain a significant contributor to morbidity and mortality in the U.S. Approximately 10,830 calls are placed to the Poison Control hotline daily, while The American Association of Poison Control Centers (AAPCC) reported over 2.3 million human exposure calls in 2011, most commonly due to analgesics (12.9%), sedatives and antipsychotics (11%), and antidepressants (6.4%).

The American Academy of Clinical Toxicology (AACT) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) provide detailed guidance regarding overdose, poisoning and withdrawal. In addition assistance should always be obtained from regional poison control centers.

The American Association of Poison Control Centers (AAPCC) can be contacted by the following means: www.aapcc.org or 1-800-222-1222.

History and Physical

Clinicians must follow a systematic and consistent approach throughout evaluation and management. A basic history and physical exam, followed by a more focused poison-specific exam, is vital, from which point management is directed toward the provision of acute stabilization, supportive care, prevention of absorption and, when applicable, the use of antidotes and enhanced elimination techniques.

Due to depressed mentation or reluctance to cooperate useful information may be obtainable from a patient's associates (family, friends, and coworkers), or from first responders and bystanders. Environmental clues such as suicide notes, drug paraphernalia and empty pill bottles can provide valuable information. Once the patient is identified, reviewing prior hospital records may reveal a history of recent prescriptions, previous overdoses and any psychiatric history.

Specificity regarding the type of drug or toxin (including; prescription, illicit, over the counter and herbal medications), the dosage, route of exposure, time of exposure or ingestion and intent requires close attention. Unknown pills or chemicals require

TABLE 58–1 Toxidrome oriented physical exam.

Toxidrome-Oriented Examination
Vital signs
Focused neurologic exam centered on level of consciousness (alert, responsive to voice, responsive to pain, unresponsive)
Pupillary and motor reaction
Skin examination (moisture, cyanosis, rashes)
Respiratory examination
Assessement of bowel sounds

Reproduced with permission from Rumack BH, Matthew H: Acetaminophen poisoning and toxicity, Pediatrics. 1975 Jun;55(6):871-876

identification by consultation with a regional poison control center, computerized drug database, or product manufacturers.

Toxidromes are specific symptoms and physical signs that correlate with the manifestations of a drug class on a particular set of neuroreceptors.

Performed quickly while resuscitative measures are being instituted, a toxidrome-oriented exam should include vital signs, a focused neurological exam centered on level of consciousness, pupillary and motor reaction, broad examination of the skin noting moisture, cyanosis, rashes, and puncture marks, focused evaluation of the respiratory system, and assessment of bowel sounds. See [Table 58–1](#) Toxidromes-oriented physical exam and [Table 58–2](#): Toxidrome clinical findings.

TABLE 58–2 Common toxidromes.

Category	Vital Signs	Mental Status	Physical Signs	Agent/Drug
Sympathomimetic	hypertension, tachycardia hyperthermia, tachypnea	Hyperalert, euphoric agitated, delirium	Mydriasis, tremor, increased peristalsis seizures	Cocaine, MDMA Mephedrone, Methamphetamine
Opioid	Hypotension, bradycardia, apnea, shallow breathing, hypothermia	Stupor, lethargy, coma	Miosis, hyporeflexia	Morphine, oxycodone, fentanyl
Sedative-Hypnotic	Hypotension, bradycardia, apnea	Stupor, coma, slurred speech	Hyporeflexia, ataxia,	Benzodiazepines, zolpidem, barbiturates
Anticholinergic	Hypertension, tachycardia, hyperthermia	Agitated, delirium, hallucinations	Mydriasis, dry flushed skin, urinary retention, decreased bowel sounds, dry mucus membranes, seizures	Atropine, antidepressants, antihistamines
Cholinergic	Bradycardia, apnea, shallow breathing	Confusion, agitation, coma	Miosis, salivation, lacrimation, diaphoresis, nausea, vomiting, urination, defecation, muscle fasciculations, weakness, seizures, arrhythmia	Organophosphates
Hallucinogenic	Hyperthermia, hypertension, tachycardia	Agitated but oriented, psychosis, anxiety	Mydriasis, synesthesia, nystagmus	PCP, LSD, mushrooms, MDMA
Serotonin	Hyperthermia, tachycardia, hypertension, tachypnea	Agitation, confusion	Increased muscle tone, hyperreflexia, clonus	SSRIs, dextromethorphan, TCAs, amphetamines

SSRI: selective serotonin reuptake inhibitor; TCA: tricyclic antidepressants; PCP: phencyclidine; LSD: Lysergic acid diethylamide; MDMA: Methylenedioxymethamphetamine

Investigations

Labs

Bedside serum glucose testing is a requirement for any patient with altered mentation, after which immediate empiric dextrose administration is recommended in cases where measurement result is low, or not available. Thiamine should also be replaced in patients suspected to be deficient, to prevent precipitation of Wernicke encephalopathy (chronic alcoholics). However, it is not recommended to delay glucose administration while thiamine is administered.

Salicylates, acetaminophen, and alcohol are all easily available and commonly used agents, therefore may be co-ingested in addition to other medications in deliberate overdose attempts. Acetaminophen and salicylates are also found in numerous combination preparations of prescription drugs and over-the-counter medications. These agents therefore may worsen outcomes or complicate presenting symptoms and signs in an overdose. Because these agents are so commonly used and potentially treatable, it is recommended to routinely check these blood levels in all overdose patients.

Additional basic investigations should include, complete blood count (CBC), serum electrolytes, blood urea nitrogen, serum creatinine, coagulation profile, liver function tests (LFTs), creatine kinase (CK), arterial blood gas (ABG), serum osmolality, calculated osmolar gap, and a urine analysis (crystals, myo- or hemoglobinuria).

Specific scenarios may necessitate additional testing including specific drug levels, or testing for methemoglobin and carboxyhemoglobin. Serum concentrations may be of utility in the management of salicylate, acetaminophen, barbiturates, digoxin, ethanol, iron, lithium, and theophylline overdose as these serum assays provide rapid result and are widely available.

Urine toxicology screen does not necessarily reflect current intoxication, and may serve in some cases as a distracter rather than a diagnostic aid in patients with change in mental status.

EKG

An electrocardiogram may assist in the evaluation for the presence and severity of specific ingestions, or may demonstrate drug-related cardiotoxicity. Serially, the electrocardiogram (EKG) can facilitate

the monitoring of progression of specified toxicities. Performed in all subjects with suspected drug ingestion, the key features to note include heart rate, dysrhythmia, axes, and intervals (QRS and QTc).

Imaging

In some cases, a plain abdominal film may demonstrate radiopaque medications such as iron tablets, and enteric-coated preparations, while indirect visualization of drug packets (body packers and stuffers) may be demonstrated by the alteration of bowel gas patterns. Additionally, visualized radiographic evidence of non-cardiogenic pulmonary edema and/or Adult Respiratory Distress Syndrome on an anterior posterior (AP) chest film, can suggest the exposure to specific toxic agents.

A non-contrast head Computerized Tomography (CT) should be considered in anyone with a change in mental status to exclude non-toxicological causes. In addition significant hypertension and change in mental status, in the setting of overdose with agents with stimulant properties, may be secondary to intracranial complications such as hemorrhage, stroke or encephalopathy.

Initial Hospital Care

“Treat the patient, not the poison” is the adage summing the guiding principle of medical toxicology, and the treatment of this certain population of patients. Still, the methods are generally similar to those utilized frequently in the care of critically ill patients.

In the majority of cases, general supportive care is paramount and frequently sufficient to affect complete recovery, yet initial therapeutic measures will depend on the toxin ingested, severity of illness, and time elapsed between exposure and presentation. Assistance should always be obtained from regional poison control centers.

Airway

Acute respiratory failure and severe acid-base disturbances demand endotracheal intubation and mechanical ventilation. Intubation for the purpose of airway protection should be undertaken early in the poisoned patient with depressed mental status unless a rapidly reversible cause is known given high risk of aspiration, which is increased at times when gastric decontamination must be performed.

Hemodynamic Support

Abnormal hemodynamics such as blood pressure, heart rate, and temperature should be treated in the standard way as per hospital guidelines. An appropriate volume of isotonic intravenous crystalloids should be used to treat hypotension. Refractory hypotension and shock should be treated with direct-acting vasopressors (norepinephrine, epinephrine, or vasopressin) however this may be ineffective in cases of calcium channel overdose (see calcium channel overdose).

Hypertension as sequelae of agitation, or arising directly from ingestion of agents with stimulant properties, can be treated initially with sedatives such as benzodiazepines. Should hypertension require specific therapy due to associated end-organ dysfunction (hypertensive emergency), dihydropyridine subclass calcium-channel blockers are preferable given a profile of potent vasodilatation and few negative effects on cardiac conduction and contractility.

Hyperthermia should be very closely monitored. When the temperature exceeds 39 degrees Celsius urgent cooling is required. Numerous techniques exist and initially should include the use of fans, antipyretic medications (unless contra-indicated), cold IV fluids and ice baths. More specialized methods include the use of intravenous cooling catheters and cooling pads applied to the skin. Those with excessive agitation, recurrent seizures or increased muscular tone may require sedation and paralysis to prevent excessive heat production.

Control of Seizures

Seizures resulting from poisoning or withdrawal are best initially treated with benzodiazepines from which escalation to antiepileptic drugs may be necessitated by persistence of seizures, noting that phenytoin is not recommended in the poisoned patient. In case of refractory seizure, general anesthesia and paralytic agents may be required, and treatment should be monitored with serial or continuous electroencephalography (EEG).

Altered Mental State-Agitation or Coma

Drug associated agitated behavior is best treated with benzodiazepine administration, complemented by high-potency antipsychotics as indicated.

Antipsychotics should however be used with caution as they can lower seizure threshold and worsen hyperthermia and arrhythmias (prolong QT) in certain cases of poisoning. Coma or depressed mental state management should focus on protection of the airway. In those patients with a depressed mental status with no compromise in airway, empiric treatments with naloxone, glucose and thiamine can be administered. The routine use of flumazenil, in the obtunded patient, for potential benzodiazepine overdose is not recommended due to the numerous adverse reactions associated.

Rhabdomyolysis

Rhabdomyolysis is a clinical condition characterized by myocyte injury and leakage of intracellular contents into the extracellular space. The most serious complication is renal failure and it is estimated that 8%-15% of all cases of acute renal failure (ARF) are caused by rhabdomyolysis. There are numerous triggers of rhabdomyolysis, however the final common pathway is depletion of muscle ATP stores causing loss of myocyte integrity causing dysfunction and release of intracellular contents.

Myocyte injury leads to release and increased levels of creatine kinase (CK), myoglobin, potassium, phosphorous, and uric acid. Calcium levels may be low. Myoglobin is excreted in the urine, which becomes a red/brown color. Heme pigment casts cause renal tubular injury and renal failure, which may worsen electrolyte abnormalities and produce an anion gap metabolic acidosis. Other serious complications include cardiac arrhythmias and arrest, compartment syndrome and disseminated intravascular coagulation (DIC). Patients usually report muscle pain, weakness and dark urine. Diagnosis is made by detecting markedly elevated levels of CK (usually greater than 5000 IU/L) with evidence of myoglobinuria on urine dipstick and microscopy.

Drug overdose or poisoning is a common cause of rhabdomyolysis and falls into 3 groups. 1. Trauma: Overdose victims may suffer muscle trauma from accidents or impulsive behavior leading to direct muscle injury. 2. Non-traumatic exertional: Overdose patients may develop extensive muscle activity from agitation or seizures, which can also cause extreme hyperthermia leading to myocyte

TABLE 58–3 Common drugs associated with rhabdomyolysis.

Common drugs associated with rhabdomyolysis	
Lysergic acid diethylamide (LSD)	HIV medications
Alcohol	Statins
Heroin	Macrolides
Cocaine	Colchicine
Amphetamines	Carbon monoxide
Methadone	Cyclosporine
Mushrooms	Antipsychotics
Antihistamines	selective serotonin reuptake inhibitor (SSRIs)

injury. 3. Non-traumatic non-exertional: Certain drugs or toxins can lead to direct myocyte damage. Other drugs may induce coma leading to ischemic compression. Drug induced hyperthermia, without muscle activity, can lead to increased muscle energy demands and subsequent injury. See Table 58–3: Common drugs associated with rhabdomyolysis.

Management of rhabdomyolysis from a poison, drug or toxin initially involves discontinuing the offending agent and using decontamination or enhanced elimination techniques to remove any drug or toxin. Aggressively control any hyperthermia, hyperactivity or agitation. Early and aggressive fluid resuscitation is the mainstay of treatment to prevent renal injury. Fluids should be started if CK levels are > 5000 IU/L. The optimal fluid and rate of repletion are unclear. Fluid repletion should be continued until plasma CK levels decrease to < 5000 IU/L and urine is dipstick negative for hematuria. A forced alkaline diuresis, raising urine pH is raised to above 6.5 with sodium bicarbonate, may diminish the renal toxicity of heme however there is no strong evidence to support this.

Decontamination and Enhanced Elimination
Decontamination involves removal of the toxin/poison from patient surfaces and gastrointestinal (GI) tract. In addition enhanced elimination techniques including ion tapping, chelation

therapy, hemodialysis, hemoperfusion, and lipid emulsion can be used to remove poisons/toxins already absorbed.

Decontamination
Surface Decontamination

Surface decontamination involves the removal of dermal and ocular toxins by irrigation. The eye should be irrigated with an isotonic crystalloid until a physiological pH is restored.

Gastrointestinal Decontamination

The practice known as GI decontamination refers to the functional removal of ingested toxins from the GI tract in order to decrease absorption. No controlled clinical studies have demonstrated that the “routine” use of GI decontamination reduces morbidity and mortality in poisoned patients. However, evidence from human volunteer trials and clinical studies suggest that decontamination may reduce the absorption of toxins in the GI tract and may be helpful in select circumstances

Many methods have faded from clinical practice due to evidence based delineation of poor efficacy, and high risks, as well as position papers compiled by AACT and EAPCCT.

1. **Ipecac**—The only emetic suitable for use in humans is syrup of ipecac, and despite its unique niche, use has significantly declined due to lack of proven efficacy and risk of adverse events and therefore is not recommended.
2. **Orogastric lavage**—Gastric lavage involves the insertion of a large-bore 36- to 40-French orogastric tube and the subsequent positioning of the patient in the left lateral decubitus position with the head of the bed in Trendelenburg position. The instillation of approximately 250mL of water or saline follows, with the immediate evacuation via suction applied to the distal end of the tube. This cycle is completed until the evacuated solution is free of pill fragments or particulate matter. This method is only considered to be useful in the first hour post ingestion and has been used for agents that do not bind well to activated charcoal as well as for specific life threatening poisons such as tricyclics, theophylline and cyanide.

Recent papers however, suggest that gastric lavage may be associated with serious complications,

namely aspiration, esophageal perforation, hypothermia and death. The American Association of Poison Centers (AAPC) and the European Association of Poisons Centres and Clinical Toxicologists (EAPCCT) have issued a joint statement that gastric lavage should not be employed routinely, if ever, in the management of poisoned patients.

3. Activated charcoal—Activated charcoal (AC) is an organic material, which adsorbs chemicals with a molecular weight range of 100-1000 Daltons, preventing gastrointestinal absorption and subsequent toxicity. The agent can be administered orally or via a nasogastric tube, in single- and multi-dose regimens depending on the toxin ingested, and is administered in a slurry in water containing 25 to 100 g initially (or for single dosing) followed by 25 to 50 g every 2 to 4 hours in adults, unless the toxin dose is known, in which case the dosing of charcoal to toxin is a 10:1 ratio.

Many chemicals adsorb avidly to AC in a dose dependent fashion but certain substances particularly highly ionic compounds with low molecular weight, mineral acids, and strong bases do not bind well. AC has not been shown to adsorb ethanol, even when administered prior to ethanol ingestion. See [Table 58–4](#): Poisons not well bound to activated charcoal.

The one most likely to benefit from single dose activated charcoal (SDAC) must present within one hour of poison ingestion, but despite lack of evidence, potential for benefit later in the course cannot be excluded.

Contraindications include a depressed mental status without airway protection (risk of aspiration), increased risk of severity of aspiration based on ingested toxin (eg, hydrocarbon ingestion), a need for endoscopy, ingestion of a poorly adsorbed toxin (metals including iron, lithium, alkali, mineral acids, alcohols), presence of intestinal obstruction, or concern for decreased peristalsis.

The AACT/EAPCCT recommends multiple-dose activated charcoal (MDAC) be considered only for patients having ingested life threatening amounts of carbamazepine, dapsone, phenobarbital, quinine or theophylline. See [Table 58–5](#): AACT/EAPCCT recommended drugs amenable to repeat dosing of activated charcoal.

TABLE 58–4 Poisons not well bound to activated charcoal.

Mercury
Iron
Zinc
Acid/Alkalis
Hydrocarbons
Alcohols
Lithium
Calcium
Magnesium
Potassium

4. Bowel irrigation—Whole bowel irrigation refers to the rapid elimination of unabsorbed toxin from the GI tract through the use of iso-osmotic polyethylene glycol solution at 25 to 40 mL/kg/hr until the rectal effluent is clear. Enteric-coated and extended-release preparations, certain metals, as well as drug packets could be expelled expeditiously in this manner.

Despite an absence of specific evidence to support improved outcomes, sizeable iron overdoses, carrying high morbidity, may benefit from this therapy noting the lack of an alternative.

TABLE 58–5 AACT/EAPCCT recommended drugs amenable to repeat dosing of activated charcoal.

Drugs amenable to repeat dosing of activated charcoal

Theophylline

Enhanced Elimination Techniques

Ion Trapping and Forced Diuresis

The urinary excretion of some drugs can be enhanced by alkalization of the urine with the administration of intravenous sodium bicarbonate to produce urine with a pH ≥ 7.5 , exploiting the fact that the ionization of a weak acid is increased in an alkaline environment thereby making it lipid in-soluble, reducing reabsorption and enhancing elimination by trapping the toxin in the urine.

Urine alkalization should be considered first line treatment in patients with moderate to severe salicylate poisoning that do not meet criteria for hemodialysis. See Table 58–6: Drugs with enhanced elimination by alkaline diuresis.

Chelation Therapy

Chelation therapy involves intravenous, intramuscular or oral administration of chelation agents to bind heavy metals in the blood stream promoting enhanced renal excretion. See Table 58–7: Different chelation therapies.

Extracorporeal Techniques

Hemodialysis (HD) can be used to remove certain toxins and correct electrolyte and acid-base disturbances induced by toxins. For HD to be effective, the toxin must reside primarily in the extracellular fluid.

Hemoperfusion (HP) refers to the circulation of blood through an extracorporeal circuit containing

TABLE 58–7 Different chelation therapies.

Agent	Route of Administration	Metals Bound
Dimercaprol	IM with urine alkalizing agent	Arsenic, gold, lead, mercury
Penicillamine	Oral	Copper, arsenic, lead
Deferoxamine	IV, IM, or SC	Iron

an adsorbent such as activated charcoal or polystyrene resin. Drugs that are adsorbed by activated charcoal are the same drugs that are amenable to HP.

Hemofiltration, peritoneal dialysis, plasmapheresis, and exchange transfusion can also help eliminate certain toxins. See Table 58–8: Poisons amenable to hemodialysis.

Lipid Emulsion

Intravenous lipid emulsions (ILE) are the fats used in total parenteral nutrition, and ILE has been used to treat toxicity due to lipophilic medication including verapamil, beta blockers, some tricyclic antidepressants, bupivacaine and chlorpromazine.

The proposed mechanism of action is that the ILE acts as a “lipid sink” surrounding a lipophilic drug molecule and rendering it ineffective. A second mechanism proposed is that fatty acids

within the ILE provide the myocardium with a ready energy source thus improving cardiac function.

Antidotes

While in the majority of poisoning cases supportive care is the key element to improving the survival, a small number of toxins are amenable to a “silver bullet” in the form of an antidote.

By varied means, antidotes reduce or reverse the effects of a poison, but half-life of both the toxin and the antidote must be taken into account during treatment, especially regarding instances of antidotes that antagonize end-organ effects or inhibit conversion to toxic metabolites. See [Table 58–9](#): Common antidotes/treatments.

Disposition

After the initial evaluation, treatment and observation period, patients who suffer from severe toxicity or who are at risk for complications should be admitted to the ICU. Advanced age, abnormal body temperature, and suicidal intent are associated with an increased risk of death.

Sustained-release products, and agents with delayed onset or prolonged action may require up to 24 hrs. of observation to ensure safety.

SEDATIVE-HYPNOTIC OVERDOSE

Sedatives and hypnotics are very commonly abused agents and include; benzodiazepines, barbiturates, and nonbenzodiazepines (zolpidem, zopicline, buspirone, GHB gamma-hydroxybutyric acid). Their use is frequently combined with alcohol and other drugs such as opiates. Typically patients have depressed neurological signs and can develop cardiac, respiratory, renal and gastrointestinal dysfunction. Withdrawal from sedative-hypnotics is often associated with seizures, which can be fatal.

Benzodiazepines

Benzodiazepines (alprazolam, diazepam, lorazepam) are sedative-hypnotic agents used to treat anxiety, seizures, withdrawal states, insomnia and drug

associated agitation. Benzodiazepines enhance the inhibitory effect of the neurotransmitter gamma-aminobutyric acid (GABA), which manifests in central nervous system depression.

Clinical Features

Benzodiazepine overdose produces a specific sedative-hypnotic toxidrome. Mild to moderate overdose resembles that of ethanol. The majority of symptoms and signs are neurological and include somnolence, emotional lability, confusion, incoordination, impaired cognition, ataxia, and slurred speech, and may induce horizontal and vertical nystagmus, midriasis and hyporeflexia. Cardiovascular signs include hypotension and bradycardia. Short-term amnesia is a common and often desirable effect especially when used for procedural sedation or general anesthesia. Ingested alone these agents rarely cause significant toxicity, however coma and respiratory and cardiac arrest can be seen in the setting of co-ingestion with other depressants. Rarely patients can exhibit paradoxical excitement, agitation and disinhibition. Predisposition appears to be for younger and older age groups, as well as underlying psychiatric disorders though the mechanism remains unknown.

Differential Diagnosis

Barbiturates, nonbenzodiazepine sedatives (zolpidem, gamma hydroxybutyrate, etc), alcohol and opiates can all cause similar features. Serum and urine toxicological testing is of limited value, as levels do not correlate with clinical findings.

Treatment

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Decontamination with activated charcoal should be considered if ingestion is within 1 hour of presentation. Due to the sedating effects of benzodiazepines and risk of aspiration, the airway should be secured prior to administration. Gastric lavage, forced diuresis and enhanced elimination techniques are not effective.

TABLE 58–9 Common antidotes/treatments.

Common Antidotes/Treatments		
Poison/Condition	Antidote/Treatment	Dose
Acetaminophen	N-Acetylcysteine	140 mg/kg po load, then 70 mg/kg every 4 hr for 17 doses OR 150 mg/kg IVload over 60 min then 50 mg/kg over 4 hr, then 100 mg/kg over 16 hr
Anticholinergic	Physostigmine	0.5-2 mg IVover 5 min
Benzodiazepines	Flumazenil	0.2 mg/kg IV
Beta blockers	Glucagon	0.05 mg/kg IVbolus may repeat every 10 min
Bupivucaine/local anesthetic	Lipid emulsion 20% IV	100 ml IVover 1 min, then 400 ml IVover 20 min
Calcium channel antagonists	Calcium chloride 10%	0.2-0.25 ml/kg IV
	Insulin	1 unit/kg bolus with 50 ml 50% dextrose followed by 1 unit/kg/hr with D10 W 200 ml/hr
	Glucagon	0.05 mg/kg IVbolus may repeat every 10 min
	Lipid emulsion 20% IV	100 ml IVover 1 min, then 400 ml IVover 20 min
Cholinergic agents	Pralidoxime (2-PAM)	1-2 g IVover 5-10 min, then 500 mg/hr infusion
Chronic alcohol/ Wernicke syndrome	Thiamine	100 mg IV
Cyanide and nitroprusside	Hydroxocobalamin Sodium thiosulfate (25%)	70 mg/kg IV(max 5 g in 30 min) Can repeat up to 3 times 50 ml IV
Digoxin	Digoxin Fab	5-10 vials IV
Ethylene glycol and methanol	Ethanol 10% IV Fomepizole	10 ml/kg IVover 30 min then 1.2 ml/kg/hr 15 mg/kg IV, then 10 mg/kg every 12 hr
Heparin	Protamine	25-50 mg IV
Iron	Deferoxamine	2 g IM, or 15 mg/kg/hr IV(max dose, 6-8 g/day)
Methemoglobin/oxidizing chemicals	Methylene blue	1-2 mg/kg IV
Methotrexate	Folic acid	1-2 mg/kg IVevery 4-6 hr
Neuroleptic malignant syndrome	Dantrolene	1-2.5 mg/kg IV
	Bromocriptine	2.5 mg po every 6 hr
Opioids	Naloxone	0.1-2 mg IVTitrate to response
Serotonin syndrome	Cyproheptadine	4-12 mg po Repeat every 2 hr
Tricyclic antidepressants	Sodium bicarbonate	1-2 mEq/kg IVbolus Repeat as needed

Specific Therapy—Administration of flumazenil, a competitive antagonist of the benzodiazepine receptor, remains controversial due to the low morbidity and mortality associated with overdose, and the potential for inducing withdrawal seizures in patients who chronically take or abuse benzodiazepines, or in cases of pro-convulsant co-ingestion. Therefore flumazenil should not be used empirically for the sedative-hypnotic toxidrome. Its use is reserved for iatrogenic respiratory depression, in a benzodiazepine naïve patient, undergoing procedural sedation with benzodiazepines. The dose is 0.2mg IV over 30 seconds. Onset of action may take 6 to 10 minutes, with repeat dosing sometimes necessary. A maximum of 3 mg should not be exceeded in a one hour period.

Withdrawal

Withdrawal from benzodiazepines may be fatal. Abrupt abstinence is marked by tremor, anxiety, perceptual disturbances, dysphoria, insomnia, sweating, psychosis, and seizures. Onset is usually within 8 to 48 hours dependent on the half-life of the benzodiazepine and the chronicity of use.

Treatment usually involves reintroduction of a benzodiazepine. Tapering of a long-acting benzodiazepine, such as diazepam, over a few months may circumvent withdrawal, and should initially be started at a dose that abates symptoms.

Barbiturates

Barbiturate use is much less common than benzodiazepine use however is associated with greater mortality and morbidity. Barbiturates cause a dose dependent neuronal depression with symptoms and signs similar to benzodiazepines. Blood levels of barbiturates are useful and may help guide therapy. Treatment is supportive. Myocardial depression is more common with barbiturates over other sedatives and may require vasopressor therapy to maintain blood pressure. Decontamination with activated charcoal within 1 hour of ingestion helps reduce absorption. The AACT/EAPCCT recommends multiple-dose activated charcoal should be considered for cases of phenobarbital toxicity. Alkalinization of the urine with sodium bicarbonate may enhance renal elimination. Hemodialysis can be used in severe cases of phenobarbital toxicity.

Nonbenzodiazepine Sedative-Hypnotics

This includes medications such as buspirone, carisoprodol, chloral hydrate, melatonin, and zolpidem. In general treatment is supportive. Activated charcoal is recommended within 1 hour of ingestion. Of note flumazenil is ineffective. Gamma hydroxybutyrate (GHB) is a nonbenzodiazepine sedative that is potentially fatal and becoming more popular in Europe and the United States and is discussed in detail below.

Gamma Hydroxybutyrate (GHB)

Gamma hydroxybutyrate or gamma hydroxybutyric acid (GHB) is a naturally occurring 4-carbon central nervous system (CNS) depressant with a structure similar to gamma aminobutyric acid (GABA) capable of crossing the blood brain barrier. GHB is lipid-soluble with no significant protein binding and exerts its effects via a novel GHB receptor as well as GABA B receptors.

Initially it was synthesized in Europe and used as a general anesthetic however, its use was discontinued due to numerous adverse effects. GHB has also been used legitimately as treatment for insomnia, narcolepsy, depression and to help wean people from alcohol. It is currently FDA approved in the USA for treatment of narcolepsy and cataplexy as sodium oxybate. GHB causes numerous different clinical effects and was marketed in the 1980s as a bodybuilding and weight loss supplement due to its effects on increasing growth hormone levels. The drug more recently has become abused in nightclubs for its euphoric, relaxation and sexual stimulation effects. GHB is currently illegal in most countries and is produced illicitly and is easily available on the internet or can be produced at home. The drug is also available as GBL (gamma butyrolactone) and BD (1,4 butanediol) both precursor drugs that are not as tightly controlled, however are rapidly metabolized to GHB in the bloodstream. GBL and BD are found in many industrial organic solvents such as acetone-free nail polish removers, paint strippers, cleaning products, and glue debonders and are often marketed as such to avoid detection. The prevalence of GHB use is not known, partly because the drug is not included in drug surveys or on hospital drug screens. Assays are available but are

not easily accessible. However due to the low cost, ease of availability and questionable legal status its use is becoming more popular. Users develop dependence and experience significant withdrawal on discontinuation.

GHB is sold as a sodium salt, in a powder or granular form and dissolves in water to form a clear, colorless, odorless liquid. GBL is sold directly as a colorless, odorless liquid. GHB has a salty taste and is frequently added to various drinks to mask the flavor. GHB is rapidly absorbed and eliminated with a half-life of approximately 30 minutes. It exhibits zero order kinetics at low doses and has a very narrow therapeutic index. Users find it difficult to titrate doses and only need to consume slightly more than their usual dose to develop significant toxicity. GHB manifests a steep dose-effect curve with rapid onset of effect followed by abrupt clearing. Typically the effects last up to 2 hours however, dependent users may dose the drug every 30 minutes to 1 hour.

Clinical Features

Illicit users of GHB and GBL generally fall into two groups. The first group uses the drugs for possible therapeutic health benefits, such as bodybuilders and people attempting self-treatment of insomnia, depression and anxiety. GHB has been shown to increase growth hormone levels and lean body mass. A second group is recreational users, who take the drug at clubs, and bars. At low therapeutic doses GHB has stimulant properties with users experiencing euphoria, disinhibition and enhanced sensuality and empathic states. This can lead to unsafe sexual practices and increased rates of sexually transmitted diseases. Also the drug is often abused concurrently with other illicit drugs such as MDMA, methamphetamine, cocaine, and alcohol.

Due to the narrow therapeutic index acute toxicity is common and users may accidentally overdose. Toxicity manifests as a dose dependent CNS depressant. Hypotension, bradycardia, hypothermia, and respiratory depression are common. At lower doses patients can be agitated and show self-destructive behavior. At higher doses rapid sedation and coma is common and patients can be completely unresponsive to painful stimuli. However due to the steep dose-effect curve, abrupt recovery is common, and users can awake suddenly 1-2 hours after

intoxication. Miosis may be evident as well as nystagmus. Respiratory arrest is the most common cause of death. Amnesia after use is common and this combined with its sedating effects makes GHB a choice for drug-facilitated sexual assault.

Differential Diagnosis

GHB toxicity is a clinical diagnosis and assays are not easily available. Agitation followed by obtundation, bradycardia, and hypothermia followed by abrupt recovery points towards GHB. Barbiturates, benzodiazepines, alcohol and opiates can all cause similar features. Urine toxicology screen may not necessarily reflect current intoxication, and may serve as a distracter rather than a diagnostic aid.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Decontamination with activated charcoal should be considered if ingestion is within 1 hour of presentation as long as the airway is stable. Other elimination techniques are ineffective.

Specific Therapy—In general the treatment is supportive with no effective antidote. Vasopressors may be required for low blood pressure. Bradycardia should be treated with atropine or temporary pacing if severe. Typically once patients wake up they should be observed for several hours however, patients rarely comply and often leave against medical advice.

Withdrawal and Dependence

Due to the short half-life and dependent nature of the drug users may have to dose every 1 to 6 hours. As a result withdrawal symptoms can develop as early as 1 hour after the last dose and usually last between 4 and 14 days. Patients who use the drug for bodybuilding or to relieve insomnia or other medical conditions are more likely to develop dependence and withdrawal when compared to recreational users that use the drug only when socializing. Users admitted to the ICU for acute intoxication, or other unrelated conditions, may develop withdrawal while an inpatient. Neuropsychiatric symptoms are the most common symptoms experienced during withdrawal.

Initially users may have some autonomic symptoms including tachycardia, hypertension, and diaphoresis however vitals signs can remain normal, unlike in alcohol withdrawal. After 24 hours patients develop extreme agitation, combativeness and anxiety and often will need to be physically restrained. Psychiatric symptoms can develop including paranoia, hallucinations and delirium. On physical exam patients often have a tremor, increased muscle tone, myoclonic jerks and nystagmus. Unlike with alcohol and benzodiazepines seizures are less common. Hyperthermia and rhabdomyolysis can develop from the extreme agitation leading to electrolyte abnormalities and renal failure. Death can occur due to cardiac arrest from electrolyte abnormalities. Supportive care is the mainstay of treatment. Long acting benzodiazepines such as diazepam are titrated to control agitation and anxiety. Extremely large doses may be required which may cause significant respiratory depression and require endotracheal intubation and mechanical ventilation. Baclofen (GABA agonist) can be given in combination with benzodiazepines. Patients resistant to benzodiazepines may require barbiturates or propofol and a secure airway. Creatine kinase (CK) levels should be followed due to the risk of rhabdomyolysis, which should be treated with fluids. The role of urine alkalization with bicarbonate to treat rhabdomyolysis in poisoned patients is unclear.

DRUGS OF ABUSE

“Drug of abuse” is a very broad term and is defined as any drug (illicit or prescription), chemical, or plant product that is known to be misused for recreational purposes. The term narcotic generically refers to any psychoactive drug that causes sedation. However, in legal terms it refers to any drug that is prohibited or regulated by the government. Many classes of drugs have potential for abuse, however in this section we will discuss opioids, sympathomimetics and hallucinogens. Sedatives are covered in the sedative-hypnotic section. See Table 58–10: Common drugs of abuse.

Opioids

Opioid refers to any drug, natural or synthetic, that is active upon opioid receptors. Opiate refers to naturally occurring drugs extracted from the opium

TABLE 58–10 Common drugs of abuse.

Class	Drug
Opioids	Morphine, oxycodone, codeine, fentanyl, heroin
Sympathomimetics	Cocaine, methamphetamine, mephedrone, MDMA
Hallucinogens	MDMA, mushrooms, PCP, LSD, cannabis
Sedatives	Benzodiazepines, barbiturates, GHB

poppy plant (morphine and codeine). Opioid receptors are found throughout the central and peripheral nervous system and modulate the release of neurotransmitters with a wide diversity of clinical effects including analgesia, euphoria and anxiolysis. The potency, duration of action and half-life vary widely between different opioids and significant tolerance can develop.

Clinical Features

Opioid overdose produces a specific toxidrome of reduced level of consciousness, respiratory depression, and pinpoint pupils. Other common findings include vomiting, ileus, urinary retention, loss of deep tendon reflexes, bradycardia, and histamine release causing hypotension, urticarial and bronchospasm. Respiratory depression is usually the most serious sequelae. Non-cardiogenic pulmonary edema and ARDS has been associated with heroin (diacetylmorphine) overdose. Opioids may be administered by almost any route, however most are abused intravenously, which can often be associated with cutaneous findings as well as systemic illnesses such as hepatitis, HIV, and endocarditis.

Differential Diagnosis

Opioids are commonly used with other intoxicants such as alcohol or cocaine. The diagnosis of intoxication is largely clinical and is supported by the brisk response to naloxone. Blood and urine toxicology screening can identify coingestants however levels are not helpful. Clonidine can produce a similar clinical picture as opioid intoxication however the response to naloxone is not as pronounced. Sedatives such as benzodiazepines and barbiturates can

look very similar to opioids and there coingestion can make diagnosis challenging.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing, and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Abdominal imaging may display evidence of body packing or stuffing. Decontamination with activated charcoal is advisable in suspected oral ingestion especially if co-ingestants are suspected and presentation is within 1 hour. It is reasonable to assume that administration of activated charcoal later than 1 hour post ingestion may be beneficial for sustained release oral preparations but there is no clinical trial evidence to support this. Whole bowel irrigation with polyethylene glycol can be used in asymptomatic body packers to help expel packets.

Specific Therapy

1. Transdermal opioids patches should be looked for and removed.
2. An EKG may reveal a prolonged QT interval (in cases of methadone use) with increased risk of developing torsades de pointes, which may require intravenous magnesium sulfate.
3. Naloxone is the primary treatment for respiratory depression. Aim for reversal of respiratory depression, not full reversal of consciousness. For apnea administer 0.4 mg IV, SC or IM, if no response after 60 seconds give additional 0.8 mg every 60 seconds up to 2 mg. If still no response give additional 2 mg. For opioid dependent patients with respiratory depression administer 0.05-0.1 mg doses, to prevent acute withdrawal, until the desired response is achieved. The preferred route of administration of naloxone is intravenous. For large overdoses consider a naloxone infusion at an hourly rate of 2/3 s of the dose required to wake up the patient per hour.

Withdrawal

Withdrawal from opioids produces a surge in catecholamines producing autonomic instability as well as agitation and personality changes. Onset will

depend on the individual opiate and can by up to 48 hours when associated with long acting drugs such as methadone or extended release preparations. Symptoms include dysphoria, diaphoresis, rhinorrhea, sneezing, muscle aches and cramps and abdominal pain and diarrhea. Methadone is a long acting opiate and is the mainstay of treatment for withdrawal and dependence. Clonidine has been used to blunt some of the autonomic symptoms. Withdrawal seizures will require high doses of long acting benzodiazepines.

Sympathomimetics

Sympathomimetics drugs are a stimulant class of drug that have similar clinical effects as neurotransmitters of the central nervous system such as catecholamines (norepinephrine, epinephrine, and dopamine). These drugs can act through several mechanisms, such as directly activating alpha and beta adrenergic postsynaptic receptors, blocking breakdown and reuptake of certain neurotransmitters, or stimulating production and release of catecholamines. Sympathomimetic drugs are used routinely in hospitals to help support blood pressure and are available with a prescription to treat common medical conditions such as asthma, narcolepsy or hypotension. Sympathomimetics are also available without a prescription in over the counter cold and flu preparations. Illicit street preparations are commonly abused and include, cocaine and designer drugs such as MDMA (3,4-methylenedioxy-methamphetamine), methamphetamine and more recently mephedrone (see Table 58–11).

TABLE 58–11 Common sympathomimetic drugs.

Drug	Use
Norepinephrine, epinephrine, dopamine, midodrine	Blood pressure support
Albuterol, levalbuterol	Bronchodilation
Modafinil	Narcolepsy
Phenylephrine, pseudoephedrine	Over the counter cold and flu preparations
Cocaine, MDMA, methamphetamine, mephedrone	Most commonly used illicitly

Poisoning from sympathomimetic agents can occur secondary to the use of prescription and nonprescription agents. In 2011, approximately 66,540 cases of sympathomimetic and street drug exposures were reported to the American Association of Poison Control Centers.

Cocaine

Other than alcohol, cocaine is the most common cause of acute drug-related emergency department visits in the United States. Extracted from the leaves of the coca plant (*Erythroxylum coca*) the drug originally found utility as a local anesthetic in eye, nose, and throat surgery in its ability to limit bleeding via blood vessel constriction. Cocaine's effects are primarily mediated by blocking re-uptake of presynaptic dopamine, serotonin and norepinephrine. Cocaine has a short half-life and the effects typically last no more than 30 minutes.

Designer Drugs

Designer sympathomimetic drugs are substances commonly used in nightclubs to enhance social intimacy and sensory stimulation. They are synthetic derivatives of federally controlled substances created by slightly altering the molecular structure illegally in clandestine laboratories for illicit use. Many are amphetamine or cathinone analogs, such as mephedrone, methamphetamine and MDMA, with psychoactive properties causing visual disturbances, but are not true hallucinogens.

Mephedrone is a synthetic cathinone derivative of an amphetamine like stimulant, found naturally in the khat plant, which has become extremely popular and is marketed and sold, on the internet and in stores throughout Europe and the USA, as "bath salts." The name derives from instances in which the drugs have been sold disguised as true bath salts. Mephedrone is known to raise both dopamine and norepinephrine, however its exact mechanism of action is unclear.

Methamphetamine is a strong, highly addictive, neurotoxic, amphetamine derived CNS stimulant that has become cheaper and more popular than cocaine in some parts of the USA. Its effects are mediated by both increasing the release and by blocking re-uptake of dopamine, norepinephrine and serotonin. It is more potent and much longer

acting than cocaine, with a half-life of approximately 12 hours, and can be produced from over the counter cold and flu medications. Its use, and associated behaviors, has been associated with increased risk of contracting HIV and hepatitis.

MDMA, more commonly known as "ecstasy" or "molly," is a synthetic amphetamine derived drug with both stimulant and hallucinogenic properties that's effects last typically between 4-6 hours. It causes presynaptic release of dopamine, and norepinephrine but also significantly increases the neurotransmitter serotonin which may precipitate serotonin syndrome. One of its more serious complications is alteration of thermoregulation causing significant increases in body temperature. See Table 58–11: Common sympathomimetic drugs.

Clinical Features

Sympathomimetic toxicity, regardless of the specific drug, produces a specific toxidrome of hypertension, tachycardia, hyperthermia with mydriasis and diaphoresis. Hyperthermia is multifactorial and can be caused by extreme agitation in the setting of a hot club environment as well as due to direct toxicity to thermoregulation. CNS toxicity is manifested as psychomotor agitation, teeth grinding, euphoria, anxiety, psychosis, increased sexual stimulation, hallucinations and can progress to seizures. Cardiovascular complications include tachy and bradyarrhythmias and extreme hypertension leading to myocardial ischemia, aortic and coronary artery dissection, intracranial hemorrhage, encephalopathy and ischemic strokes. Other complications include rhabdomyolysis and renal failure. Death is most commonly secondary to seizures, cardiac arrest or hyperthermia. Sympathomimetic drugs are commonly associated with body packers and stuffers, which if associated with rupture of a bag, can lead to extreme systemic symptoms as well as local bowel ischemia and bleeding. Serotonin syndrome (change in mental status, autonomic stimulation and neuromuscular activity) can occur with MDMA, cocaine and amphetamines. In addition to the above symptoms specific drugs can produce unique features:

Cocaine—Cocaine is frequently associated with chest pain and EKG changes. Cocaine use in pregnancy has been associated with spontaneous abortion, placental abruption, and intrauterine

growth retardation. Crack cocaine can cause pulmonary complications such as pulmonary edema and bronchospasm. Due to the very short acting nature of cocaine it is typically abused in a binge pattern.

Mephedrone—Patients intoxicated with mephedrone can present with “excited delirium.” Although not specific, this may be more common in mephedrone users over other sympathomimetics.

Methamphetamine—Methamphetamine is highly addictive and can be associated with frequent emergency department visits and long-term health problems such as weight loss, dental problems, and skin sores. Its neurotoxic effects can lead to a loss of fine motor skills and impaired verbal learning. Methamphetamine is also associated with increased risk of HIV and hepatitis due to needle sharing and increased sexual stimulation.

MDMA—MDMA use can be associated with more hallucinogenic symptoms and distortions in sensory and time perception. Users can be very emotionally labile and can show extreme empathy towards others. MDMA is often combined with multiple other drugs such as GHB, Viagra and other stimulants. Further more MDMA is commonly associated with serotonin syndrome, extreme hyperthermia and death.

Differential Diagnosis

Diagnosis of sympathomimetic overdose is usually based on clinical signs. Urine drug screens can detect cocaine but are less reliable at detecting amphetamine derivatives. Withdrawal from opiates, sedatives and alcohol can produce a surge in catecholamines that may present like sympathomimetic overdose. Psychopharmacological medication overdose, such as tricyclics and SSRIs can also raise levels of serotonin and norepinephrine. Any drug causing serotonin syndrome may mimic sympathomimetic overdose. Disease states such as psychosis and thyrotoxicosis can present in a similar way. The use of co-ingestants can complicate the diagnosis.

Treatment/Work Up—Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Troponin levels should be trended to assess for cardiac ischemia. CT imaging of the head may be required

to exclude intracranial complications. Close attention should be given to suspected body packers or stuffers as a sudden release of large amounts of sympathomimetics can be rapidly fatal. Abdominal imaging may be helpful. Decontamination with activated charcoal is advisable in suspected oral ingestion if presentation is within 1 hour. Whole bowel irrigation with polyethylene glycol can be used in asymptomatic body packers to help expel packets.

Specific Therapy

1. Benzodiazepines are the mainstay of treatment in sympathomimetic overdose for both cardiovascular (hypertension and tachycardia) and neurological effects (agitation and seizures). Lorazepam should be administered IV in 2 mg doses and titrated to response. Alternatively diazepam in 5-10 mg increments can be used. Extremely high doses may be required. Avoid using antipsychotics as they may lower seizure threshold and can worsen arrhythmias and hyperthermia. Status epilepticus may develop and require phenobarbital or phenytoin if unable to be controlled with benzodiazepines. Continuous EEG is recommended in this situation.
2. Hypertension not controlled adequately with benzodiazepines should be treated with intravenous titratable medications such as nitroprusside, phentolamine or calcium channel blockers. Beta-blockers have been used, however they are generally best avoided due to the risk of causing unopposed alpha stimulation and worsening hypertension.
3. Cardiac ischemia should be treated with aspirin, nitrates, morphine, and oxygen with appropriate specialist referral.
4. Arrhythmias are very common and usually respond to benzodiazepines and intravenous fluids. Persistent narrow complex tachyarrhythmias can be treated with verapamil 5-10 mg IV over 5-10 minutes. Wide complex tachyarrhythmias should be treated with sodium bicarbonate 1-2 mEq/kg IV titrated to a serum pH of 7.45-7.5.
5. Hyperthermia should be closely monitored. When temperature exceeds 39 degrees Celsius urgent cooling is required.

Numerous techniques exist and initially should include the use of fans, anti-pyretic medications, cold IV fluids, and ice baths. More specialized methods include the use of intravenous cooling catheters and cooling pads applied to the skin. T ose with excessive agitation or recurrent seizures may require paralysis to prevent excessive heat production. Renal function and CK levels should be followed closely.

- 6. Rhabdomyolysis should be treated with intravenous fluids. Urine alkalization has not been shown to be beneficial in rhabdomyolysis secondary to poisoning. See [Table 58–12](#): treatment summary.

Hallucinogens

A hallucinogen is a psychoactive agent that can cause hallucinations, distortions in a person’s perception of reality and changes in thought and emotion. Broadly they are divided into 2 categories: classic hallucinogens and dissociative drugs (see [Table 58–13](#)). Hallucinogens are found naturally in plants and mushrooms but can also be manmade. Almost all hallucinogens contain nitrogen and are classified as alkaloids. T e exact mechanism underlying hallucinogens is unclear but is thought to involve the interaction of numerous neurotransmitters, including serotonin (5-HT), dopamine and glutamate (NMDA). Due to increases in serotonin associated with hallucinogens they increase the risk of developing serotonin syndrome. See [Table 58–13](#): Hallucinogens.

TABLE 58–12 Treatment summary.

Treatment summary of sympathomimetic overdose
Continuous vital signs and serial EKGs
Trend troponin, CKand electrolytes
Consider head CT
Benzodiazepines titrated to response
Nitroprusside or phentolamine for uncontrolled HTN
Sodium bicarbonate for wide complex tachyarrhythmia
Aggressive cooling methods
Consider endotracheal intubation for airway protection

TABLE 58–13 Common hallucinogens.

Classic Hallucinogens	Dissociative Hallucinogens
LSD (d-lysergic acid diethylamide)	PCP (Phencyclidine)
Mushrooms/Psilocybin (4-phosphoryloxy-N, N-dimethyltryptamine)	Ketamine
Peyote (Mescaline)	DXM (Dextromethorphan)
DMT (Dimethyltryptamine)	

T e most commonly abused hallucinogens are LSD (d-lysergic acid diethylamide), PCP (phencyclidine) Ketamine and mushrooms (Psilocybin).

LSD

LSD is an alkaloid similar to ergotamine and synthesized from lysergic acid, which is found to occur naturally in several species of plant. LSD is one of the most potent mood-changing chemicals. T e most common form is LSD-soaked paper punched into small individual squares, known as “blotters” which are taken orally. T e effects can last up to 12 hours.

PCP

PCP is synthetic arylcycloamine developed as a non-narcotic anesthetic to exert a calming effect at low dose and cataplexy at higher dose without suppression of blood pressure or respiration. Use was discontinued due to postoperative dysphoria and hallucination. It is used recreationally, available in powder, crystal, liquid, and tablet forms. PCP is normally snorted, smoked, or orally ingested and the effects typically last for 4-6 hours.

Mushrooms

Psilocybin (4-phosphoryloxy-N,N-dimethyltryptamine) is a naturally occurring tryptamine compound structurally similar to serotonin and is found in dozens of species of mushrooms. T ese are commonly known as “magic mushrooms” or “shrooms” and may be orally consumed fresh or dried and are usually added to other foods to mask their bitter flavor. Effects typically last up to 6 hours.

Ketamine

Ketamine is a dissociative NMDA receptor antagonist, structurally similar to PCP, which has many uses in medicine. It has anesthetic, analgesic, local anesthetic, amnestic, and bronchodilating properties. It is frequently used by medical professionals for induction and maintenance of anesthesia, procedural sedation and acute and chronic pain relief. Ketamine is usually abused orally and has a short half-life of approximately 2 hours.

Clinical Features

Hallucinogens produce a specific toxidrome dominated by numerous neuropsychiatric symptoms including a heightened perception of sensory input, a distorted sense of time, euphoria, and an enhanced sense of well-being. Users typically report spiritual and out of body experiences and feelings but remain oriented and maintain insight. Negative neuropsychiatric effects include fear, anxiety, dysphoria and an overwhelming sense of dread. Psychosis may occur and may persist for days. Synesthesia is a unique sensation and occurs when a certain sense or part of a sense is activated leading to another unrelated sense or part of a sense to be activated concurrently. For example patients may report “hearing” colors. Vital signs can be normal but usually show tachycardia and hypertension. Hyperthermia can occur with significant overdose. Other physical exam findings include increased muscle tone, dystonic reactions and mydriasis. Serotonin syndrome (change in mental status, autonomic stimulation and neuromuscular activity) can occur directly with LSD. Other hallucinogens raise serotonin, which, in the setting of concurrent use of SSRIs or other serotonergic agents, can increase the risk of developing serotonin syndrome. Rarely rhabdomyolysis due to hyperthermia and increased muscle activity can occur and lead to renal failure.

Certain clinical signs can point towards specific hallucinogens:

PCP

PCP can be associated with violent destructive behavior and a perception of super human strength, which may lead users to suffer trauma as a result. Physical signs include hypersalivation and horizontal and vertical nystagmus. In high doses patients can be catatonic or in a coma. Users typically experience

amnesia, reduced perception of pain, flushing, profuse sweating, and generalized numbness. Elevations in CK are seen more commonly in PCP intoxication.

Mushrooms

Mushroom intoxication is frequently associated with gastrointestinal symptoms such as diarrhea, colicky abdominal pain, nausea, and vomiting. Users also may exhibit muscle weakness and ataxia. Certain mushrooms can also cause hepatotoxicity with elevation of liver enzymes.

LSD—LSD users are more likely to experience synesthesia and extremes of emotion with severe anxiety. As with PCP, users can be very impulsive and suffer serious injuries as a result of poor judgment. Vasospasm leading to strokes and peripheral ischemia has been reported.

Ketamine—Ketamine typically causes tachycardia, hypertension, increased muscle tone, hypersalivation and is associated with amnesia. Rarely users can develop laryngospasm. Once the effects of ketamine begin to dissipate patients may develop an emergence phenomenon characterized by delirium and agitation. Long-term users can develop a chronic cystitis leading to decreased bladder compliance and volume.

Differential Diagnosis

The diagnosis of hallucinogen toxicity is usually based on clinical signs. Drug urine screens can detect PCP but are unreliable. The main differential diagnosis would include sympathomimetic toxicity and acute withdrawal from opiates, benzodiazepines or alcohol. Other causes of altered mental status should be considered such as metabolic derangements, CNS infections and psychiatric conditions.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Decontamination with activated charcoal is advisable in suspected oral ingestion, if presentation is within 1 hour.

Specific Therapy

1. Patients should be placed in a quiet darkened room with minimal stimulation.

2. Benzodiazepines should be used to treat agitation, hypertension and tachycardia. Lorazepam 1-2 mg IV or diazepam 5-10 mg IV or PO as needed is recommended.
3. Seizures will require higher doses of lorazepam or diazepam. Avoid using antipsychotics as they may lower seizure threshold and worsen hyperthermia.
4. Hyperthermia should be closely monitored. Persist hyperthermia should be treated with the use of fans, antipyretics, cold IV fluids and ice baths. When temperature exceeds 39 degrees Celsius more urgent cooling is required. More specialized methods including the use of intravenous cooling catheters and cooling pads applied to the skin are rarely needed.
5. Rhabdomyolysis should be treated with intravenous fluids. Urine alkalization has not been shown to be beneficial in rhabdomyolysis secondary to poisoning.

PSYCHIATRIC MEDICATION OVERDOSE

Psychiatric medications are used to treat a wide variety of mental disorders. Mental health medications were first introduced in the mid-20th century. Prior to this psychiatric patients were treated with morphine and sedatives or confined to hospital. Chlorpromazine was developed in Paris in 1951 and was the first drug developed specifically with psychopharmacologic actions. It was the first antipsychotic and worked by indiscriminately blocking central nervous system receptors producing potent anticholinergic, antidopaminergic, antihistaminic and antiadrenergic effects giving rise to the proprietary name of Largactil, that is, large in action.

Antidepressants frequently feature in the top 10 most prescribed medications in the United States. Abilify (antipsychotic) has the highest sales of any drug in the United States generating \$6.9 billion in 2013. Due to the widespread use of psychiatric medications accidental and intentional overdose is common. In this section we will focus on tricyclic antidepressants and antipsychotics. Management of stimulants and hypnotics is covered elsewhere.

Tricyclic Antidepressants

Though largely displaced by selective serotonin reuptake inhibitors (SSRIs) and other agents as first line therapy, tricyclic antidepressants (TCAs) are still used to treat depression and poisoning remains a significant clinical issue. Examples include amitriptyline, doxepin, and imipramine.

TCAs work therapeutically by blocking reuptake of norepinephrine and serotonin, however in toxic amounts they have anticholinergic, antiadrenergic, and antihistaminic properties as well as blocking GABA receptors and cardiac sodium channels. In overdose blood levels can become extremely high due to slow GI transit from the anticholinergic effects.

Clinical Features

Ingestion of 15-20 mg/kg would be expected to result in serious, potentially life-threatening symptoms. Patients can present with relatively few symptoms but can deteriorate rapidly and require urgent assessment on presentation. The effects of poisoning are a combination of central and peripheral nervous system toxicity and cardiovascular dysfunction. Central and peripheral nervous system effects are due to anticholinergic and antihistaminic properties. Cardiac toxicity is due to sodium channel blockage and anticholinergic (antimuscarinic, atropine-like) effects. In addition blockage of alpha 1 adrenergic receptors causes peripheral vasodilatation.

Anticholinergic effects produce a combination of peripheral and central nervous system effects including hyperthermia, tachycardia, mydriasis, dry flushed skin, urinary retention, dry mucus membranes, ileus, delirium, agitation, coma and seizures. Other findings include nystagmus, divergent squint, increased muscle tone and respiratory depression. Cardiovascular effects can be fatal and include tachyarrhythmias, heart block, negative inotropy, and vasodilatation causing hypotension. Coma signals a high risk for severe toxic complications (seizures and arrhythmias) more reliably than EKG changes. Common EKG findings include right axis deviation, right bundle branch block (RBBB), sinus tachycardia, QT, PR and QRS prolongation, which can precipitate VF and VT.

Laboratory tests may reveal metabolic acidosis. Death is most commonly due to cardiac arrhythmias.

Differential Diagnosis

Suspect TCA overdose if patients present with the anticholinergic toxidrome but also have cardiovascular abnormalities. Antihistamine and antipsychotic overdose can produce a similar picture. Always consider non-toxicological causes.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). A urinary catheter is useful to monitor urine pH. Decontamination with activated charcoal should be initiated, if presentation is within 1 hour of ingestion. Gastric lavage should be considered if the patient presents within 1 hour and has ingested a large amount. This will help prevent further absorption from the decreased GI motility. Dialysis is ineffective due to high protein binding.

Specific Therapy

1. TCA overdose is one of the few conditions where bicarbonate has been shown to be beneficial. Alkalization of the blood with sodium bicarbonate IV bolus of 1-2 mEq/kg should be given and repeated until blood pH is 7.5-7.55. This will improve hypotension and cardiac arrhythmias. If intubated transient hyperventilation may be used until bicarbonate is effective. Sodium bicarbonate's effects are mediated by increasing extra-cellular sodium to increase the electrochemical gradient, and by alkalization of the blood, which decreases the amount of ionized drug.
2. Refractory hypotension that does not respond to fluids or bicarbonate may require a vasopressor and inotrope such as norepinephrine. If this fails then hypertonic 3% sodium chloride could be given cautiously, 100 mls over 10 minutes through a central line with close monitoring of sodium levels. This may be repeated no more than 3 times.
3. Arrhythmia's refractory to bicarbonate should be treated with magnesium sulfate 1-2 g IV over 15 minutes. Lidocaine can also be used. If cardiotoxicity is still unresponsive then

intravenous lipid emulsion (ILE) may be given at 1.5 mL/kg of 20% as an IV bolus followed by 0.25-0.5 mL/kg/min for 30-60 minutes to an initial maximum of 500 mL. Any unstable tachyarrhythmia should be treated with synchronized DC cardioversion.

4. Patients with life threatening instability that fail to respond to the above measures should be considered for veno-arterial extracorporeal membrane oxygenation (VA-ECMO) to support cardiac output and oxygen delivery as a bridge to recovery.

Serotonin Agents and Serotonin Syndrome

Newer antidepressants including SSRIs, SNRIs, and SDRIs are much more commonly used than TCAs. SNRIs and SDRIs are more toxic than SSRIs but in general these drugs are much safer than TCAs in overdose.

Serotonin syndrome is a potentially life threatening complication of any medications or illicit substance known to increase serotonin levels (see Table 58–14). Serotonin syndrome can occur from any combination of drugs that increase serotonin levels and does not have to in the setting of a deliberate overdose. The syndrome is classically associated with the simultaneous administration of two serotonergic agents. However, it can occur after initiation of a single serotonergic drug or after increasing

TABLE 58–14 Common drugs known to cause serotonin syndrome.

Drugs of Abuse	Prescription Drugs
MDMA	SSRIs
Amphetamines	SNRIs
Cocaine	SDRIs
LSD	MAOIs
	TCAs
	Linezolid
	Fentanyl

the dose of a previous drug. Serotonin syndrome is usually more pronounced from monoamine oxidase inhibitor use. See Table 58–14: Common drugs known to cause serotonin syndrome.

Clinical Features

Classically serotonin syndrome produces a triad of mental status changes, autonomic hyperactivity, and neuromuscular abnormalities. Mental status changes can be anxiety, delirium, restlessness, and disorientation. Autonomic hyperactivity manifests as diaphoresis, mydriasis, tachycardia, hyperthermia, hypertension, vomiting, and diarrhea. Neuromuscular abnormalities include, tremor, muscle rigidity, myoclonus, hyperreflexia, ocular clonus, and akathisia. Neuromuscular findings are generally more pronounced in the lower extremities.

Differential Diagnosis

Serotonin syndrome is a clinical diagnosis and requires a thorough history and physical exam. The main differentials include, neuroleptic malignant syndrome (NMS), malignant hyperthermia anticholinergic toxicity, sympathomimetic toxicity, or withdrawal from opioids, sedatives or alcohol. Other non-toxicological causes such as meningitis, hypoglycemia etc should also be considered. To assist with diagnosis you can use the Hunter toxicity criteria. See Table 58–15: Hunter toxicity criteria.

TABLE 58–15 Hunter toxicity criteria for serotonin syndrome.

Hunter Toxicity Criteria	
To fulfill the criteria, the patient must have ingested a serotonergic agent and meet one of the stipulated conditions:	
• spontaneous clonus	• inducible clonus plus agitation or diaphoresis
• ocular clonus plus agitation or diaphoresis	• tremor plus hyperreflexia
• hypertonia plus temperature above 38°C plus ocular clonus or inducible clonus	
The Hunter Toxicity Criteria Decision Rules are 84% sensitive and 97% specific when compared with the gold standard of diagnosis by a medical toxicologist. ⁷	

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). In cases of deliberate overdose, decontamination with activated charcoal should be initiated, if presentation is within 1 hour of ingestion.

Specific Therapy

1. In mild cases of serotonin syndrome simply discontinuing the medication will result in resolution of symptoms in 24 hours. Of note neuroleptic malignant syndrome may take days to resolve.
2. Prolonged QT and Torsades de pointes should be managed with magnesium sulfate 1-2 g IV over 15 minutes.
3. Hyperthermia should be closely monitored. When temperature exceeds 39 degrees Celsius urgent cooling is required. Numerous techniques exist and initially should include the use of fans, antipyretics, cold IV fluids, and ice baths. More specialized methods include the use of intravenous cooling catheters and cooling pads applied to the skin. Those with excessive agitation, recurrent seizures or increased muscular tone may require paralysis to prevent excessive heat production. Renal function and CK levels should be followed closely.
4. Benzodiazepines not only help with agitation and seizures but also help improve autonomic symptoms such as tachycardia, hypertension, and hyperthermia.
5. If supportive care and benzodiazepines are ineffective then cyproheptadine may be used. This is an antihistamine that has some anti-serotonergic properties. The initial dose is 4-12 mg orally, repeated at 12-hour intervals if no response. Propranolol, bromocriptine, chlorpromazine, olanzapine, and dantrolene are not recommended.
6. Rhabdomyolysis should be treated with intravenous fluids. Urine alkalization has not been shown to be beneficial in rhabdomyolysis secondary to poisoning.

Antipsychotics

Antipsychotic, also known as neuroleptics and major tranquilizers, are used to treat a variety of conditions including psychosis, movement disorders, nausea, and agitation. Typical antipsychotics were first developed in 1951 and work by non-specific antagonism of central dopamine receptors. Atypical antipsychotics were developed in 1998 and are much more specific therefore produce much fewer side effects. They selectively antagonize mesolimbic D2 receptors. All classes of antipsychotic medications drugs also have varying degrees of antihistaminic, antiadrenergic, antiserotonergic, and anticholinergic properties leading to numerous side effects, especially in overdose. Aripiprazole is a newer atypical antipsychotic that has a low affinity for serotonin, α -1 adrenergic, and histamine-1 receptors and as a result a more favorable side effect profile.

Antipsychotic use is very common in the United States where deliberate and accidental overdose occurs. Mortality from overdose is low. A specific but rare and potentially fatal complication to be aware of is neuroleptic malignant syndrome.

Clinical Features

Symptoms and signs are related to the numerous receptors that are blocked. Histamine receptor antagonism produces lethargy, sedation and coma. Other central effects include ataxia, dysarthria, myoclonus and seizures. Alpha-adrenergic antagonism may produce miosis, tachycardia and orthostatic hypotension. Anticholinergic effects can produce the classic anticholinergic toxidrome of blurry vision, dry mouth, flushed skin, constipation, dilated pupils and urinary retention.

On examination patients may have extrapyramidal signs such as acute dystonic reactions and akathisia. These are common side effects of typical antipsychotics and normal therapeutic doses. These effects can be seen with overdose but are rare. Antipsychotics can also affect cardiac sodium ion channels producing EKG changes including QT, PR and QRS prolongation, ST and T wave abnormalities and right axis deviation. The most common EKG finding is sinus tachycardia.

Neuroleptic Malignant Syndrome (NMS)—NMS is a potentially life threatening neurological emergency due to an idiosyncratic reaction to antipsychotics

with a mortality of 10%-20%. It presents with a tetrad of fever (38°C - 40°C), muscular rigidity (lead pipe), autonomic dysfunction (tachycardia, diaphoresis, and labile blood pressure), and altered mental status (confusion, delirium and catatonia).

Death usually occurs from complications from autonomic dysfunction including rhabdomyolysis and cardiac and respiratory failure. Onset of symptoms is usually gradual over 3-7 days. CK levels are often significantly elevated $> 100,000$ IU/L.

Differential Diagnosis

Due to the fact that antipsychotics interact with multiple different receptors producing several clinical toxidromes, diagnosis can be difficult. Anticholinergic toxicity, TCA overdose, sympathomimetic abuse, and sedative-hypnotic overdose can produce similar signs.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing, and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). In cases of deliberate overdose, decontamination with activated charcoal should be initiated, if presentation is within 1 hour of ingestion.

Specific Therapy

1. Prolonged QT or torsade de pointes should be treated with intravenous magnesium sulfate 1-2 g IV over 15 minutes.
2. Vasopressors such as norepinephrine may be required for hypotension that does not respond to fluid resuscitation.
3. Mild hyperthermia should be treated with conventional cooling methods. When temperature exceeds 39°C urgent cooling is required. Numerous techniques exist and initially should include the use of fans, antipyretics, cold IV fluids, and ice baths. More specialized methods include the use of intravenous cooling catheters and cooling pads applied to the skin.
4. Neuroleptic malignant syndrome is treated as above. In addition high dose

benzodiazepines can help muscle rigidity. Dantrolene 1-2.5 mg/kg IV load may be useful when rigidity is pronounced. Bromocriptine, a dopamine agonist, may be administered orally to counter the dopamine antagonism.

- 5. Rhabdomyolysis should be treated with intravenous fluids. Urine alkalization has not been shown to be beneficial in rhabdomyolysis secondary to poisoning.

CHOLINERGIC AND ANTI-CHOLINERGIC TOXICITY

Acetylcholine is the most abundant neurotransmitter in the peripheral and central nervous system with actions on both somatic and autonomic nerves via nicotinic and muscarinic receptors.

Anti-cholinergic toxicity is produced by blocking the effects of acetylcholine. Anticholinergic drugs competitively inhibit binding of the neurotransmitter acetylcholine to post synaptic muscarinic acetylcholine receptors found in smooth muscle but not nicotinic acetylcholine receptors found in the neuromuscular junction.

Numerous drugs and classes of drugs have anticholinergic properties at therapeutic levels and in overdose. See Table 58–16: Classes of anticholinergic drugs.

Cholinergic toxicity is produced by an excess of acetylcholine usually by inhibition of the enzyme acetylcholinesterase on the post synaptic membrane. This enzyme is responsible for the breakdown of acetylcholine, which then terminates the nerve signal transmission. This produces nicotinic,

muscarinic and CNS effects. Cholinergic toxicity is usually due to exposure to organophosphates in the form of insecticides, herbicides or nerve agents used in chemical warfare or terrorism. Organophosphates cause irreversible inactivation, through phosphorylation, of acetylcholinesterase. Acetylcholinesterase inhibitors are used in medicine for reversal of neuromuscular blockade in general anesthesia and to treat certain neuromuscular disorders such as myasthenia gravis but toxicity from these agents is rare.

Anticholinergics

Clinical Features

Anticholinergic toxicity is usually caused by accidental or deliberate overdose of a prescribed medication and produces a characteristic toxidrome. Patients have tachycardia, mydriasis, urinary retention, dry flushed skin, blurred vision, absent bowel sounds, hyperthermia and can have hypo or hypertension. Mental status changes include confusion, agitation, hallucinations and disorientation. The classic symptoms and signs are described below: See Table 58–17: Classic anti-cholinergic symptoms and signs.

Serious complications of toxicity include status epilepticus, rhabdomyolysis, and cardiovascular collapse.

Differential Diagnosis

Drugs or abuse, psychiatric disorders, encephalitis and withdrawal states can produce similar symptoms and signs. Numerous medications have

TABLE 58–16 Classes of drugs with known anticholinergic properties.

Drug Class/Plant
Antihistamines
Antipsychotics
Antispasmodics
Tricyclic antidepressants
Deadly nightshade

TABLE 58–17 Classic anti-cholinergic symptoms and signs.

Symptom/Sign	Etiology
Dry skin (dry as a bone)	Anhidrosis
Hyperthermia (hot as a hare)	Anhidrosis
AMS (mad as a hatter)	CNS effects
Flushed (red as a beet)	Vasodilatation
Blurred vision (blind as a bat)	Mydriasis
Abdominal pain (full as a flask)	Urinary retention
Tachycardia	Atropine effect

anti-cholinergic properties as part of their toxic profile; therefore clinicians should look for other symptoms and signs associated with other classes of medication.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing, and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). In cases of deliberate overdose, decontamination with activated charcoal should be initiated, if presentation is within 1 hour of ingestion.

Specific Therapy

1. If toxicity is related to underlying tricyclic overdose then sodium bicarbonate may be required (see TCA overdose).
2. If toxicity is related to anti-psychotics then watch for signs of neuroleptic malignant syndrome (see anti-psychotic overdose).
3. Mild hyperthermia should be treated with conventional cooling methods. When temperature exceeds 39°C urgent cooling is required. Numerous techniques exist and initially should include the use of fans, antipyretics, cold IV fluids, and ice baths. More specialized methods include the use of intravenous cooling catheters and cooling pads applied to the skin.
4. Rhabdomyolysis should be treated with intravenous fluids. Urine alkalization has not been shown to be beneficial in rhabdomyolysis secondary to poisoning.
5. Physostigmine (acetylcholinesterase inhibitor) use is controversial and may be indicated if conventional supportive care is not effective and should only be used in pure anti-cholinergic toxicity. Dose as 0.5-2 mg IV slowly over 5 minutes. Please consult specialist advice before administering.

Organophosphates

Clinical Features

Organophosphate toxicity can be from oral, inhalational (nerve gas) or dermal exposure. This causes

an excess of acetylcholine producing a cholinergic crisis and characteristic toxidrome with symptoms due to muscarinic, nicotinic and CNS stimulation.

Peripheral muscarinic effects include bronchorrhea, bronchospasm, salivation, blurred vision, diaphoresis, lacrimation, urinary incontinence, vomiting, and defecation. Nicotinic effects include muscle fasciculations, weakness and paralysis, which can lead to respiratory failure. CNS effects cause headaches, blurred vision, confusion, coma, and seizures. A useful mnemonic for the muscarinic effects is SLUDGE/BBB: salivation, lacrimation, urinary incontinence, defecation and gastric emesis, bradycardia, bronchorrhea and bronchospasm. If muscarinic effects predominate then patients may be bradycardic with miosis versus tachycardic with mydriasis if nicotinic effects predominate. Blood pressure can be either high or low.

Differential Diagnosis

Diagnosis of organophosphate poisoning is a clinical diagnosis. Myasthenia gravis patients who take an excessive amount of their medications can present with a cholinergic crisis.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Organophosphate poisoning is often from dermal exposure making surface decontamination important. Personal protective clothing should be worn by medical staff to prevent secondary contamination. The patient should be washed with soap and water and any clothing worn by the patient should be disposed of. Other decontamination and enhanced elimination techniques are ineffective.

Specific Therapy

1. If intubation is required avoid succinylcholine due to the prolonged paralysis effects.
2. Atropine antagonizes the peripheral muscarinic effects of excess acetylcholine and should be given if muscarinic symptoms predominate. Give 1 mg IV every 5 minutes until symptoms improve (most importantly

tracheobronchial secretions should slow down). Large doses of atropine may be required. Of note atropine has no effect on nicotinic receptor function therefore will not effect paralysis or muscle weakness. Tachycardia and mydriasis are not a contraindication to atropine.

3. Pralidoxime is effective at restoring the activity of acetylcholinesterase by reversing the phosphorylation. It predominantly improves the nicotinic effects, such as weakness, and therefore should be used in conjunction with atropine. Give 1-2 g mixed with normal saline over 5 to 10 minutes. Repeat dosing or an infusion may be required.

CARDIAC MEDICATION OVERDOSE

Introduction

Cardiac medications are very commonly prescribed medications with antihypertensives frequently featured in the top 10 most prescribed drugs in the United States. Accidental or deliberate overdose is common and potentially fatal. Cardiac medication toxicity usually presents with hypotension, due to either vasodilatation or decreased myocardial contractility, and arrhythmias, however non-cardiac effects can also present a management challenge. Cardiac medications discussed here include, beta-blockers, calcium channel blockers, and digoxin.

Beta-Blockers

Beta-blockers are competitive antagonists of the B-receptors, with B₁-receptors found in the heart, and B₂-receptors found in the bronchial tree and blood vessels. They are used to manage acute coronary syndrome, hypertension, thyrotoxicosis, glaucoma, and arrhythmias. Toxicity leads to negative inotropy and chronotropy causing hypotension and bradycardia. Some agents (acebutolol, betaxolol, pindolol, propranolol) demonstrate myocardial membrane stabilizing activity that can cause QRS widening and decrease myocardial contractility as well as potentiate dysrhythmias.

Clinical Features

Patients with significant toxicity present with bradycardia and depressed myocardial contractility causing significant hypotension, which can progress to cardiogenic shock. EKG changes can include atrioventricular blocks, a widened QRS/ventricular arrhythmias and asystole. Global hypoperfusion may cause elevated lactic acid and changes in mental status including seizures. Onset is within 6 hours for immediate release preparations and can be delayed up to 12 hours with extended release. Propranolol may cause more CNS effects independent of hypoperfusion. Other effects include bronchospasm (rare) and hypoglycemia.

Differential Diagnosis

Diagnosis is based on history and physical signs. Beta-blocker overdose may be hard to distinguish from calcium channel blocker (CCB) overdose. Beta-blocker toxicity usually causes hypoglycemia whereas CCB toxicity induces hyperglycemia. Barbiturates can also produce similar signs however patients usually have a significantly depressed mental status.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Decontamination with activated charcoal should be initiated, if presentation is within 1 hour of ingestion. Late administration of activated charcoal may be beneficial for sustained release preparations if a potentially toxic amount has been ingested. Gastric lavage performed within 1 hour of ingestion has been used. Whole bowel irrigation, for cases of sustained release preparations, may be effective, however is generally not recommended. Hemodialysis may be beneficial in cases of atenolol, nadolol or sotalol overdose.

Specific Therapy

1. Atropine 0.5-1 mg should be administered for bradycardia.
2. Glucagon has both chronotropic and inotropic effects independent of beta-receptors and should be administered as an IV bolus of 3-5 mg followed by a continuous infusion

of 0.25 ml/kg/min. The main side effect is vomiting which can lead to aspiration.

3. Norepinephrine, epinephrine, or dobutamine can be administered in high doses, for refractory hypotension and bradycardia, to overcome the competitive blockade.
4. Hyperinsulinemia-euglycemia therapy has been shown to improve myocardial contractility and hypotension. Initially administer 50 ml of 50% dextrose. Start high dose regular insulin 1 unit/kg IV bolus followed by a continuous infusion of 0.5-1 unit/kg/hr with dextrose 10% in water at 200 ml/hr. Serum glucose should be monitored every 20 min and the dextrose infusion rate adjusted to maintain serum glucose between 150-300 mg/dL.
5. Calcium supplementation is of limited benefit however should be considered in refractory cases. Calcium chloride is preferred.
6. Intravenous lipid emulsion (ILE) may be considered and administered with a bolus of 1.5 ml/kg followed by a continuous infusion of 0.25 ml/kg/min.
7. For severe cases refractory to the above measures consider transvenous pacing, placement of an intra-aortic balloon pump or veno-arterial extracorporeal membrane oxygenation (VA-ECMO) as a bridge to recovery.

Calcium Channel Blockers

Calcium channel blockers (CCB) are used primarily in the treatment of hypertension, angina pectoris, and supraventricular arrhythmias. CCB all block L-type calcium channels which are known to control myocardial contractility (inotropy), vascular smooth muscle contractility and conduction and pacemaker cells (chronotropy). These agents hold the potential for substantial toxicity and can be fatal in overdose. There are 2 main classes of CCB; dihydropyridines and non-dihydropyridines. At therapeutic dosage, dihydropyridines are potent vasodilators with only a slight negative effect on cardiac contractility and conduction, whereas non-dihydropyridines are weak vasodilators, but exert a depressive effect on

TABLE 58–18 Classes of calcium channel blockers.

Dihydropyridines	Non-Dihydropyridines
Amlodipine	Verapamil
Felodipine	Diltiazem
Nifedipine	
Nicardipine	
Nimodipine	

cardiac conduction and contractility. See Table 58–18: Classes of calcium channel blockers.

Clinical Features

Patients ingesting more than 5 to 10 times the usual dose can develop severe intoxication within 6 hours, or up to 12 hours in extended release formulations. Toxicity causes bradycardia, depressed myocardial contractility and vasodilatation leading to significant hypotension. Dihydropyridines cause more vasodilatation and sometimes induce a reflex tachycardia. Non-dihydropyridines have more myocardial depressing affects however both classes have significant overlap at high doses. Global hypoperfusion may cause drowsiness and elevated lactic acid. Hyperglycemia may develop due to inhibition of calcium-mediated insulin release. EKG findings include PR prolongation and 2nd and 3rd degree atrioventricular block.

Differential Diagnosis

Diagnosis is based on history and physical signs. Beta-blocker overdose may be hard to distinguish from CCB overdose. Beta-blocker toxicity usually causes hypoglycemia whereas CCB toxicity induces hyperglycemia. Barbiturates can also produce similar signs however patients usually have a significantly depressed mental status.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose

and poisoning). Decontamination with activated charcoal should be initiated, if presentation is within 1 hour of ingestion. Late administration of activated charcoal may be beneficial for sustained release preparations if a potentially toxic amount has been ingested. Gastric lavage performed within 1 hour of ingestion has been used. Whole bowel irrigation, for cases of sustained release preparations, may be effective, however is generally not recommended.

Specific Therapy

1. Atropine 0.5-1 mg should be administered for bradycardia, however this is usually ineffective.
2. Calcium should be replaced with calcium gluconate or chloride (10 ml of 10%), however this may also be ineffective. Calcium chloride is preferred because it contains more elemental calcium however may cause irritation and should ideally be given through a central line.
3. Norepinephrine, epinephrine or dobutamine can be administered for refractory hypotension and bradycardia but have varying results.
4. Hyperinsulinemia-euglycemia therapy has been shown to improve myocardial contractility and hypotension. Initially administer 50 ml of 50% dextrose. Start high dose regular insulin 1 unit/kg IV bolus followed by a continuous infusion of 0.5-1 unit/kg/hr with dextrose 10% in water at 200 ml/hr. Serum glucose should be monitored every 20 min and the dextrose infusion rate adjusted to maintain serum glucose between 150-300 mg/dL.
5. Glucagon can be both chronotropic and inotropic and should be administered as an IV bolus of 3-5 mg followed by a continuous infusion of 0.25 ml/kg/min. The main side effect is vomiting which can lead to aspiration.
6. Intravenous lipid emulsion (ILE) may be considered and administered with a bolus of 1.5 ml/kg followed by a continuous infusion of 0.25 ml/kg/min.
7. For severe cases refractory to the above measures consider transvenous pacing, placement of an intra-aortic balloon pump or veno-arterial extracorporeal membrane oxygenation (VA-ECMO) as a bridge to recovery.

Digoxin

Cardiac glycosides are derived from the foxglove plant and are used to treat supraventricular tachyarrhythmia and cardiac heart failure. They increase vagal tone resulting in decreased chronotropy and competitively inhibit the sodium potassium ATPase pump to increase inotropy and extracellular potassium. Toxicity can develop from acute ingestion, drug interactions (amiodarone, diuretics, spironolactone, macrolides, and CCB) leading to elevated digoxin levels or from chronic use in the setting of renal failure and electrolyte abnormalities. Low potassium and magnesium may precipitate toxicity by lack of competition for the sodium potassium ATPase pump.

Clinical Features

Toxicity produces non-specific cardiac, GI, CNS, and electrolyte abnormalities. CNS effects include dizziness, headache, confusion, and visual complaints. The patient may report yellow or green vision or halos. GI effects include nausea and vomiting. Hyperkalemia is a potentially serious complication of digoxin toxicity. EKG changes include tachy and bradyarrhythmias, atrioventricular block, and changes associated with hyperkalemia. Ventricular arrhythmias can occur in severe toxicity. Other non-specific findings include weakness, anorexia, and fatigue.

Differential Diagnosis

Digoxin toxicity may be hard to diagnose clinically due to the numerous non-specific effects. Hyperkalemia is frequently seen in acute toxicity but may be normal in cases of chronic toxicity. EKG changes can help to distinguish toxicity from other more benign conditions. Specific drug levels may be helpful in acute toxicity but may be only minimally elevated in chronic toxicity and therefore the diagnosis may be overlooked by false reassurance. Barbiturate, beta-blocker and CCB overdose may produce similar features.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose

and poisoning). In cases of acute toxicity activated charcoal should be administered if presentation is within 1 hour of ingestion.

Specific Therapy

1. DC cardioversion should be used for any unstable supraventricular or ventricular tachy-arrhythmias.
2. Brady-arrhythmias should initially be treated with atropine 0.5-1 mg IV or temporary pacing if severe.
3. Stable supraventricular tachy-arrhythmias can be treated with magnesium sulfate IV 1-2 g over 15 minutes. Stable ventricular arrhythmias may be treated with lidocaine IV or phenytoin.
4. Correct any underlying electrolyte abnormalities. Hyperkalemia should be treated with insulin and dextrose, resins or hemodialysis if severe.
5. Digoxin-specific Fab (antigen binding fragment) should be administered to patients who have an unstable arrhythmia that has not responded to conventional therapy, in those who have a potassium of greater than 5 mEq/L after an ingestion of more than 10 mg of digoxin and in patients who have a blood digoxin level of greater than 10 ng/ml.

OVER THE COUNTER ANALGESIC OVERDOSE

Over-the-counter (OTC) drugs as a whole were the second leading substance type used in suicides representing approximately 10% of suicides due to substance overdose. Prescription drugs are the leading type of drug used in suicides representing 79% of suicides due to substance overdose. Analgesics such as acetaminophen and aspirin (ASA) are easily available over the counter and at low cost. They can be fatal in overdose but early identification and appropriate treatment can significantly improve outcomes.

Acetaminophen

Background

Acetaminophen is the most widely used antipyretic and analgesic available OTC in the United States and

can be found in numerous different preparations. It is rapidly absorbed in the GI tract and metabolized by the liver. At therapeutic doses a very small percentage of acetaminophen is metabolized to a toxic intermediate called N-acetyl-p-benzoquinoneimine (NAPQI), which is rapidly conjugated with hepatic glutathione forming non-toxic compounds. In overdose the metabolic pathways become saturated leading to higher levels of NAPQI, which causes depletion of glutathione stores. NAPQI then begins to react with hepatocytes causing necrosis. The antidote, N-Acetylcysteine (NAC), acts by enhancing glutathione stores and providing a substitute to allow for detoxification. Acetaminophen poisoning has become the most common cause of acute liver failure in the United States.

Clinical Features

Patients can overdose in several different ways:

1. Single acute overdose in < 1 hour,
 2. Staggered overdose where doses are taken over more than 1 hour,
 3. Therapeutic excess where patients ingest multiple smaller doses over a 24 hour period,
 4. Uncertain or unclear knowledge of overdose.
- For single acute overdose patients may present in less than 4 hours, between 4 and 8 hours or after 24 hours.

Toxic exposure is likely to occur if patients ingest > 150 mg/kg in a single dose or over a 24 hour period. Rarely, toxicity can occur with ingestions between 75 and 150 mg/kg within any 24-hour period in some patients. Clinical features of acetaminophen overdose are detailed in the Table below: See [Table 58–19](#): Four stages of acetaminophen toxicity.

Differential Diagnosis

A full history and physical is important to help establish diagnosis. Acetaminophen levels should be drawn for all patients after a single acute overdose if they present between 4-24 hours post ingestion. The serum level can then be plotted on the Rumack-Matthew normogram to ascertain patient risk of toxicity (see [Figure 58–1](#)). If possible levels should be drawn and resulted before 8 hours because NAC is most effective given within the first 8 hours. Levels drawn before 4 hours are unreliable at predicting toxicity. Levels drawn after 24 hours are usually not useful because treatment is likely to be ineffective. This normogram can only be used for acute single

TABLE 58–19 Four stages of acetaminophen toxicity.

Stage	Manifestations
Stage I: 0.5 to 24 hours	Nausea, vomiting diaphoresis, lethargy, and malaise, though some remain asymptomatic. Lab studies are typically normal. CNS depression and elevated anion gap metabolic acidosis can rarely be observed following massive overdose, and if present are likely due to coingestants.
Stage II: 24 to 72 hours	Clinical and laboratory evidence of hepatotoxicity +/- nephrotoxicity become evident. While appearing to improve clinically, elevations of from those who develop hepatic injury, over half will demonstrate aminotransferase elevations within 24 hours and all have elevations by 36 hours. ³² Patients develop right upper quadrant pain with liver enlargement and tenderness. Elevations of prothrombin time (PT) total bilirubin, oliguria and renal function abnormalities become evident.
Stage III: 72 to 96 hours post ingestion	Marked by a peak in liver function abnormalities, systemic symptoms of stage I reappear in conjunction with jaundice, confusion due to hepatic prolongation of PT or INR, hypoglycemia, lactic acidosis, and a total bilirubin concentration above 4.0 mg/dL (primarily indirect). Acute renal failure occurs in 10% to 25% of patients with significant hepatotoxicity and > 50% of those with hepatic failure. ³³
Stage IV: 4 to 14 days	Patients that survive stage III enter a recovery phase by day four that completed by day seven. Symptoms and laboratory abnormalities may not abate for several weeks. When recovery occurs, it is complete; chronic hepatic dysfunction is not a sequelae of acetaminophen poisoning.

overdose between 4-24 hours. Acetaminophen levels in staggered overdose, therapeutic excess or unknown time of ingestion are misleading and usually not recommended however, some centers recommend treating if acetaminophen levels are over 10 mcg/ml in the setting of an unknown time of ingestion. See [Figure 58–1](#): Acetaminophen treatment protocol normogram.

FIGURE 58–1 Acetaminophen treatment protocol normogram. (Adapted with permission from Rumack BH, et al. Acetaminophen overdose: 662 cases with evaluation of oral acetylcystein treatment. Arch Intern Med. 1981; 141:382 [PMID: 7469629].)

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Decontamination with activated charcoal should be initiated if presentation is within 1 hour of ingestion. Activated charcoal may also inadvertently absorb oral NAC in which case the oral dose may need to be adjusted or converted to IV.

Specific Therapy

1. NAC, the antidote, is most effective if given within the first 8 hours after a single acute overdose. Indications for NAC are detailed below (see [Table 58–20](#)). NAC can be given intravenously over 21 hours or orally over 72 hours. Intravenous dosing involves an initial load of 150 mg/kg given over 15-60 minutes, followed by 50 mg/kg given over 4 hours, followed by 100 mg/kg in 16 hours. NAC is infused in 5% dextrose in water. Oral dosing

TABLE 58–20 Indications for NAC therapy.

Indications for NAC Therapy	
1	Serum acetaminophen level, drawn after 4 hours after a single ingestion, above the treatment line on the normogram
2	Suspected single ingestion of > 150 mg/kg where serum levels will not be available until after 8 hours of ingestion
3	Staggered overdose
4	Unknown time of ingestion and a serum level of > 10 mcg/ml
5	History of acetaminophen ingestion with ANY evidence of liver injury
6	Delayed presentation of > 24 hours but with evidence of liver injury

involved a loading dose of 140 mg/kg once, followed by 70 mg/kg every 4 hours for 17 doses. NAC can induce histamine release, especially in the intravenous form, resulting in urticaria and bronchoconstriction. See Table 58–20: Indications for NAC.

2. Liver failure and resulting multi-organ failure should be managed in a specialist liver transplant center. Significant complications include coagulopathy, cerebral edema, renal failure, and acidosis.

Salicylates

Background

Salicylic acid derivatives are non-steroidal anti-inflammatories used commonly to treat fever, inflammation, and pain. Aspirin is cheaply and easily available over the counter and is present in many different preparations from cold and flu medications to topical gels. Aspirin is also a widely prescribed antiplatelet therapy as prophylaxis in patients with cardiovascular and cerebrovascular disease. Salicylates are rapidly absorbed, undergoing hepatic metabolism and renal excretion. They exert their effects primarily by inhibition of cyclooxygenase with decreased production of prostaglandins, prostacyclin, and thromboxanes. Aspirin causes a direct stimulation of the respiratory center in the medulla

leading to respiratory alkalosis. Aspirin can also interfere with metabolism and oxidative phosphorylation leading to increased oxygen consumption, hyperthermia and an anion gap metabolic acidosis due to increased production of endogenous acids, ketone bodies and lactate.

Clinical Features

Aspirin toxicity can occur from an acute intentional overdose or be more chronic from unintentional gradual misuse. Chronic poisonings tend to occur in the elderly and are associated with a higher mortality. Acute toxicity can be mild < 150 mg/kg ingested, moderate 150–300 mg/kg, or severe > 300 mg/kg. Mild symptoms include nausea, vomiting, tinnitus, and dizziness. Moderate symptoms include hyperventilation, hyperthermia, ataxia, and anxiety. Severe toxicity can result in coma, seizures, agitation, renal failure, cardiac arrhythmia, pulmonary edema, and shock. Chronic toxicity may initially have vague subtle signs that are missed and gradually progress to severe toxicity with behavioral changes, neurological signs, hyperthermia, tachypnea and evidence of pulmonary edema. Acid base disturbances initially show a respiratory alkalosis then a coexisting anion gap metabolic acidosis.

Differential Diagnosis

Aspirin toxicity is a clinical diagnosis supported by acid base changes. Salicylate levels in acute toxicity can be helpful with mild toxicity associated with levels of < 300 mg/L and severe toxicity with > 700 mg/L. However, chronic toxicity develops gradually with lower drug levels, which correlate poorly with toxicity, therefore drug levels may provide false reassurance and should be viewed with caution. Differential diagnosis includes sepsis, encephalitis, stimulant toxicity, and other causes of anion gap metabolic acidosis.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Salicylate levels should be checked every 2 hours. Decontamination with activated charcoal should be initiated if presentation is

within 1 hour of ingestion. Consider whole bowel irrigation should be considered with large overdoses or sustained release preparations. Enhanced elimination techniques are discussed below.

Specific Therapy

1. If endotracheal intubation is required care must be taken to prevent worsening acidosis from apnea during intubation or hypoventilation due to a low set respiratory rate. Salicylate is less protein bound in acid environments, with more tissue penetration, and therefore more toxic.
2. Ion trapping with alkaline therapy is effective at removing salicylates. In an alkaline environment weak acids, like salicylates, remain ionized and protein bound, therefore do not penetrate the tissues, and are more easily excreted and trapped in the urine. Administer a bolus of 1-2 mEq/kg of sodium bicarbonate then begin an infusion to maintain urine pH of > 7.5 . Potassium levels may need to be supplemented.
3. Hemodialysis should be considered for severe toxicity when levels are > 1000 mg/L in acute poisoning or > 600 mg/L in chronic or in patients who fail to improve despite the above measures.

TOXIC ALCOHOLS

Any alcohol can be toxic if ingested in large enough quantities. The term “toxic alcohol” has traditionally referred to isopropanol, methanol, and ethylene glycol. Compared to ethanol use, toxic alcohol use is relatively uncommon, however can be significantly more poisonous.

Alcohols are organic compounds characterized by one or more hydroxyl (-OH) groups attached to a carbon chain. Alcohol as a solute acts as an osmole and increases the serum osmolality. This can be detected by calculating the osmolal gap. This is determined by subtracting the calculated serum osmolality from the measured osmolality. Alcohols are not included in the calculated osmolality; therefore there will be a gap proportionate to the serum concentration of the alcohol and inversely proportionate to the molecular weight.

- Calculated Osmolality (mOsm/kg) = $2 \times \text{Na}^+ (\text{mEq/L}) + \text{Glucose} (\text{mg/dL})/18 + \text{BUN} (\text{mg/dL})/2.8$
- Osmolal gap = Measured osmolality – calculated osmolality

Ethanol Toxicity

Ethanol use is very common in the United States. Approximately 10% of adults abuse alcohol to become intoxicated with numerous health and social problems associated. The national institute of health reports that in 2013 86.8% of people ages 18 or older reported that they drank alcohol (ethanol) at some point in their lifetime; 70.7% reported that they drank in the past year and 56.4% reported that they drank in the past month. Ethanol use is present in 15% to 40% of unselected emergency department patients. Death can occur from acute overdose but is most likely from trauma associated with being intoxicated. Ethanol is not only found in alcoholic beverages but is present in mouthwash, OTC cold and flu medications, perfume and some cleaning products. Ethanol is rapidly absorbed and metabolized in the liver via alcohol dehydrogenase.

Clinical Features

Over 5 standard alcoholic drinks on one occasion can produce intoxication. Signs and symptoms include slurred speech, nystagmus, disinhibited behavior, incoordination, unsteady gait, memory impairment, stupor, or coma. Hypotension and tachycardia may result from ethanol-induced peripheral vasodilation, or volume loss. Multiple metabolic derangements including hypoglycemia, lactic acidosis, hypokalemia, hypomagnesemia, hypocalcemia and hypophosphatemia may be seen. Intoxicated patients may present with a wide range of traumatic injuries. Alcohol is also a very common coingestant with other drugs of abuse and OTC medications.

Differential Diagnosis

Ethanol intoxication can mimic many causes of altered mental status. Serum ethanol levels will confirm the diagnosis, however due to frequent presence of alcohol in emergency visits, other causes must still be excluded. Acute intoxication will cause

an elevated osmolal gap without affecting the anion gap. However chronic alcoholics can develop a starvation ketoacidosis that will lead to an elevated anion gap acidosis. Ethanol levels are diagnostic.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Activated charcoal does not bind alcohols.

Specific Therapy

1. If the patient is suspected to be a chronic alcoholic then administer thiamine 100 mg, folic acid 1 mg and a multivitamin to help prevent Wernicke's encephalopathy. These can be given orally or added to IV fluids.
2. Hypoglycemia should be corrected. There is no evidence to suggest delaying glucose administration until thiamine has been repleted.
3. Any other electrolyte abnormalities should be corrected.

Alcohol Withdrawal

The complications related to alcohol withdrawal create a significant demand on healthcare resources and are associated with an increased morbidity and mortality. Alcohol withdrawal syndrome occurs in up to 31% of trauma patients and 16% of postsurgical patients, and there are proximally 500,000 episodes of alcohol withdrawal per year severe enough to require pharmacologic treatment.

Minor symptoms of autonomic hyperactivity can occur within 6 hours of cessation of drinking. This can include tremor, anxiety, palpitations, diaphoresis, and insomnia. Delirium tremens and seizures can develop 12-48 hours after the last alcohol intake and can be accompanied by arrhythmias with a mortality of 5%. Multiple other electrolyte abnormalities can be present. Management should target symptom control and supportive care with correction of metabolic derangements. Escalating doses of long acting benzodiazepines, such as diazepam, are used to control psychomotor agitation and prevent seizures. Patients usually require close observation in an ICU with a

symptom triggered approach using the Clinical Institute Withdrawal Assessment for Alcohol Scale (CIWA). This scale provides medication only when required. Thiamine (B1) and other vitamins should always be repleted in chronic alcoholics to help prevent Wernicke-Korsakoff syndrome. Wernicke's classically causes a triad of ophthalmoplegia, ataxia, and confusion. Left untreated this can progress to irreversible Korsakoff syndrome of memory loss and confabulation.

Ethylene Glycol and Methanol Toxicity

Ethylene glycol and methanol are toxic alcohols causing CNS depression and multiple other systemic complications. They are toxic in very small amounts (30-60 ml) and can be rapidly fatal. Both these alcohols are present in antifreeze/coolant, paint solvents, and windshield washer fluid or are produced illicitly as an ethanol substitute. Both parent alcohols are relatively non-toxic, however are rapidly absorbed and undergo hepatic metabolism by alcohol dehydrogenase to form severely toxic metabolites. Methanol is converted into formate/formic acid and ethylene glycol is metabolized to glycolate/glycolic acid and oxalate/oxalic acid. Formic acid is toxic to the optic nerve and will eventually cause permanent blindness. Glycolic acid and oxalic acid are toxic to the kidney and can lead to acute tubular necrosis, oxalate crystalluria and calcium oxalate stones. As with all alcohols, the osmolal gap will be elevated early, however as the alcohol is metabolized this may normalize. As the toxic metabolites are produced a severe anion gap metabolic acidosis will develop. Acute ingestions may have a normal anion gap with an elevated osmolal gap because the toxic metabolites have not yet accumulated. Unlike with ethanol, methanol and ethylene glycol do not produce a characteristic odor. Of note the alcohol dehydrogenase enzyme preferentially metabolizes ethanol, so if ethanol has been ingested at the same time this may delay presentation.

Clinical Features

Methanol—Methanol has a half-life of 14-18 hours so toxicity may not develop for 12-24 hours until enough time has passed for toxic metabolites to develop. Presentation may be further delayed if ethanol has also been ingested. Initially patients

present with inebriation. Once toxic metabolites have developed patients complain of visual changes including cloudy, blurred vision or the appearance of a snowstorm. Other symptoms include headache, nausea, vomiting and abdominal pain. Fundoscopic exam may reveal retinal edema and a hyperemic optic disc.

Ethylene Glycol

Ethylene glycol has a half-life of 3-8 hours and has 3 distinct clinical phases as toxic metabolites accumulate. Again presentation may be delayed if ethanol has been ingested. The initial stage (CNS) occurs in 12 hours and is characterized by CNS signs including inebriation, slurred speech, ataxia, and coma. The second stage (cardiopulmonary) develops from 12-24 hours and is characterized by tachycardia, tachypnea and hypertension, which can progress to circulatory collapse. The third and final stage (renal) includes flank pain, costovertebral angle tenderness and acute renal failure. Hypocalcemia can develop from calcium oxalate deposition. The urine may show calcium oxalate crystals however this is rarely diagnostic. Of note, ethylene glycol is commonly used in engine coolant where fluorescein may be added to allow the mechanic to use a UV light to detect coolant/radiator leaks. If ethylene glycol is ingested fluorescein may be excreted in the urine causing it to fluoresce under UV light. This is however very rarely helpful. Lactic acid levels may be falsely elevated due to glycolate cross-reacting with lactate in lab assays.

Differential Diagnosis

Diagnosis of toxic alcohol ingestion is clinical with supportive laboratory findings. Initially the osmolal gap will be significantly elevated and will gradually decrease. After several hours patients will begin to develop a progressive anion gap metabolic acidosis. Ethylene glycol toxicity usually shows leukocytosis, elevated lactic acid (not a true lactic acidosis) and hypocalcemia with evidence of renal dysfunction and a normal fundoscopic exam. Urine testing for crystals or fluorescence is not recommended. Methanol and ethylene glycol levels are diagnostic but may take several hours to result. Other causes of altered mental status and a high anion gap metabolic acidosis should always be considered.

Treatment/Work Up

Supportive care is the mainstay of treatment including stabilization of the airway, breathing, and circulation followed by routine lab tests, control of agitation and seizures and management of any subsequent complications (see general principles of overdose and poisoning). Activated charcoal is ineffective at binding alcohols. Enhanced elimination techniques include hemodialysis to remove both the parent alcohols and toxic metabolites and urine alkalization are discussed below.

Specific Therapy—Treatment is based on: blocking the production of toxic metabolites, removing toxic metabolites and correcting the metabolic acidosis.

1. Sodium bicarbonate 1-2 mEq/kg should be administered and titrated to correct the acidosis and maintain a normal pH. Formic acid and glycolic acid may have enhanced renal clearance by this method.
2. Fomepizole, a competitive inhibitor of alcohol dehydrogenase, can block the formation of toxic metabolites. The AACT recommends starting fomepizole if the ethylene glycol or methanol levels are > 20 mg/dL or if there is a high clinical suspicion. Administer 15 mg/kg IV load followed by 10 mg/kg every 12 hours. If unavailable or contra-indicated then ethanol can be used to preferentially block metabolism. Administer 10 ml/kg IV load of 10% ethanol, followed by 1.2 ml/kg/h. The infusion rate is adjusted to maintain a blood ethanol level of 100-150 mg/dL. Oral dosing can also be used with commercial 80% proof alcohol and dosed to keep the patient mildly inebriated.
3. Hemodialysis is effective at removing the parent compounds and the toxic metabolites and should be initiated in cases of severe poisoning with evidence of renal failure, optic toxicity, refractory acidosis or deteriorating vital signs. Of note if ethanol is being used as a treatment this will also be removed by hemodialysis.
4. Treatment with fomepizole, alcohol and hemodialysis until the levels of toxic alcohol are below 20 mg/dL. Once ethylene glycol levels are < 20 mg/dL administer pyridoxine

TABLE 58–21 Comparison of different alcohols.

	Ethanol	Methanol	Ethylene Glycol	Isopropanol
Metabolites	Acetaldehyde Acetate	Formaldehyde Formate	Glycoaldehyde Glycolate Oxalate	Acetone
Anion gap	Normal (unless develops ketoacidosis)	Early: normal Late: elevated	Early: normal Late: elevated	Normal
Osmolal gap	Elevated (25% more than predicted)	Early: elevated Late: normal	Early: elevated Late: normal	Elevated
Signs	Inebriation	Inebriation, blindness	Inebriation, acute kidney injury, Falsely elevated lactate, Oxalate crystals (urine), Fluorescein presence in urine, Hypocalcemia	Inebriation, Urine ketones, Fruity breath (ketones)

- 100 mg IV and thiamine 100 mg IV. Once methanol levels are < 20 mg/dL administer folate 40 mg IV. This will shift the metabolism of to less toxic metabolites.
5. Calcium gluconate supplementation may be required in cases of ethylene glycol poisoning.

Isopropyl Alcohol Toxicity

Isopropyl alcohol is commonly used in rubbing alcohol, as a disinfectant, antifreeze, and in solvents. The usual goals of ingestion are intoxication or self-harm but fatality is rare. Isopropyl functions primarily as a central nervous system inebriant and depressant and presents much like ethanol toxicity. It is also a gastric irritant and has been associated with upper GI bleeding. Isopropyl alcohol is metabolized by alcohol dehydrogenase to acetone, a ketone that does not cause acidosis or an elevated anion gap. Urine ketones will be positive and patients may have a fruity odor to their breath. As with all alcohols the osmolal gap will be elevated. Treatment is supportive. Dialysis is rarely required. See Table 58–21: Comparison of different alcohols.

OTHER POISONS

Acquired Methemoglobinemia

Methemoglobin is an abnormal state of hemoglobin and that can be induced by numerous medications.

It occurs when the iron in heme is oxidized from Fe²⁺ (ferrous) to Fe³⁺ (ferric) which is unable to bind oxygen resulting in a functional anemia due to decreased oxygen carrying capacity and availability to tissues causing the hemoglobin dissociation curve to shift to the left. Topical local anesthetics (benzocaine, lidocaine), dapsone, antimalarials, amyl nitrate, and nitroglycerin are commonly implicated. Patients present with headache, nausea, fatigue and SOB with a slate grey or blue cyanotic discoloration. Symptoms usually occur when methemoglobin levels reach 20%. Levels over 50% can cause loss of consciousness and be life threatening. Levels over 70% can be fatal. Clinically the cyanosis will not respond to increased oxygen administration. Blood will appear a chocolate brown color and cause inaccurate pulse oximetry. Typically the pulse oximeter will always produce a reading of 85%. Arterial blood gas (ABG) analysis will reveal very high PaO₂ (if placed on supplemental oxygen) as this is only a measure of dissolved oxygen, not oxygen bound to hemoglobin. SaO₂ on an ABG may also be 100%, however this only measures saturation of normal ferrous hemoglobin. Newer ABG machines can also measure the percentage of methemoglobin, which is diagnostic. Patients with levels over 25% should be treated with methylene blue, a reducing agent that will convert ferric Fe³⁺ heme back into ferrous Fe²⁺. The initial dose is 1-2 mg/kg as a 10% solution given IV over 15 minutes.

Cyanide

Cyanide is a highly toxic substance that causes death via mitochondrial cytochrome dysfunction preventing oxidative phosphorylation. Cyanide exposure is uncommon and usually from the result of fires involving synthetic materials including wool, silk, and plastics. In the hospital setting patients treated with sodium nitroprusside, for hypertension over a prolonged period of time can develop cyanide toxicity. Clinically patients present with headache, anxiety, confusion, vomiting, and abdominal pain. Vital signs may reveal tachycardia, bradycardia, hypotension, hypertension, and hyperventilation. This can progress rapidly to cardiovascular collapse and coma. On exam patients may have flushed skin causing a cherry red appearance. ABG analysis may reveal a severe anion gap metabolic acidosis and elevated lactate due to increased anaerobic metabolism. Diagnosis is based on history and clinical signs. Cyanide levels are not rapidly available. Rapid assessment and treatment is essential to prevent decline. Supportive care with oxygen and fluids should be given. There are different antidotes available that can reduce toxicity by 3 different mechanisms: 1. Binding to cyanide directly, 2. Inducing methemoglobin, and 3. Providing a sulfur donor. Hydroxocobalamin binds directly to intracellular cyanide producing a stable molecule. It is administered as 2 vials, 2.5 grams in 100 ml of saline. Amyl nitrite, an oxidizing agent, can induce formation of methemoglobin. Cyanide can bind to methemoglobin, instead of to mitochondrial cytochromes and forms a less toxic molecule. Amyl nitrate is normally given pre hospital inhaled from a vial over 30 seconds. Sodium thiosulfate provides a source of sulfur that promotes enzymatic formation of less toxic thiocyanate. It is usually administered as 50 ml of a 25% solution IV.

Iron

Iron toxicity usually results from intentional or accident ingestion of iron tablets or multivitamins and is most common in the pediatric population. The amount of elemental iron varies between different preparations. For example ferrous sulfate 325mg tablets only contain 20% of elemental iron. Pre-natal vitamins typically contain the most iron. Ingestions of 60 mg/kg usually will result in blood levels of

> 500 mcg/dL causing severe toxicity. Iron toxicity goes through several stages. The first stage (GI) develops within the first 6 hours and causes abdominal pain, nausea, vomiting, and diarrhea and GI bleeding due to the direct toxic effects of iron on the GI mucosa. The second stage (latent) occurs when GI symptoms resolve and there is relative stability or lack of symptoms for up to 24 hours. The third stage (cardiovascular) develops up to 72 hours and is characterized by shock and cardiovascular collapse. The etiology of this stage can be multifactorial from hypovolemia due to diarrhea or blood loss, direct vasodilatation and cardiac dysfunction from direct toxic effects of iron on smooth muscle and the myocardium. Patients can also develop a coagulopathy (direct effect of iron on prothrombin) and metabolic acidosis. This stage is the most common cause of death. The fourth stage (hepatic) involves evidence of hepatotoxicity and develops 2-5 days after ingestion. This can progress to liver failure. The fifth and final stage (delayed) occurs 4-6 weeks after ingestion and involves gastric outlet obstruction caused by scarring of the gastric mucosa. Treatment of iron toxicity initially involves supportive resuscitation. Patients may require aggressive fluid resuscitation and vasopressors to correct hypotension. Decontamination with activated charcoal is not recommended. Gastric lavage may be beneficial if patients present within 60 minutes. Whole bowel irrigation should also be attempted to clear the GI tract. The coagulopathy should be corrected with fresh frozen plasma. Enhanced elimination techniques involve chelation of iron in the plasma with deferoxamine. This can be administered IM or IV however the IV route is preferred. The initial infusion rate is 15 mg/kg/hour as tolerated to provide a total of 1 gram in the first hour. The rate can then be adjusted to provide a total of 6 grams during the first 24 hours. Patients who develop liver failure may require transplant evaluation.

Environmental Injuries and Toxic Exposures

Zafar K. Haque and Tihomir Stefanec

KEY POINTS

- 1 Early recognition and implementation of appropriate therapy is essential in the care of the patient who has suffered environmental injury.
- 2 The 2 main forms of heat stroke are exertional and nonexertional. Rapid initiation of cooling is essential to management.
- 3 The mildly hypothermic patient should be rewarmed at a rate of 0.5 to 2°C/h. Indications for a more rapid rate include cardiovascular instability and temperature below 32°C.
- 4 In the pre-hospital management of frostbite, protect the affected area from thawing; if thawing is inevitable, then prevent refreezing. In the hospital, immerse the affected body part in circulating water 37°C to 39°C.
- 5 Seek expert toxicology advice if considering administration of antivenom in the management of injury incurred by Crotalidae (pit vipers), black widow spiders, or scorpions.
- 6 A thorough physical examination will dictate the management of lightning injury, with specific attention paid to the integument, tympanic membrane, and eye.
- 7 The physical examination can be misleading following electrical injury. Deep tissue injury may result in compartment syndrome and rhabdomyolysis.
- 8 The acute radiation syndrome affects 3 systems: hematopoietic, gastrointestinal, and integument.

INTRODUCTION

Man's interactions with the environment may result in an untoward affliction of injury for both. From the patient's standpoint, the common theme in prevention of environmental injury is preparedness and sound awareness of environmental factors. From the practitioner's standpoint, a sound grasp of the diagnosis and management of these relatively rare presentations may aid the patient in these sometimes-critical settings. This chapter will focus on heat stroke, accidental hypothermia, drowning,

envenomation, electrical injury and injury due to ionizing radiation. Emphasis will be on basic understanding of the epidemiology, pathophysiology and management of the individual disorders, with some added focus on problems the practitioner might encounter in the critical care setting. For detailed discussions of the individual disorders the reader is advised to consult the references.

One common theme among all disorders included in this chapter is the need for their early recognition and speedy initiation of appropriate

therapy in the prehospital environment and emergency department, with critical care continuing such care and management of any associated organ failures in the in-hospital setting. Any deviation from such timely response is likely to result in significant additional injury and increased risk of poor outcome.

HEAT STROKE¹⁻⁵

Essentials of diagnosis are as follows:

- Temperature $> 40^{\circ}\text{C}$ (104°F)
- Central nervous dysfunction

General Considerations

The body's basal rate of metabolism is responsible for heat generation. Almost all energy released in the body will end in heat production. The body's core temperature is maintained in the vicinity of 36°C to 37.5°C to ensure optimal functioning of the enzymatic and molecular machinery. The principal responses to an elevated core temperature are vasodilatation and sweating. Vasodilatation intensifies the rate of heat transfer to the skin, and the evaporation of sweat from the skin surface dissipates this heat. Heat loss via electromagnetic radiation is a negligible form of energy loss, while conduction, that is, heat loss via direct contact with substances of lower temperatures (such as swimming in cool water on a hot day), can play a significant role in maintaining adequate body heat in the right circumstances. Excessive environmental heat and humidity, or increased core heat production (exercise), and interference with sweating (dehydration, hyponatremia, medications), skin perfusion (cardiovascular disorders, medications) or dissipation of heat from the surface of the skin (excessive clothing, such as in firefighters or soldiers) will result in an imbalance of heat production and heat dissipation, exposing the individual to a risk of hyperthermia, and the resulting molecular and subsequent cellular malfunction. This malfunction can manifest itself in a spectrum of presentations, ranging from transient dehydration, hypotension, tachycardia, electrolyte disturbances, heat exhaustion, lower extremity edema and heat cramps, all the way to heat stroke and the associated organ dysfunctions, and death. Pathophysiologically,

temperatures above 42°C are generally thought to result in cessation of adequate function of many enzymes and will be associated with uncoupling of oxidative phosphorylation, with neural tissue, hepatocytes and vascular endothelium being the most sensitive cell types. This will be accompanied by findings that are consistent with systemic inflammatory response syndrome (SIRS) with varying degrees of multiple-organ dysfunction.

Although the critical care practitioner will usually not encounter either heat exhaustion or heat cramps as sole presentations, it is worthwhile expanding on the presentations of these milder disorders.

Heat Exhaustion results from the depletion of water and salt (sweat production and dehydration) in the setting of vasodilated integument and muscles (decreased effective plasma volume). The depletion of salt occurs as the patient consumes fluids without sufficient salt quantities. The patient's presentation will vary, but may include weakness, fatigue, headache, nausea, and vomiting. Laboratory data will demonstrate hyponatremia and hypochloremia. Fluid therapy targeted toward the basic metabolic panel and clinical scenario should correct this syndrome.

Heat Cramps manifest as muscle cramps after strenuous exertion; the patient may endorse a history of copious sweating and consumption of hypotonic fluids. The hyponatremia and hypochloremia will correct with crystalloid infusion, as will the patient's symptoms.

Heat stroke is defined by a body temperature above 40°C (or 104°F) with evidence of central nervous system dysfunction, and is classified as exertional or nonexertional.

The exertional form of heatstroke afflicts the unacclimatized individual performing strenuous activity in hot or excessively humid conditions, such as military recruits, athletes during training or competition and other persons who overexert themselves in conditions of high temperature. In these individuals, the heat loss mechanisms (through the skin and lungs) are overwhelmed by the endogenous heat production (which can rise up to 20 times the baseline of ~ 100 kcal/h). The reduced effects of vasodilatation and sweating in an excessively hot and humid climate result in a decreased transition

of thermal energy to the environment, compounding the situation.

The nonexertional form of heat afflicts typically the elderly, economically disadvantaged and chronically debilitated, and reflects an inability to either liberate oneself from or hydrate oneself in an excessively hot environment. Prescribed therapeutics (diuretics, anticholinergics, psychotropic medications), alcohol and illicit drugs increase one's susceptibility. As opposed to the rapid development of exertional heatstroke, nonexertional heat stroke develops over a longer period.

Clinical Features of Heat Stroke

Symptoms and Signs

Fever above 40°C and central nervous dysfunction must be present to satisfy the definition of heat stroke. The presentation may range from mild confusion in the earliest stages of the illness in an elderly individual to multiorgan failure in the severe extreme. Lethargy, delirium, stupor, obtundation, and seizures, may be seen. Myocardial depression may result in jugular venous distention. The patient may be hypotensive or in a state of high-output cardiac failure, tachycardic and tachypneic, with presence of acute respiratory distress syndrome (ARDS), disseminated intravascular coagulation (DIC), acute kidney injury, hypoglycemia, rhabdomyolysis, and hepatic dysfunction.

Laboratory Findings

Basic metabolic panel, magnesium, and phosphorus, may reveal hyponatremia, hyperkalemia, hypophosphatemia, hypomagnesemia, and acute kidney injury. Complete blood count may initially reveal hemoconcentration. Coagulation panel, fibrin degradation products, and D-dimer may reveal DIC. Elevated creatinine phosphokinase, LDH, urine myoglobin may point toward increased muscle breakdown and rhabdomyolysis. ABG and lactic acid may reveal a metabolic acidosis.

Differential Diagnosis

Hyperthyroidism should be evaluated for on presentation. Drug ingestion and therapeutic prescriptions should be evaluated for by corroborative history and toxicology screen. Malignant hyperthermia,

neuroleptic malignant syndrome, and serotonin syndrome can be included or excluded from the differential after evaluation of drug history. Infection (meningitis, encephalitis, sepsis) should be excluded based on clinical, biochemical, microbiologic, and hematologic evaluation. The exclusion of a cerebral insult (eg, hemorrhage, infarct) may require imaging.

Treatment of Heat Stroke

Following initial assessment and stabilization of vital cardiopulmonary function, it is essential to immediately begin the cooling process. This should take precedence over all additional investigations. The principle of the "golden hour" should guide initial management choices. Cooling should commence as soon as the victim is encountered and should essentially be nearly completed before the patient reaches the critical care environment.

Continual temperature monitoring via rectal or esophageal thermistor is indicated. Although previous recommendations stressed that a target of 38°C should not be exceeded, recent case reports suggest that there may be a role for induction of controlled hypothermia in patients who fail to respond to the initial temperature reduction.^{6,7}

Suggested cooling methods include the placement of the naked patient on a net followed by spraying with water in addition to the application of a cooling fan. One can place the naked patient in sheets, which have been submerged in ice-cold water, with the application of a cooling fan. One can also place the patient in ice-cold water, though this may hamper further resuscitative efforts. The recent use of therapeutic hypothermia for patients with cardiac arrest led to the development of protocols for strict temperature control and maintenance in many institutions, and it appears intuitive that the same protocols could be used for rapid temperature reduction from excessively high to normal or near-normal levels in patients who did not suffer from cardiac arrest.^{6,7} However, this specific approach will need to be tested before it is adopted as a standard in patients with heat stroke. Additional measures include administration of crystalloid infusions; however, one should avoid overzealous resuscitation, and instead utilize goal-oriented approaches (eg, CVP monitoring, ultrasound evaluation of the

inferior vena cava with specific attention to respirophasic variation or urine output). As the vasodilation is addressed with the above stated methods, the intravascular volume status will change accordingly. Other measures may include lavage of various spaces with ice-cold saline (GI tract, pleural space, bladder) and use of cold humidified oxygen. Neither antipyretics (acetaminophen and salicylate) nor dantrolene are indicated, as neither of these drugs' targeted pathways will ameliorate the pathophysiology of heatstroke. Under favorable circumstances failure to respond to simpler measures to cool the patient can be addressed with cardiopulmonary bypass (CPB) or extracorporeal membrane oxygenation (ECMO), although these options are available only in specialized centers. Subsequent standard care for individual organ dysfunctions should not be any different than for other disorders encountered in the critical care setting. Some sources advocate the avoidance of vasopressive agents, with concern that they could diminish skin perfusion and further impede efficient heat removal.⁵ However, these recommendations may be difficult to follow in the setting of refractory hypotension that threatens organ perfusion and survival while the patient fails to respond to resuscitative crystalloid infusion.

HYPOTHERMIA⁸⁻¹⁰

Essentials of diagnosis are as follows:

Mild (35°C to 32°C): shivering, impaired judgment, "cold diuresis"

Moderate (less than 32°C to 28°C): CNS depression, loss of shivering, atrial arrhythmias

Severe (less than 28°C to 24°C): coma, ventricular arrhythmias, hypotension, oliguria

Profound (less than 24°C): absence of vital signs

General Considerations

The definition of accidental hypothermia is an unintentional drop of core body temperature to less than 35°C.

Risk factors for accidental hypothermia include extremes of age, alcohol or drug use, homelessness, psychiatric illness, endocrine disorders,

and low temperatures during the winter season (in addition to wind-chill). A professional, lifestyle or recreational activity that is based in remote environments (eg, boating, mountain climbing, back-country skiing, military missions in remote areas) runs the risk of exposure to a frigid environment without easy access to either warm shelter or medical facilities.

Heat loss occurs via 5 mechanisms: convection, conduction, radiation, respiration, and evaporation. The initial response to cold is shivering, a process that serves to generate heat, so long as the energy and glycogen stores permit. Hypothermia results when the environmental cold temperature overwhelms this internal heat generation mechanism.

Clinical Features

Symptoms and Signs

The patient will initially exhibit shivering, tachycardia, and peripheral vasoconstriction. The mental status will be changed to a degree that is roughly correlating with the temperature drop (see above); altered sensorium may be the first subtle feature of hypothermia. Cold-induced diuresis may occur even in the setting of dehydration; it may not be "productive urine" in the sense that the urination does not reflect adequate excretion of nitrogenous waste products. The stiff chest wall will cause increased work of breathing and ultimately contribute to hypoventilation. The hypothermic heart shows a predisposition to develop arrhythmias, and is extremely sensitive to mechanical irritation; any unnecessary movement of the patient may precipitate fatal ventricular fibrillation. The altered level of consciousness favors aspiration. At the most extreme form (< 28°C), "paradoxical undressing" may occur.¹¹

Electrocardiography Findings

The bradycardia of hypothermia is caused by decreased pacemaker cell depolarization, and may be refractory to cardiovascular drugs. The characteristic EKG finding in bradycardia is the Osborn (J) wave, which appear at temperatures less than 32°C. As the temperature lowers, the irritable myocardium is predisposed to atrial and ventricular dysrhythmias.

Laboratory Findings

It is essential to monitor serial ABGs (results are typically reported as if the patient has a normal temperature and may be different if corrected for actual body temperature), Basic metabolic panel, Magnesium, Phosphorus, calcium, creatinine phosphokinase, coagulation panel, amylase, and lipase. Endocrine markers such as TSH and Cortisol should be evaluated, as should a toxicology screen. If trauma is suspected, the appropriate imaging should be evaluated.

Temperature Monitoring

The patient should be monitored via a thermistor probe in the esophagus that has been placed 24 cm below the larynx (or in the lower third of the esophagus). The temperature recorded via devices in the bladder or rectum may be markedly different from core temperatures in the proximity of the heart (as measured by a distal esophageal probe). The esophageal probe is the device of choice.

Management

Survival after prolonged CPR, and downtime of up to several hours, in the setting of hypothermia has been described. It is essential that resuscitative efforts be continued until the patient is rewarmed, unless other findings, such as severe injuries incompatible with life, a frozen and nondeformable chest wall, or changes present in prolonged death suggest that such efforts will be futile. Available data suggests that serum potassium can serve as a guide and that levels more than 12 mmol/L are not compatible with survival.⁸ While cardiovascular interventions (medications, defibrillation) used in ACLS may show decreased response in the hypothermic patient, current lack of other evidence suggests that it is reasonable to apply the standard ACLS protocol while actively rewarming the patient.⁹

Airway

Orotracheal intubation should be performed unless the patient demonstrates mastery of the airway. As ileus is common in hypothermia, an orogastric tube should be inserted at the time of intubation.

Breathing

Mechanical ventilation with warm humidified air should be delivered.

Circulation

Crystalloids should be warmed and infused with a general assumption that the patient is hypovolemic, while the volume status should be serially assessed. One should ensure that central venous catheters, or guidewires used during their placement, are not inserted into the ventricle, as this may precipitate fatal dysrhythmias.

Rewarming

As wet clothing will strikingly increase heat loss via conduction, these items should be removed. Passive Rewarming consists of simply insulating the patient (eg, with a blanket) with the intent of preventing further heat loss. However, in the typical patient admitted to the ICU with hypothermia, this alone will not be an adequate intervention. In general, the patient should be rewarmed at a rate of 0.5°C to 2°C/h in mild hypothermia cases without significant hemodynamic instability.

Indications for a more expedient rewarming rate (active rewarming) include cardiovascular instability, temperature below 32°C, examination suggestive of peripheral vasodilatation, and endocrine insufficiency. If the patient fails to rewarm in appropriate fashion with “passive rewarming,” then “active rewarming” should be performed. Faster rates of rewarming (> 2°C/h) can be achieved with active rewarming.

Active rewarming falls under following 2 categories:

Active external rewarming—involves application of heat to the body surface, and is the method of choice used in Operating rooms (the “Bair Hugger”).

Active core rewarming—includes the use of warm humidified oxygen (40°C-45°C), warm intravenous crystalloids (42°C), irrigation of the peritoneal or pleural surfaces with warmed isotonic fluid, hemodialysis, venovenous rewarming circuits, or suitable devices used for therapeutic hypothermia that are capable of active rewarming (eg, endovascular devices commercially available for that purpose). Additional techniques to be considered

when core temperature is less than 28°C, or if there is cardiac instability, are extracorporeal membranous oxygenation (ECMO) or cardiopulmonary bypass (CBP).

FROSTBITE^{12,13}

Essentials of diagnosis are as follows:

Numbness/paresthesias

Peripheral vasoconstriction

Clumsiness of extremity (“chunk of wood”) sensation

Frostbite describes local tissue injury incurred during exposure to cold or freezing temperatures. It occurs when the tissue temperature drops below 0°C. Ice crystal formation will result in disruption of cell structure. Damage to the vascular endothelium promotes stasis and thrombosis. At the macroscopic level, edema, thrombosis, ischemia, and superficial necrosis will result.

Clinical Features

Symptoms and signs always include sensory deficit affecting light touch, pain, and temperature perception, particularly in the acral areas and distal extremities. The hands, feet, nose, ears, and face are especially susceptible. Patients may complain of a clumsy or “chunk of wood” sensation in the extremity. Deep frostbitten tissue may appear waxy, mottled, yellow, or violaceous-white. In advanced cases and delayed presentation there may be bullous formation (the bullae may be filled with clear or hemorrhagic fluid), or changes progressing to eschar formation and tissue necrosis. Superficial frostbite does not entail subsequent tissue loss unless subjected to additional trauma or subsequent infection.

Treatment

Before Thawing

The best field management essentially involves protecting the frozen part, and avoiding attempts at thawing, especially if there is risk of refreezing present, as this will markedly exacerbate any tissue injury.

If thawing is inevitable, then it is essential to prevent refreezing of the injured part. The current literature is quite insistent on forbidding the practitioner from rubbing or massaging the affected part, as this action may exacerbate injury.

During Thawing

Immerse the body part in circulating water 37°C to 39°C (water containing antiseptic flush) for 10 to 45 minutes. Encourage patient to move the body part. If pain is refractory, reduce the temperature to 33°C to 37°C. Parenteral analgesia may be required. Hyperemia is to be expected during the thawing process. In general, these patients may be hypovolemic, and crystalloid infusion should be administered accordingly.

After Thawing

Skin care should be directed by plastic surgery or burn care specialists. The decision about viability of deeper tissue structures, and the need and timing of amputation will also require specialized surgical input. Vascular thrombosis is characteristically present in the affected tissue. Anticoagulation and administration of thrombolytic therapy are options that should be discussed with appropriate surgical consultants.^{10,14} Other possible therapies such as pentoxifylline, acetylsalicylic acid (ASA), surgical or chemical sympathectomy to the affected tissue, or use of prostacyclin analogues, are supported by limited data and are not recommended for routine use.

DROWNING^{9,15-18}

Essentials of diagnosis are as follows:

- Obtundation
- Asystole
- Hypoxemia
- Hypotension

General Considerations

The WHO defines drowning as: “the process of experiencing respiratory impairment from submersion/immersion in liquid.” Immersion syndrome refers to syncope resulting from arrhythmias/vagally

mediated asystole induced upon the patient's exposure to cold water.

Risk factors include alcohol, lapses in supervision of children, aquatic sports, boating, seizures, and central nervous system depressants.

In contrast to the general image of the victim waving and shouting for help, the "instinct drowning response" takes over. The individual, in an attempt to increase buoyancy, spreads the arms horizontally under the water surface and breath holds. After this mechanism is overcome by involuntary gasping for air, water is aspirated. The irritation induced by the water induces laryngospasm that results in hypoxemia and hypercapnia. The contents of the water may inactivate the surfactant, promoting alveolar collapse and atelectasis. The actual contents of the water may obstruct the terminal airways. The fluid-filled alveolar sacs are rendered incapable of providing adequate gas exchange. This series of events culminates in cardiac arrest. It is emphasized that it is the hypoxemia that initiates the cascade of events, and is responsible for the cardiac arrest.

Clinical Features

The victim will be cold to touch, and appear mottled and discolored. Water or "foam" may be coming out of the mouth. The respiratory manifestations will be those of distress and will include tachypnea, rhonchi, rales, and cyanosis. The hypoxemia, to an extent, will dictate neurologic sequelae (from altered sensorium to coma). The metabolic state will dictate the arrhythmias.

Management

Taking into account the primary respiratory nature of the event, the current C-A-B approach in resuscitation should be modified to the more traditional A-B-C.⁹

Airway—The act of "mouth-to-mouth" resuscitation should not wait for arrival to the shore, and should instead be initiated immediately upon meeting the victim in the water. The Heimlich maneuver is contraindicated unless there is evidence of a foreign object obstructing the airway. The possibility of cervical injury must be considered in cases of drowning in shallow water after a fall or a dive, and this should prompt appropriate precautions during transport, resuscitation, and airway management. The gastric distention caused by manually ventilating the

patient may promote aspiration, and further exacerbate the situation. Chin-lift and rapid orotracheal intubation can prevent gastric inflation. In the same spirit, bag-mask ventilation should be performed by only those experienced in the technique.

Breathing—If Mechanical ventilation is instituted, one generally avoids liberation trials for the first 24 hours. Complications may include the Acute Respiratory Distress Syndrome, hemothorax, and pneumothorax. One should demonstrate findings of pneumonia (infiltrate upon resolution of pulmonary edema, sustained leukocytosis and fever) prior to initiation of antibiotics.

Circulation—CPR must be initiated promptly. Following initial resuscitation or stabilization in the field and the emergency department, the patient will frequently require admission to a critical care area for close monitoring and subsequent management of the expected complications.

Specific manifestations of drowning are as follows:

- **Cardiac:** arrhythmias may result due to prolonged hypoxia or cardiac arrest may develop
- **Pulmonary:** mechanical ventilation is frequently necessary for development of pulmonary edema and ARDS. Pulmonary infections may be present and this will be dependent on the characteristics of the aspirated water. Case reports describe the use of ECMO in drowning victims.¹⁹
- **Neurologic:** various degrees of anoxic injury with subsequent seizures, and cerebral edema can be expected in prolonged submersion or with associated cardiac arrest
- **Hypothermia:** can be a complication of prolonged immersion in cold water. This may be associated with additional complications as described above in the separate section of this chapter, but may also contribute to a better outcomes after prolonged immersion due to some degree of associated cerebral protection. However, therapeutic hypothermia has not been associated with improvements in outcome in drowning, and is currently not recommended for routine clinical use.¹⁷

ENVENOMATION SNAKEBITES²⁰⁻²³

Essentials of diagnosis are as follows:

1. Crotalidae
 - Potential for limb-threatening local reactions
 - Coagulopathy, bleeding
 - Compartment syndrome
 - Rhabdomyolysis
 - Capillary leak with intravascular volume depletion and shock
 - Metallic taste, nerve paralysis and respiratory failure
2. Elapidae
 - Minor local reactions
 - Neurotoxicity
 - Respiratory depression

General Considerations

In North America, venomous snakes include:

- Crotalidae (pit viper): Crotalus (rattlesnakes), Agkistrodon (copperheads), and cottonmouths. Crotalidae are present in most states of the US and are the cause of most snakebites.
- Elapidae (coral snakes). Elapidae are present in Gulf Coast states.

Clinical Features: Crotalidae (pit vipers)

Pit viper venom contains numerous proteins with complex and variable effects. Digestive enzymes, myotoxins, metalloproteinases, fibrinolytic and thrombin-like molecules, amongst others, induce extensive local tissue damage, edema, and rhabdomyolysis with a cascade of events that may incorporate acute kidney injury, compartment syndrome, coagulopathy, thrombocytopenia, hemorrhage, diffuse capillary leak, and shock. The rattlesnake may deliver an anticholinergic neurotoxin imparting weakness, cranial nerve palsies, and in some cases respiratory failure. The severity of pit viper envenomation can range from very minimal local reactions with no systemic reactions, to very severe limb-threatening local reactions and vital organ failure-inducing systemic reactions. Generally rattlesnakes cause more systemic

symptoms, sometimes associated with minimal local reactions, while the other Crotalid snakes cause more local reactions.

Treatment in the in-hospital setting and ICU consists of administration of polyvalent Crotalide antivenom for more serious reactions, and additional supportive care and management of the usual complications (hypovolemia, shock, bleeding, compartment syndromes, respiratory failure, acute kidney injury, and others). Initiation and dosing of antivenom is dependent on the severity of reaction observed and should be made with expert toxicologic consultation through the toxicology center network at 1-800-222-1222. Antivenom administration can be associated with immediate life-threatening anaphylaxis and delayed hypersensitivity reactions; preparations should be made for the possibility of severe immediate systemic reactions as the antivenom is prepared for administration. Anaphylaxis and other severe immune reactions associated with antivenom administration are treated in the standard fashion, and may preclude repeat administration of such treatment. Close communications with expert toxicology support is essential for determining the optimal course of action in the individual patient. Some of the above complications of Crotalide envenomation, such as severe local reactions, hemorrhages and compartment syndrome, will require surgical consultation and subsequent management.

Clinical Feature of Elapidae (coral snakes)

The venom of these snakes contains phospholipase and a neurotoxin, respectively causing local wound reactions and neurotoxic effects. Systemic reactions can occur in the absence of local reactions and be delayed in onset up to 12 hours. Envenomation from the Eastern coral snake results in predominant systemic reactions consisting of nausea, vomiting, headache, paresthesias or numbness, and may progress to paralysis with respiratory failure. The Texas coral snake causes mostly minor local reactions resulting in local pain, swelling, erythema and paresthesia, requiring mostly management of local pain. Given the delayed systemic reaction that could be associated with respiratory failure and significant paralysis following Elapidae envenomation, close observation in a monitored setting is indicated for the first 12 to

24 hours. Treatment of patients is complicated by limited availability of the antivenom whose production has ceased in 2006. If residual stock of FDA-approved antivenom is available, it should be administered in the presence of any systemic signs of envenomation and this should be done with expert consultative support from the poison control center (1-800-222-1222). The serum used in this antivenom is derived from horse serum and can cause similar hypersensitivity reactions as the Crotalide antivenom; similar degrees of precaution are advised before its use.

SPIDER BITES AND SCORPION STINGS²³⁻²⁹

Essentials of Lactrodecism (Black Widow Spider Bite) are as follows:

- Throughout United States
- Intense pain
- Muscle spasms
- Hyperadrenergic response
- Neuromuscular manifestations (fasciculations, ptosis, facial spasm)
- Abdominal pain may mimic surgical abdomen

Essentials of Loxoscelism are as follows:

- Southeastern United States
- Intense local pain and reaction that may result in necrotic eschar formation
- Systemic manifestations (hemolysis, acute kidney injury, rhabdomyolysis)

Essentials of Scorpion Stings are as follows:

- Southern United States
- Intense pain
- Neuromuscular manifestations (muscle jerking, opsoclonus, tongue fasciculations, paralysis, and respiratory failure)

Spider Bite

General Considerations

In North America, the clinically important insults incurred by spider bites are Lactrodecism (bite from Black Widow Spider—*Lactrodectus* species) and Loxoscelism (bite from the *Loxosceles* species).

Clinical Features—Lactrodecism (Black Widow Spider Bite)

Present throughout the US, this spider resides mostly in dark places, such as woodpiles or garages. The venom contains a toxin that causes catecholamine and acetylcholine release from presynaptic terminals. The ensuing muscle spasms and severe pain are generally accompanied by a hyperadrenergic response. The resulting presentation may suggest an acute abdomen, a primary cardiovascular condition such as an acute coronary syndrome, as well as rabies or tetanus. Treatment of severe reactions requiring admission to an ICU includes management of symptoms with opiates for pain and benzodiazepines for muscle spasms. Expert toxicology consultation via the regional poison control center (1-800-222-1222) should be sought before administration of the available black widow spider antivenom for severe reactions. As in all animal-derived serums, this antivenom can cause serious immediate and delayed hypersensitivity reactions that have resulted in patient fatalities.

Clinical Features—Loxoscelism (Recluse or Brown Spider Bite)

Loxoscelism is the term used to describe the syndrome caused by the *Loxosceles* species (the recluse or brown spider) that is present in the Southeastern US. Envenomation is most likely to be incurred by the female upon unintended provocation; sphingomyelinase D and hyaluronidase are the active enzymatic components of the venom. As the initial bites are often painless, the victim will often be unaware of the insult and thus unable to identify the spider. Cutaneous insult is manifested as pain and erythema (within 12-24 hours). Painful edema, irregular areas of ecchymosis and hemorrhagic blisters may form. Within 72 hours, there is a possibility of ulcer and necrosis formation. This may eventually culminate in dry necrotic eschar formation within 5 to 7 days. The progression of events, if it is to occur, will culminate in a fairly well defined ulcer with granulation formation in 2 to 3 weeks. In about 50% of cases, the cutaneous form will be accompanied by nonspecific symptoms such as headache, nausea, and vomiting. The systemic variant of loxoscelism may occur in approximately 10%, and includes renal failure, rhabdomyolysis, and intravascular hemolysis. Systemic loxoscelism

occurs 24 to 72 hours after the bite, and this presentation may require ICU admission.

Management of the rare systemic loxoscelism is supportive, and may include mechanical ventilation and hemodialysis. In other cases, expertise from a wound specialist should be sought. *Loxosceles* antivenom is not available in the United States, but is used in South America.

Scorpion Envenomation

Scorpions, located in the Southern USA, are nocturnal and favor dry environments. Accidental transport of scorpions as stowaways may result in envenomation outside of their endemic area. Only the *Centruroides sculpturatus* (also known as *Centruroides exilcauda* or the “bark scorpion”) causes clinically relevant presentations in the USA. The intent of the scorpion venom, which acts as a neurotoxin via its action on sodium channels, is to immobilize the victim. Envenomation may result in vomiting, adrenergic effects (tachycardia, hypertension), localized pain, paresthesias, muscle jerking, opsoclonus, tongue fasciculations, rhabdomyolysis, and respiratory failure (loss of airway muscle tone in combination with increased salivation resulting in the inability to handle secretions). In the absence of antivenom administration, 24% may end up requiring mechanical ventilation. Symptom onset will begin 15 minutes after envenomation. Severity of envenomation ranges from self-limited local discomfort and paresthesia, to a more generalized pain with associated skeletal and cranial nerve paralysis, and autonomic nervous dysfunction. Supportive management will include analgesia (opioid analgesia is indicated), benzodiazepines, and intravenous fluid administration. Severe systemic symptoms warrant the administration of the antivenom, immune F(ab')₂ (equine) injection, with readministration at 30 minute serial evaluations if symptoms persist. This equine preparation has been successfully demonstrated to resolve *Centruroides* scorpion envenomation mediated neurotoxicity in children if administered within 4 hours of insult. Expedient administration in the emergency room may altogether obviate the need for ICU admission. For patients admitted to the intensive care unit with persistent symptoms or significant organ dysfunction

expert consultation with toxicology specialists at a regional poison control center (1-800-222-1222) is advised.

Marine Life Envenomations^{30,31}

Essentials of diagnosis are as follows:

- Local pain and edema
- Erythema
- Systemic symptoms including cardiovascular collapse are possible

Stingrays (Class Chondrichthyes)

Stingrays are found worldwide, and account for around 2000 emergency room visits per year in the United States. The insult inflicted on the human will be the result of an unintended encounter, as opposed to an attack. The stingray is often buried in the sand; the victim may unknowingly step on it, causing the stingray to unleash its tail (decorated with up to 6 barbs) on the extremity. The laceration induced by this may cause hemorrhage if an artery is struck. The embedded spines then release their venom. The venom of the Stingray consists of amino acids, serotonin, 5'-nucleotidase, and phosphodiesterase. The net effect of the venom is potent vasoconstriction and wound necrosis, with the victim experiencing considerable pain and edema. Clinical examination reveals swelling, erythema, and cyanosis. The symptoms peak at 30 to 90 minutes, and last up to 48 hours. The embedded spines, if not removed, remain an active source of venom. The affliction of the heart or secondary trauma accounts for mortality. Systemic symptoms may include excessive salivation, muscle cramps, nausea, and vomiting.

The hallmarks of therapy include hemostasis, hot-water immersion, analgesia, and wound-exploration. Hemostasis should be the first priority. The treatment of hot water immersion (43.3°C-45.6°C) takes advantage of the heat-labile nature of the venom. Imaging and exploration should be directed at removing embedded spines.

Spiny Fish

The Scorpaenidae Family (spiny fish) consists of Stonefish and Lionfish. In the United States, the

afflicted victims will usually be aquarium owners. The affected extremity will be edematous and painful, with the possibility of wound necrosis development. Systemic effects, though rare, may include myotoxicity, neurotoxicity, and cardiotoxicity. It is suggested that the systemic effects of nausea and syncope may actually be due to the pain inflicted by envenomation from the embedded spines.

As with the envenomation induced by the Stingray, the hallmarks of therapy include hemostasis, hot-water immersion (45°C), analgesia, and wound exploration. In the case of the Stonefish, antivenom may be administered intramuscularly. All spines must be removed (and confirmation should be sought with plain radiographs). The affected extremity must be elevated and washed with water. The wounds may take months to heal, and expert consultation from a Wound specialist should be sought.

Portuguese-man-of-war (Physalia physalis)

The Portuguese-man-of-war is found in the Atlantic Ocean, in shallow water and along the shore. Its nematocysts may remain active for months. The victim experiences pain upon exposure; the erythematous skin irritation that accompanies it may eventually progress to wound necrosis. Some may develop a delayed hypersensitivity reaction. Systemic reactions in the form of nausea, vomiting, dyspnea, headache, abdominal pain, and cardiovascular compromise are infrequent but have resulted in death.

The victim should be removed from the water to prevent further envenomation. The tentacles can be removed manually (preferably with forceps or the gloved hand) or by pouring salt water over the affected area. Hot-water immersion will serve to inactivate the heat-labile venom. As of yet, there is no definitive antivenom targeting *Physalia physalis*.

ELECTRIC SHOCK & LIGHTNING INJURY³²⁻³⁶

Essentials of diagnosis are as follows:

- Arrhythmias
- Skin lesions or burns
- Deep tissue injury and rhabdomyolysis

Lightning Injury

General Considerations

Although lightning strikes the earth more than 8 million times per day, its infliction on the human remains relatively rare. Lightning strike occurs when a potential energy gradient (between the clouds and the earth) exceeds the resistance of the air.

Lightning strike can afflict the patient via following 1 of 5 manners:

- A.** Direct Contact—this is the rarest and deadliest form of injury. Either the person is the direct recipient of the lightning strike. The entire energy of the lightning strike is discharged into the patient (possibly via an open orifice such as the ears).
- B.** Contact injury—the victim is touching the object (eg, car), which is the strike point of the lightning path.
- C.** Side Flash or “Side Splash”—Part of the energy from the strike is diverted to the victim, who happens to be within proximity (~6 feet) of the lightning strike’s recipient (object or living creature).
- D.** Ground current or Step Voltage—the lightning strike hits the ground and travels along the ground to the victim, who is within close proximity (usually up one leg and down the other). This is the mechanism that afflicts farm animals.
- E.** Blunt trauma—the current imposes an opisthotonic contraction on the victim; in addition to the explosive/implosive force that the recipient suffers from the blast effect.

Clinical Features

Cardiac manifestations include Asystole predominantly, Ventricular fibrillation, and myocardial contusion (in those who have suffered blunt injury). Absence of peripheral pulses in the aftermath of a Lightning injury should raise suspicion for significant vasospasm. The Clinician should assess for skin lesions or burns, muscle injury, and compartment syndrome in extreme cases.

Neurologic sequelae include loss of consciousness, headache, amnesia, paresthesias, injuries sustained during blunt trauma (eg, traumatic subdural hematoma), and transient paralysis associated with the hyperadrenergic state (keraunoparalysis). Ophthalmologic evaluation should assess for “lightning cataract” and corneal burns. Tympanic membrane rupture is fairly common and should be evaluated on admission.

Management

- A. General Measures**—Duration of the lightning strike is measured in milliseconds; the first responder will not be at any risk in approaching the victim. Standard evaluation should address the Airway, Breathing, and Circulatory status, with interventions as indicated. The patient should be evaluated in the same manner as a trauma victim with particular attention paid to the cervical spine.
- B. Specific Considerations**—Hypotension should prompt an investigation into a possible source of bleeding, resulting from blunt trauma.
If there is concern for rhabdomyolysis or clinical signs of dehydration, adequate tissue perfusion needs to be ensured with intravenous crystalloids. Any resulting kidney injury may require dialysis.
If there is altered sensorium or other neurologic complaints, then evaluate for cerebral edema or traumatic intracranial bleed with CT-brain. Peripheral nerve injury is a common occurrence.
Otolaryngology should be engaged to evaluate for tympanic membrane rupture, as this is fairly common.
In the same spirit, an Ophthalmology opinion should be sought early in the patient’s course with the intent of evaluating for cataracts, vitreous hemorrhage, and optic nerve injury.
Standard wound care should be applied to burns. Patients who suffer burns as the result of lightning strike may require referral to a Burn Center.

Electrical Injury

General Considerations

Electrical injury will afflict injury on the patient via 1 of 3 mechanisms:

- i. The direct effect of the electrical current on cells and tissues
- ii. The conversion of electrical energy to heat injury, with its resultant tissue damage
- iii. The electrical current mediated muscle contractions and its subsequent traumatic sequelae.

Clinical Features

Electricity is delivered as direct current (DC) or alternating current (AC). DC induces a single muscle contraction, and its duration of delivery is brief (it will propel the patient away from the source, thus lessening the exposure time). The repetitive delivery of AC, on the other hand, when encountered with the hand will lead to a progressively tighter grip around the source of delivery (the hand flexors are stronger than the extensors). In effect, AC induces sustained contraction or tetany, thus increasing the exposure time and tissue damage.

The physical examination may be misleading, and these patients should be managed as if they are victims of crush injury, as opposed to burn injury.

Well-demarcated partial-thickness and full-thickness burns may be seen, with an evolution toward the latter.

Management

In the field, as opposed to the site of lightning strike, the first responder must be particular about disengaging active hazards such as live wires.

Cardiac arrhythmia and arrest can occur, and respiratory failure is possible, requiring advanced cardiac and mechanical respiratory support.

Deep tissue injury with development of compartment syndrome, bone fracture, osteonecrosis, and spinal injury, and injury to blood vessels may require surgical consultation and management.

Rhabdomyolysis may result in acute kidney injury and should be addressed with adequate volume infusions.

The skin may show significant burn injury at sites of entry and exit of the electrical charge and require expert burn center management.

INJURY DUE TO IONIZING RADIATION³⁷⁻³⁹

Essentials of diagnosis are as follows:

- Nausea, vomiting, diarrhea
- Hypovolemia
- Dermatitis, erythema, blister formation, ulceration
- Pancytopenia, agranulocytosis
- Infections
- SIRS, progression to multiorgan failure

General Considerations

Our clinical knowledge of ionizing radiation injury is largely derived from the occurrences in Hiroshima and Nagasaki (1945), Three Mile Island (1979), Chernobyl (1986), and Fukushima (2011).

Unlike nonionizing radiation, electromagnetic radiation not capable of displacing electrons and thereby generating ions, but with potential for injury via heat production, ionizing radiation (subsequently referred to as “radiation”) generates ions via displacement of electrons thereby creating unstable atoms that interact with other molecules. The larger alpha particles are incapable of penetrating clothing or the skin and exert their damaging effects via ingestion or inhalation. The smaller beta particles are capable of limited penetration through skin and can reach the subcutaneous tissue, and will also be harmful when ingested or inhaled. Photons in the form of X-rays or gamma rays are capable of penetration through all tissues. At the biochemical and molecular level, the mechanism of injury is via damage to deoxyribonucleic acid (DNA).

Radiation is measured in units of Gray (Gy) or radiation absorbed dose (rad). (1 Gray = 1 joule of radiation absorbed per kilogram of tissue, with 1 Gray = 100 rads). The exposure of the human body to 1 Gray of radiation may result in acute radiation syndrome (ARS).

Clinical Features

The critical care practitioner may be primarily involved with ARS, a syndrome that involves 3 organ systems: the hematopoietic system, the gastrointestinal tract, and the skin. Exposures of less than 1 Gy are unlikely to result in ARS, doses more than 10 Gy are usually fatal in 5 to 12 days. Massive exposure to more than 20 Gy may result in acute neurovascular compromise, but such exposures may be infrequent in the absence of a nuclear explosion; for comparison, the highest absorbed dose at Chernobyl was 16 Gy.

The hematopoietic system will manifest varying degrees of bone marrow suppression and this will result in the expected complications related to leukopenia, anemia, and thrombocytopenia. Changes in the gastrointestinal tract will result in abdominal pain, nausea, vomiting, diarrhea, ileus, and result in disruptions of the mucosal barrier. The skin will show varying degrees of erythema, edema, blistering, desquamation, ulceration, and necrosis. Changes in all these systems will predispose to infections. The combined effects of injury experienced by these organ systems may be presenting as SIRS or sepsis, and in severe cases as multiorgan failure and lead to death.

The acute radiation syndrome is divided into 3 phases:

- Prodrromal phase—nausea, vomiting, diarrhea, erythema, hypotension, hypovolemia, and headache.
- Latent phase—the symptoms will lessen and even disappear. Lymphocyte depletion kinetics may help determine the possible length of this phase.
- Manifestation phase—depending on the intensity and nature of the radiation exposure, this phase will show changes involving the hematopoietic system, the gastrointestinal tract, the skin, and the neurovascular system. This phase may occur after several weeks in case of a mild exposure (1-2 Gy) or may occur immediately following the initial exposure in severe lethal exposures (> 10-20 Gy).

The Combined Injury Syndrome incorporates the generalized trauma, burns, and wounds,

inflicted upon the victim, in addition to the radiation exposure.

Management

The culprit radioisotope(s) must be identified, as this will dictate decontamination techniques, helping to maximize the safety of the involved first responders and the victims.

The provider is referred to specific guidance from governmental agencies; latter should direct all aspects of the decontamination process.

Poison Control should be engaged regarding the early administration of blocking agents (eg, Potassium iodide for I^{131} exposure) and chelating agents (eg, Penicillamine for radioactive lead poisoning).

The extreme result of hematopoietic insult is pancytopenia. Transfusion support and colony stimulating factors are used as needed to correct anemia, reduce the risk of or control bleeding, and increase the leukocyte count. Hematopoietic cell transplantation may be considered, with the appropriate triaging and consultations. The immunosuppressed radiation victim is at risk for graft-versus-host disease following transfusions, and all cellular products must be leukoreduced and irradiated.

The cutaneous damage may require specialized care by burn specialists and plastic surgeons in a specialized center.

The management of gastrointestinal symptoms is supportive, and should include prophylaxis against gastric ulceration and avoidance of invasive instrumentation due to the friability of the mucosa that is very prone to bleeding.

The patients are at very high risk of development of infections due to combined effects of damage to the integument and mucosal surfaces, and the immune suppression. Current guidelines advise the use of prophylactic broad-spectrum antimicrobials targeted at bacterial, viral, and fungal organisms. Because control of infections is of critical importance in patients who, otherwise, do not have a lethal exposure to ionizing radiation, specialist input by infectious disease experts may be of critical benefit.

Patients who have been exposed to radiation doses that are more than 10 Gy have a universally fatal outcome and appropriate focus on comfort should be the mainstay of management.

Critical Care Issues in Pregnancy

Alina Dulu, MD; Ellie S. Ragsdale, MD and Dena Gofman, MD

KEY POINTS

- 1 Critical illness in obstetrics can be the result of pregnancy-specific conditions or due to commonly seen critical care diagnoses with unique-management considerations in pregnancy as a result of physiologic alterations and fetal concerns.
- 2 Any pregnant patient requiring ICU level care should be in a facility with obstetric and neonatal teams for collaborative multidisciplinary care.
- 3 A critically ill pregnant patient is at risk for labor and delivery, regardless of the initial inciting condition.
- 4 For patients who are still pregnant, in general, the rule is for maternal stabilization prior to delivery of the fetus. In most cases, appropriate treatment of the mother will improve fetal status.
- 5 The American Heart Association publishes guidelines for cardiac arrest in special situations including pregnancy. Key interventions to prevent arrest in a critically ill pregnant woman include left lateral positioning, 100% oxygen, IV access above diaphragm, and treatment of hypotension.
- 6 In maternal cardiac arrest not immediately reversed by basic life support and advanced cardiovascular life support (ACLS), prompt consideration for emptying the uterus must be undertaken (“perimortem cesarean”). For this to be feasible, resuscitation teams must activate a protocol for possible cesarean delivery as soon as a maternal cardiac arrest is identified.
- 7 Important obstetric conditions outlined within the text include preeclampsia, eclampsia, hemolysis, elevated liver enzymes, and low platelets syndrome, acute fatty liver of pregnancy, anaphylactoid syndrome of pregnancy/amniotic fluid embolism, peripartum cardiomyopathy, and obstetric hemorrhage.
- 8 Nonobstetric conditions with a focus on presentation in pregnancy outlined within the text include thromboembolic disease, severe sepsis, septic shock, and multiorgan failure, pulmonary edema, arrhythmia, diabetic ketoacidosis, and status asthmaticus.

INTRODUCTION

The mortality rate for critically ill obstetric patients ranges from 12% to 20%. A recently published retrospective study described the current leading diagnoses associated with ICU admission in obstetrics.

ICU admissions related to abortions and ectopic pregnancy accounted for 10% of all ICU admissions among pregnant and postpartum women. Leading causes for antepartum admissions included obstetric-related hypertensive disease (23%), trauma

(17%), and cardiac disease (13%). Delivery-related ICU admissions were overwhelmingly related to obstetric-related hypertensive disease (38%), hemorrhage (33%), and cardiac disease (18%). Postpartum admissions were most often attributed to cardiac disease (37%), obstetric-related hypertensive disease (21%), and cerebrovascular disease (20%).

Critical illness in obstetrics can be the result of pregnancy-specific conditions or due to commonly seen critical care diagnoses which may have unique-management considerations in pregnancy as a result of physiologic alterations and fetal concerns. Herein, we will review physiologic adaptations due to pregnancy by systems, general considerations for the critically ill pregnant patient, and management strategies for both pregnancy-specific conditions and critical medical conditions seen most commonly in gravid women.

PHYSIOLOGIC ADAPTATION TO PREGNANCY

Gestation in singleton pregnancies lasts an average of 40 weeks spanning from the first day of the last menstrual period to the estimated date of delivery. Previously, “term pregnancy” was defined as the period between 37 and 42 weeks gestation. However, recent data have shown improved neonatal outcomes with increasing gestation within this window. The American College of Obstetricians and Gynecologists (ACOG) and the Society of Maternal-Fetal Medicine now endorse the use of “early term” (37 0/7 through 38 6/7 weeks of gestation), “full term” (39 0/7 through 40 6/7 weeks of gestation), “late term” (41 0/7 through 41 6/7 weeks of gestation), and “postterm” (greater than 42 0/7 weeks of gestation) for classification.

Major adaptations in maternal physiology are required during gestation to sustain a healthy pregnancy. Many of these adaptations would be considered pathologic in a nonpregnant patient. Understanding of these changes is imperative in clinical decision making when pregnant women become ill.

Cardiovascular System

Pregnancy causes profound physiologic changes in the cardiovascular system. These adaptations begin

very early in gestation, often before pregnancy is diagnosed, and are required to maximize oxygen delivery to the uteroplacental unit. In healthy women, these changes are generally well tolerated. However, in certain cardiac diseases, maternal morbidity and even mortality may occur.

Increased uterine volume elevates the diaphragm which displaces the heart up and to the left. The heart rotates along its long axis and the cardiac apex is deviated laterally. This results in an increased cardiac silhouette on routine radiography. Myocardial hypertrophy is observed due to the expanded blood volume and increasing afterload resulting in about a 12% increase in the overall size of the heart. Normal pregnancy can also result in changes in standard echocardiograms and electrocardiograms, including nonspecific T-wave changes and mitral/tricuspid regurgitation.

Cardiac output (CO) is the product of stroke volume and heart rate, both of which increase during pregnancy. The initial rise in heart rate occurs by 5 weeks gestation and continues to rise until it peaks at around 32 weeks gestation at 15 to 20 beats above the pregravid state (16%-20% increase in resting heart rate). The stroke volume begins to rise between 5 and 8 weeks gestation and reaches its maximum at 20 weeks, 20% to 30% above the pregravid state. CO is positional in the second half of pregnancy due to the weight of the gravid uterus which compresses the inferior vena cava (IVC) and decreases venous return. The decrease in CO in the supine position compared to the lateral recumbent position is 10% to 30%. The IVC is completely occluded near term in the supine position; venous return from the lower extremities occurs through dilated paravertebral collateral circulation. There is selective distribution of the increased CO with uterine blood flow increasing 10-fold near term. Perfusion to the skin, breasts, and kidneys is also significantly increased.

Blood pressure is the product of CO and systemic vascular resistance (SVR). Despite the significant increase in CO early in gestation, systemic blood pressure is decreased until later in pregnancy as a result of decreased SVR that nadirs midpregnancy and then gradually rises until term. Progesterone-mediated smooth muscle relaxation contributes to the decrease in SVR. Central hemodynamic studies of pregnant women demonstrate

a significant decrease in pulmonary vascular resistance. Mean arterial pressure, pulmonary capillary wedge pressure, central venous pressure, and left ventricular stroke work index are unchanged. Colloid osmotic pressure is decreased.

During the intrapartum and immediate postpartum period, the hemodynamic changes of the cardiovascular system reach new heights. CO increases dramatically during labor in part due to increased venous return from 300 to 500 mL autotransfusion that occurs at the onset of each contraction as blood is expressed from the uterus. In addition, mean arterial pressure (MAP) also rises in the first stage of labor and reaches a peak at the beginning of the second stage. The increase in CO and MAP are influenced by maternal pain and anxiety. Regional anesthesia has been shown to reduce the overall increase in CO, but a surge is still present with contractions. Immediately postpartum (10-30 minutes postdelivery) CO reaches its maximum and maternal heart rate declines. Approximately 1 hour postpartum CO returns to pregnancy baseline. Return to prepregnancy levels does not occur until 6 to 8 weeks postpartum.

Respiratory System

Physiologic and structural changes occur throughout the respiratory tract during pregnancy. The nasal mucosa becomes edematous and hyperemic with increased secretions due to a rise in circulating estrogen. These changes cause marked nasal stuffiness and an increased risk of epistaxis. Placement of nasogastric tubes or nasal airways can cause excessive bleeding if adequate lubrication is not used.

The structure of the thoracic cavity is markedly altered in pregnancy and cannot be entirely explained by the mechanical pressure of the gravid uterus. The subcostal angle increases from 68° to 103° , the transverse diameter of the chest expands by 2 cm, and the chest circumference expands by 5 to 7 cm. The resting level of the diaphragm is 4 cm higher at term than in the nongravid state. However, the diaphragmatic excursions are increased by 1 to 2 cm over nonpregnant values.

Intrinsic pulmonary function and static lung volumes are altered throughout the pregnancy. Elevation of the diaphragm decreases the volume of the lungs in the resting state which reduces the

total lung capacity by 5% and the functional residual capacity (FRC) by 20%. FRC is the sum of expiratory reserve volume and residual volume; both decrease in pregnancy. Inspiratory capacity, the maximum volume that can be inhaled, increased by 5% to 10% because of the decrease in FRC. The vital capacity does not change (Table 60-1).

Increased progesterone levels during pregnancy leads to a state of chronic hyperventilation, which results in a decrease in PaCO_2 to below 30 mm Hg in normal women. Maternal pH does not change because there is a reciprocal decline in the bicarbonate concentration. Total body oxygen uptake at rest increases by 12% to 20%. This increased oxygen is needed to meet the high metabolic demands of pregnancy. The oxygen need is met by increased tidal volume alone because respiratory rate and pulmonary diffusing capacity do not change.

Hematologic System

Blood volume and composition change during pregnancy. Maternal blood volume begins to increase at about 6 weeks gestation and progresses until 30 to 34 weeks and then remains stable until delivery. Average blood volume expansion is 40% to 60% but this varies widely. The increase in blood volume results from a combined expansion of both plasma volume and red blood cell (RBC) mass. Without iron supplementation, RBC mass increases by about 18% by term, supplemental iron causes the increase to rise up to 30%. Plasma volume increases more than the RBC mass leading to a drop in maternal hematocrit, that is, dilutional. This so-called physiologic anemia of pregnancy reaches its nadir at 30 to 34 weeks gestation.

The white blood cell count increases to about 10,000/ μL at term and the platelet count decreases slightly. Platelet counts greater than 120,000/ μL are generally considered normal in pregnancy. In the third trimester, approximately 8% of gravidas will develop gestational thrombocytopenia with platelet counts between 70,000 and 150,000/ μL .

The biochemical characteristics of the blood change in pregnancy. Serum osmolality decreases by 10 mOsm/L early in pregnancy and then remains stable throughout gestation. Minor decreases in sodium, potassium, calcium, magnesium, and zinc occur. Chloride does not change, but bicarbonate markedly decreases. The plasma concentrations of

TABLE 60–1 Pulmonary changes in pregnancy.

Measurement	Def inition	Change in Pregnancy
Respiratory Rate (RR)	Breaths per minute	Unchanged
Vital Capacity (VC)	Max amount of air that can be forcibly expired after max inspiration (IC + ERV)	Unchanged
Inspiratory Capacity (IC)	Max amount of air that can be inspired from resting expiratory level (TV+ IRV)	Increased 5%-10%
Tidal Volume (TV)	Air inspired and expired in a normal breath	Increased 30%-40%
Inspiratory Reserve Volume (IRV)	Max amount of air that can be inspired at the end of a normal breath	Unchanged
Functional Residual Capacity (FRC)	Air in the lungs at resting expiratory level (ERV+ RV)	Decreased 20%
Expiratory Reserve Volume (ERV)	Max amount of air that can be expired from the resting expiratory level	Decreased 15%-20%
Residual Volume (RV)	Air in the lungs after max expiration	Decreased 20%-25%
Total Lung Capacity (TLC)	Total amount of air in the lungs at maximal inspiration (VC + RV)	Decreased 5%

Reproduced with permission from Gabbe SG, Niebyl JR, Simpson JL: Obstetrics: normal and problem pregnancies, 3rd edition. New York: Churchill Livingstone; 1996.

albumin and total protein decrease in proportion to the plasma volume expansion. Alkaline phosphatase increases because of the production of the placental form of the enzyme. Serum lipids increase toward term, with the levels of cholesterol and triglycerides doubling during pregnancy.

Levels of many coagulation factors are altered in pregnancy. Fibrinogen levels increase to as high as 600 mg/dL near term. The prothrombin time, activated partial thromboplastin time, and thrombin time all fall slightly but usually remain within the lower range of normal limits for nonpregnant women. Bleeding time and whole blood clotting times do not change. There is a 5 to 6 fold increased risk for thromboembolic disease in pregnancy. This greater risk is caused by increased venous stasis, vessel wall injury, and changes to the coagulation cascade that lead to hypercoagulability. The overall risk of thromboembolism in pregnancy is estimated to be 1/1500 and accounts for 25% of the maternal deaths in the United States.

Renal System

The kidneys enlarge in size and weight during pregnancy due to increased renal vasculature, interstitial volume, and urinary dead space. The dead space is

accounted for in the dilation of the collecting system. Pelvic calyceal dilation is greater on the right than the left. Anatomic changes are also observed in the bladder. The bladder trigone is elevated and increased vascularity is seen throughout the bladder, which increases the incidence of microhematuria.

Renal plasma flow and glomerular filtration rate (GFR) increase significantly early in pregnancy reaching their peak early in the third trimester. The creatinine clearance in pregnancy is increased to values of 150 to 200 mL/min. The increased GFR leads to a reduction in maternal plasma levels of creatinine, blood urea nitrogen, and uric acid. Serum creatinine falls from a nonpregnant level of 0.8 to 0.5 mg/dL by term.

Glucose excretion increases and glycosuria is common. This glycosuria is intermittent and not necessarily related to blood glucose levels or the stage of gestation. No significant increase in proteinuria occurs in a normal pregnancy in women without proteinuria before pregnancy. In women with preexisting proteinuria, the amount of proteinuria increases in both the second and third trimesters.

Other changes in the tubular function include an increase in the excretion of amino acids in the

urine and an increase in calcium excretion. The increase in calcium excretion increases the risk of nephrolithiasis in the setting of urinary stasis mediated by progesterone. Finally, the kidney responds to the respiratory alkalosis of pregnancy by increased bicarbonate excretion.

Immune System

The fetus is a semiallograft and a successful pregnancy is dependent on either evasion of immune surveillance or suppression of the maternal-adaptive immune response. A major shift occurs away from cell-mediated cytotoxic immune responses toward increased humoral and innate immune responses.⁹ This shift decreases the maternal cytotoxic potential against fetal antigens. The decrease in cellular immunity leads to increased susceptibility to intracellular pathogens such as cytomegalovirus, herpes simplex virus, varicella, and malaria. The changes in the immunologic system of a pregnant woman are complex and not fully understood. Hormones, particularly progesterone, likely play a significant role.

GENERAL CONSIDERATIONS IN THE CARE OF THE CRITICALLY ILL GRAVIDA

Any pregnant patient requiring ICU level care should be in a facility with obstetric and neonatal teams for collaborative multidisciplinary care. The critically ill pregnant patient is at risk for labor and delivery, regardless of the initial inciting condition. In addition, postpartum patients continue to have pregnancy-related physiologic changes and are prone to specific pregnancy-related conditions such as bleeding, hypertensive disorders, venous thromboembolism, and infection from an obstetric source.

For patients who are still pregnant, in general the rule is for maternal stabilization prior to delivery of the fetus. In most cases, appropriate treatment of the mother will improve fetal status. Treatment required to stabilize the mother's critical status should be undertaken, even if such intervention is potentially disadvantageous to the fetus. Short- and long-term morbidity in surviving fetuses is directly related to maternal physiologic status.

There are cases where the obstetric team will be guiding the management of care toward intended delivery (preeclampsia, acute fatty liver, amniotic fluid embolus); however, it is important to know that even in cases where delivery is not recommended, spontaneous labor may ensue. A plan for potential delivery should be made with the obstetric team in case this occurs and should include preferred location, preferred mode (vaginal vs cesarean), need for analgesia or anesthesia and plan for advanced pediatric support for the newborn. Basic supplies should be made available at the ICU bedside. ICU teams must be aware of basic signs of labor including patient pain, leakage of fluid or mucus per vagina, any vaginal bleeding, palpable contractions (tightening at the uterine fundus). Although some of these may be difficult to discern in an intubated and sedated patient, close attention may allow early identification of signs and symptoms of labor in a critically ill patient and can allow for planning and mobilization of appropriate resources to optimize maternal and fetal outcome.

Critical illness can compromise the fetus as a result of maternal hypotension, hypoxemia, and acid-base imbalances. Fetal oxygenation is dependent upon uterine blood flow that is not autoregulated, thus can fall as a result of decrease in maternal systolic blood pressure. Uterine blood flow can also be reduced from vasoconstriction related to vasopressors, maternal hypercarbia or hypocarbia. Continuous fetal monitoring of fetuses who have reached viability may be recommended. The fetal heart rate pattern should be monitored by a physician or nurse experienced in fetal heart rate interpretation and information can be used to guide maternal resuscitative strategies.

Oxygen supplementation should be used early with goal maternal oxygen saturation (SaO_2) greater than 95% and PaO_2 greater than 70 mm Hg to maintain a favorable oxygen diffusion gradient from the maternal to the fetal side of the placenta. Early intubation after preoxygenation is recommended if adequate maternal oxygenation cannot be achieved noninvasively. The indications for intubation and ventilation are the same as for non-pregnant patients.

Endotracheal intubation in pregnant women is usually more difficult. Airway edema and hyperemia

can contribute to difficult intubation and decreased lower esophageal tone leads to increased aspiration risk during endotracheal intubation. Selecting a size of 6 to 7 ET tube and applying cricoid pressure to prevent aspiration of gastric contents should be considered.

Ventilation of the pregnant patient is similar to that of nonpregnant patients, except that it should be directed to a slightly lower PCO_2 level because the normal pregnant state is a mild respiratory alkalosis with PCO_2 levels of 28 to 32 mm Hg. Excessive hyperventilation will lead to uterine vasoconstriction with decreased placental and fetal perfusion and should be avoided.

If indicated, chest tube should be placed 2 intercostal spaces above the usual landmark of the fifth intercostal space due to the elevation of the diaphragm and ideally should be done under ultrasound guidance.

Hypotension management in the parturient requires particular attention to body position and volume status. The uterus reaches the level of the maternal umbilicus by approximately 20 weeks of gestation when it is large enough to compress the IVC when the woman is supine and result in up to a 30% reduction in CO. Displacing the uterus to the left, of the vena cava, is critical to restoring CO. This is best accomplished by placing the woman on her left side, putting a wedge or rolled towel under her right side, or adjusting her platform to a 30° left lateral tilt.

Fluid resuscitation must be administered adequately because the addition of vasoconstricting agents will compromise uteroplacental flow if vasoconstriction is imposed on an insufficient circulating volume. All vasoactive agents have the potential to constrict uterine vessels and reduce blood flow to the placenta and fetus despite improving maternal blood pressures. Placental blood flow and uterine perfusion pressure are directly proportional to maternal systemic blood pressure and CO.

Attention should be paid to glycemic control, for fetal benefit, particularly if delivery is being considered. Aggressive venous thromboembolism prophylaxis should be initiated with sequential compression devices as well as pharmacoprophylaxis if no contraindication exists.

CARDIOPULMONARY ARREST IN THE PREGNANT PATIENT: SPECIAL CONSIDERATIONS

The American Heart Association publishes guidelines for cardiac arrest in special situations including pregnancy. During a maternal resuscitation, providers must consider the mother, the fetus, and anatomic and physiologic changes of pregnancy to optimize resuscitative efforts and outcome. Key interventions to prevent arrest in a critically ill pregnant woman include left lateral positioning, 100% oxygen, IV access above diaphragm and treatment of hypotension. Consideration of reversible causes of critical illness may allow initiation of early aggressive treatment.

Recommended modifications to basic life support (BLS) include patient positioning to optimize venous return and CO. Manual displacement can be accomplished by using a one-handed and two handed technique. A difficult airway should be anticipated due to pregnancy changes and optimal bag-mask ventilation and suctioning should be used while preparing for advanced airway management. Breathing should be supported to ensure adequate oxygenation and ventilation. Chest compressions should be performed the same as most current recommendations. Defibrillation may be utilized as indicated.

Recommended modifications to ACLS include anticipation of difficulty with airway and only attempting intubation with an experienced provider, with bag-mask ventilation with 100% oxygen prior to intubation. Medication and defibrillation should be utilized in the usual doses for the standard indications, however, internal/external fetal monitors should be removed prior to defibrillation. Consider and initiate appropriate therapy for reversible pregnancy-related etiologies for the arrest. Specifically, if the patient is on IV magnesium (a commonly used medication in obstetrics), magnesium should be stopped and IV calcium gluconate should be administered.

In maternal cardiac arrest, not immediately reversed by BLS and ACLS, prompt consideration for emptying the uterus must be undertaken. For this to be feasible, resuscitation teams must activate

a protocol for possible cesarean delivery as soon as a maternal cardiac arrest is identified. In general, if the gravid uterus is at the level of the umbilicus (20 weeks size), the uterus may be causing aortocaval compression and impacting maternal hemodynamics. In this case, hysterotomy should be considered for maternal benefit, regardless of exact gestational age and fetal viability. There is an assessment that must be made promptly because the recommendation is to begin the cesarean within 4 minutes of arrest with the goal of delivering a viable fetus within 5 minutes.

PREGNANCY SPECIFIC CONDITIONS

Preeclampsia–Eclampsia

Essentials of diagnosis: hypertension, proteinuria, \pm seizures (eclampsia).

Background

Preeclampsia is defined as new onset of hypertension and either proteinuria or end-organ dysfunction at more than 20 weeks gestational age in previously normotensive women or new onset proteinuria, severe hypertension, or symptoms in women with chronic hypertension. Preeclampsia is a common disorder with an incidence of approximately 15% in nulliparous women and 6% in multiparous women. The disease is also more common at extremes of age.

Hypertensive disorders in pregnancy are one of the leading causes of maternal death in the United States and worldwide. Approximately 75% of preeclampsia will be mild and self-limited. Of the remaining 25% that are severe, very few will require ICU care usually due to significant end-organ damage. Preeclampsia affects the cardiovascular, pulmonary, renal, hepatic, hematologic, and neurologic systems.

Early diagnosis of preeclampsia is imperative to optimize maternal and fetal outcomes. The only “cure” for preeclampsia is delivery, the timing of which is determined based on gestational age and severity of disease.

Clinical Features

Symptoms or Signs—Preeclampsia was historically diagnosed based on a triad of hypertension,

proteinuria, and edema. Edema has been removed from the diagnostic criteria because of the frequent occurrence of edema in late pregnancy, but a sudden and dramatic weight gain still conveys a high likelihood of imminent preeclampsia. In 2013, ACOG removed proteinuria as an essential criterion for diagnosis of preeclampsia.

Preeclampsia is defined as with or without severe features. Preeclampsia without severe features, generally, does not cause long-term maternal end-organ damage and thus can be managed expectantly until a later gestational age, that is, 37 weeks. Preeclampsia with severe features can present with a wide variety of signs/symptoms and often requires delivery regardless of gestational age (Table 60–2).

Classically, the minimum criteria for diagnosis of mild preeclampsia are blood pressure greater than 140 mm Hg systolic or 90 mm Hg diastolic on 2 separate occasions greater than 4 hours apart and proteinuria defined as 300 mg of protein in a 24 hours urine collection or at least 30 mg/dL (1+) protein on a spot urine dipstick. There has been a shift to using a urine protein/creatinine ratio of more than or equal to 0.3 to diagnose proteinuria.

Recent guidelines published by the ACOG in December 2013 encourage new diagnostic criteria for preeclampsia excluding the requirement for proteinuria for diagnosis. The authors state that evidence suggests that kidney damage can occur in the setting of preeclampsia without significant proteinuria.

TABLE 60–2 Criteria for severe preeclampsia.

Blood Pressure \geq 160 or \geq 110 (2 values at least 4 hours apart)
Central Nervous System Dysfunction (Cerebral or Visual Disturbances)
Hepatic abnormality (RUQ/epigastric pain, transaminase \geq twice normal)
Thrombocytopenia ($<$ 100Kplatelets/microL)
Renal abnormality (serum creatinine $>$ 1.1 mg/dL or doubling)
Pulmonary Edema
Seizures (Eclampsia)

Laboratory Findings

Preeclampsia is generally a clinical diagnosis. Laboratory data are useful in following the course of the disease, particularly in the case of expectant management due to prematurity of the fetus. Serial monitoring of hemoglobin, platelet count, creatinine, liver function tests, lactate dehydrogenase (LDH), and creatinine are essential.

Management

Delivery—The only definitive management for preeclampsia is delivery of the fetus. In the case of severe preeclampsia, delivery is often expedited except in specific situations including extreme prematurity. Even in these cases, the delay is often brief and used to administer corticosteroids for fetal lung maturity or facilitate transfer to a tertiary care center.

Seizure Prophylaxis—Seizure prophylaxis should be administered to all patients in whom severe preeclampsia is diagnosed or suspected. Seizure prophylaxis is continued through delivery and 24 hours postpartum or until the patient has proven stable enough to attempt expectant management.

In the United States, magnesium sulfate is the most common medication administered for seizure prophylaxis. It is generally administered as an intravenous drip, but can be given intramuscularly if intravenous access is not available. The usual regimen includes a 4 to 6 g loading dose given over 30 minutes, followed by a continuous infusion of 2 g/h. The therapeutic range is wide with goal serum magnesium levels of 4.8 to 8.4 mg/dL.

Magnesium toxicity should be monitored for clinically in alert patients with physical exam (reflexes and cognitive status). Laboratory values can also be monitored. Magnesium is contraindicated in patients with myasthenia gravis and relatively contraindicated with pulmonary edema. It should be used with caution and consideration for dosage modification in the setting of significant renal dysfunction or oliguria. The second-line medication for treatment in these cases is phenytoin.

Control of Hypertension—Severe hypertension (BP > 160/110) should be controlled aggressively. Hydralazine and labetalol are the most common medications used to treat acute hypertension in pregnancy. Hydralazine is administered in 5 to 20 mg doses based on patient response at 30 minute

intervals. Labetalol is administered starting at a 20 mg dose and can be doubled every 10 minutes up to an 80 mg dose and a maximum total of 220 mg.

The goal is to lower blood pressure out of the severe range, not to achieve a normal blood pressure. If repetitive IV doses of medication are unable to control the blood pressure, IV drips of nitroglycerin, nicardipine, or nitroprusside can be used in a monitored ICU setting. In the setting of refractory hypertension, delivery is required once the mother is stabilized. Nitroprusside administration can lead to fetal cyanide poisoning and thus should be used with caution prior to delivery of the fetus.

Physicians should exercise caution when using any vasodilators in patients with preeclampsia because patients are often intravascularly depleted making them susceptible to dramatic drops in blood pressure. Significant drops in blood pressure can lead to decreased uteroplacental perfusion and fetal compromise.

Hemodynamic Monitoring—Invasive monitoring is not contraindicated in pregnancy and can be considered in the case of refractory pulmonary edema or oliguria. Historically, it was thought that a pulmonary artery catheter may be favorable because central venous pressures are unreliable. Recently, echocardiography has been the favored method of monitoring for fluid status.

Pulmonary edema in preeclampsia may be due to left ventricular dysfunction secondary to high SVR, iatrogenic volume overload in the face of contracted intravascular space, decreased plasma colloid oncotic pressure, or pulmonary capillary membrane injury. Of note, in the event of respiratory compromise requiring intubation, it is important to note that patients often have laryngeal edema making intubation difficult. Advanced airway devices and a skilled anesthesiologist may be required.

Oliguria in preeclampsia is due to intravascular volume depletion (most common), relative volume overload with decreased left ventricular function secondary to high SVR, or renal arteriolar spasm. Echocardiographic assessment of cardiac function can help determine the cause of oliguria and course of treatment.

HELLP Syndrome—Preeclampsia can be complicated by hemolysis, elevated liver enzymes, and low platelets (HELLP) syndrome. It is unclear if

HELLP syndrome represents a separate clinical entity from preeclampsia or is just a part of the spectrum of disease. Women with HELLP syndrome are generally older and multiparous and HELLP syndrome can occur in the absence of proteinuria or hypertension.

Laboratory evidence of HELLP syndrome includes abnormal peripheral smears (burr cells, schistocytes, echinocytes), hemolysis (elevated indirect bilirubin, LDH > 600, low haptoglobin), elevated liver transaminases ($2\times$ upper limit of normal), and thrombocytopenia (plt < 100k). Severe thrombocytopenia (plt < 30k) occurs rarely and these patients may require platelet transfusion for delivery.

In the absence of liver rupture, treatment of HELLP syndrome is generally supportive other than delivery. Serial monitoring of laboratory values and magnesium administration for seizure prophylaxis are recommended. Additionally, dexamethasone 10 mg intravenously every 12 hours can be administered to speed the process of laboratory value improvement in the setting of severe thrombocytopenia. Corticosteroids have not been shown to improve maternal morbidity or mortality.

In the event of liver rupture, operative exploration should be expedited as this is a surgical emergency. Exploration should not be delayed for imaging studies. The maternal mortality rate associated with HELLP syndrome has been estimated to be 1% with most mortality occurring in the setting of liver rupture.

Eclampsia—Eclampsia is defined as the presence of grand mal seizures in women with preeclampsia without a seizure disorder or other attributable cause of seizures. Eclampsia carries a maternal mortality rate of 1% to 2% and a fetal mortality rate of 10%. Onset of seizures is often preceded by symptoms including a severe unrelenting headache, nausea, or vomiting. Seizures are usually self-limited and medication is not usually required to break the seizure activity.

Treatment of eclampsia is standard magnesium administration with a 4 to 6 g bolus and then a continuous infusion of 2 g/h. Magnesium should be administered expeditiously in the setting of eclampsia, however, the purpose is to prevent recurrent seizure. Magnesium is superior to phenytoin and diazepam for preventing additional seizures.

Once seizure activity is controlled, delivery should be affected. In many cases, labor can be induced safely and a vaginal delivery can be achieved. Magnesium prophylaxis should be continued throughout delivery and for 24 hours postpartum.

Additional Critical Care Events—Disseminated intravascular coagulation, hypertensive encephalopathy, acute myocardial infarction, acute renal failure, intracranial hemorrhage, and acute aortic dissection can also be associated with hypertensive disorders in pregnancy. In each of these settings, a multidisciplinary approach with critical care, obstetrics, anesthesia and in certain cases other services is required to provide adequate care.

Acute Fatty Liver of Pregnancy

Essentials of diagnosis: hepatic dysfunction and microvesicular fatty infiltration of hepatocytes.

Background

Acute fatty liver of pregnancy (AFLP) is a rare but life-threatening complication of pregnancy with an incidence between 1:7000 and 1:16,000. It occurs late in pregnancy or immediately postpartum, often as fulminant liver failure with sudden onset coagulopathy and encephalopathy in women with no history of liver disease. Microvesicular fatty infiltration of hepatocytes is seen on microscopy.

Historically, AFLP was thought to be universally fatal, but early recognition, aggressive stabilization of the mother, and prompt delivery have improved the prognosis. Maternal and fetal mortality are currently estimated at approximately 15%.

The exact etiology of AFLP remains unknown. In many cases, either the mother or fetus is found to have an autosomal mutation that causes deficiency of the long-chain 3-hydroxyacyl coenzyme-A dehydrogenase (LCHAD), a fatty acid beta-oxidation enzyme. The association of this mutation with AFLP is strong enough that screening for the LCHAD mutation is recommended in the infants of affected mothers. Additional risk factors include nulliparity, multiple pregnancy, male fetus, and coexisting preeclampsia.

Clinical Features

Symptoms or Signs—Patients often present with a history of 1 to 2 weeks of nausea, vomiting,

anorexia, and malaise. On physical exam, patients are ill-appearing often with some degree of jaundice. Hypertension with or without proteinuria and transient diabetes insipidus with polydipsia and polyuria are also common.

In severe disease, ascites, progressive hepatic encephalopathy, hypoglycemia, coagulopathy, metabolic acidosis, and renal failure are also often seen. Intrauterine fetal demise occurs frequently, often prior to the diagnosis, likely due to hypoglycemia and uteroplacental insufficiency.

Laboratory Findings—Diagnosis of AFLP is suspected based on clinical presentation and dramatic laboratory changes (Table 60–3), but a definitive diagnosis cannot be made without a liver biopsy, confirming microvesicular fat infiltration of the hepatocytes.

Management

Care of a patient with suspected AFLP has 4 categories: diagnosis, stabilization, delivery, and support. During the diagnosis phase of management, intensive monitoring of the mother and the fetus are required. Because the fetal status can decline rapidly, if AFLP is suspected continuous external fetal monitoring should be applied until the diagnosis is ruled out or delivery is affected. Maternal hemodynamic and metabolic status should be monitored both clinically and with laboratory values.

The stabilization phase includes treatment of the complications of AFLP that are present. This

includes establishing stable airway in an obtunded patient, normalizing intravascular volume, correcting electrolyte disturbances, treating hypoglycemia/hyperglycemia and correcting coagulation abnormalities with blood products. In certain cases, dialysis may be required for acute renal failure or desmopressin for diabetes insipidus.

Once the patient is stabilized, an expeditious delivery is recommended within 24 hours. The diagnosis of AFLP does not require a cesarean delivery. In fact, in the setting of significant coagulopathy, operative delivery may increase maternal morbidity and mortality. Regional anesthesia is often prohibited in cases of AFLP due to coagulopathy and thrombocytopenia. Care should be taken with medication choices if general anesthesia is required because certain medications can exacerbate liver failure.

Following delivery, care is supportive until the multisystem organ failure improves. This often requires ICU admission. Fluid balance, electrolyte status, and glycemic management are critical to survival. Blood glucose should be monitored hourly and electrolytes every 2 to 4 hours. Evidence of disseminated intravascular coagulation should be managed aggressively with blood products. Protein intake should be limited with the majority of caloric intake from glucose to decrease the nitrogenous waste. Colonic emptying should be facilitated with promotility agents to increase ammonia loss via stool. Neomycin 6 to 12 g or lactulose 20 to 30 g can also be administered daily to decrease colonic ammonia production. Occasionally, the liver damage from AFLP is so severe that transplantation is required.

TABLE 60–3 Laboratory changes in acute fatty liver of pregnancy.

Elevated WBC (> 20 K)	Decreased Fibrinogen
Prolonged PT and aPTT	Decreased Platelets
Elevated Ammonia	Decreased Coagulation Factors
Elevated Uric Acid	Decreased pH (acidosis)
Elevated BUN/Creatinine	Hypoglycemia
Hyperglycemia (if associated with pancreatitis)	Decreased Serum Albumin
Elevated Transaminases (< 2000 IU/L)	

Anaphylactoid Syndrome of Pregnancy/Amniotic Fluid Embolism

Essentials of diagnosis: hypotension, hypoxia, coagulopathy and frequently seizures/pulmonary edema/cardiac arrest.

Background

Amniotic fluid embolism (AFE) is a rare but catastrophic complication of pregnancy. The incidence is unknown but is thought to be between 1:8000 and 1:30,000 pregnancies. An AFE is a foreign substance (amniotic fluid with fetal squamous cells) that is

introduced into the maternal circulation which causes an acute cardiovascular and pulmonary collapse with associated coagulopathy.

AFE usually occurs during labor, delivery or the first 30 minutes postpartum. The classic presentation is an acute cardiopulmonary arrest in a previously healthy woman laboring or immediately postpartum. Seventy percent of cases occur during labor. Cardiac arrest is common and amniotic fluid emboli account for 5% to 10% of all maternal deaths in the United States. Fetal mortality is approximately 21% and fetal neurologic complications occur in more than half of infants delivered to mothers with an AFE.

Risk factors for amniotic fluid emboli include increased maternal age, uterine overdistension, cesarean delivery, uterine rupture, placental abruption, severe cervical lacerations, and maternal trauma. Links have been suggested between AFE and meconium stained amniotic fluid, augmented labor, and hypertonic contractions but these reports have not been validated.

Clinical Features

Symptoms and Signs—The diagnosis of an AFE is made clinically with the spectrum of disease ranging from mild coagulopathy to sudden and complete cardiopulmonary collapse. Patients most often present with dyspnea, hypotension (100%), and hypoxia (93%). Coagulopathy (83%) and altered mental status (70%) are also common. Seizure activity occurs in approximately 33% of patients and significantly increases maternal morbidity and mortality. Constitutional symptoms (fever, chills, nausea, vomiting, and headache) are also present to varying degrees.

Laboratory Findings—Lab values are nonspecific and do not aid in the diagnosis of AFE. Evidence of coagulopathy without previous blood loss is suggestive and significant hemorrhage is often seen acutely. Fetal squamous cells in the maternal pulmonary circulation at the time of autopsy are diagnostic but cannot always be identified due to prolonged courses following the acute event.

Management

AFE is a rare and unpredictable disorder of pregnancy. Treatment includes prompt initiation of basic and advanced cardiac life support. Continuous

cardiac monitoring and pulse oximetry are required with invasive blood pressure monitoring. Coagulopathy must be managed promptly and aggressively with hemorrhage protocol combinations of packed red cells, fresh frozen plasma, cryoprecipitate, and platelets. In catastrophic cases where hemorrhage cannot be controlled, newer procoagulant agents should be used and a hysterectomy may be required. If an AFE is suspected before delivery, delivery should be prompt once the maternal condition is stabilized.

Peripartum Cardiomyopathy

Essentials of diagnosis: heart failure in last month of pregnancy or within 5 months of delivery, no history or other identifiable cause, LV systolic dysfunction.

Background

Peripartum cardiomyopathy (PPCM) occurs in about 1:2200 to 1:3200 pregnancies in the United States but is seen much more commonly globally. It is defined as heart failure in the last month of pregnancy or up to 5 months postpartum in the absence of known heart disease or another identifiable cause. It is characterized by left ventricular systolic dysfunction with an ejection fraction of $< 45\%$ or reduced fractional shortening.

Risk factors for peripartum cardiomyopathy include multiparity, black race, maternal age more than 30, hypertensive disorders of pregnancy, multiple gestation, long term tocolytic therapy (terbutaline), and maternal cocaine abuse. The exact etiology is unknown.

About half of patients will have complete resolution of symptoms after delivery with return of normal cardiac size and function. The remainder has continued dilation and often progressive heart failure. Future pregnancies are extremely high risk in women with a history of peripartum cardiomyopathy. In women without complete resolution of symptoms, future pregnancy mortality approaches 50%.

Clinical Features

Symptoms and Signs—Patients present with symptoms of heart failure. Some of the initial nonspecific symptoms may be confusing due to the prevalence of these symptoms in normal pregnancy.

Imaging studies show enlargement of the cardiac silhouette and pulmonary edema. Echocardiography shows decreased universal contractility and left ventricular enlargement without hypertrophy. Diagnostic criteria used include: Left ventricular ejection fraction less than 45% and/or fractional shortening of less than 30% and left ventricular end systolic dimension greater than 2.7 cm/m².

Laboratory Findings—Arterial blood gas shows hypoxemia with respiratory alkalosis. Urinalysis can show concentrated urine. CBC, serum chemistries and liver function tests should be unremarkable. Brain natriuretic peptide (BNP) levels typically increase 2 fold in healthy pregnancy and are usually elevated in heart failure, however limited data are available to support the use of this test in pregnancy. Elevated BNP has been observed in pregnant women with preeclampsia and other clinical conditions associated with volume overload.

Special Considerations—Systemic and pulmonary embolization can be seen more frequently than in other forms of cardiomyopathies.

Management

Treatment of PPCM is similar to that for other types of heart failure. The goal in management is to improve cardiac function by reducing afterload and preload and increasing contractility. It is important to remember to avoid angiotensin inhibition, which is contraindicated in pregnancy.

Initial stabilization may require intravenous diuretics or inotropic support. Loop diuretics serve to decrease preload and relieve pulmonary congestion. Digoxin may improve myocardial contractility and facilitate rate control when atrial fibrillation is present. Hydralazine is the vasodilator of choice and can be used to reduce afterload before delivery and angiotensin-converting enzyme inhibitors can be used postpartum. Beta blockade has also been shown to improve cardiac function and survival in chronic heart failure but should not be used in acute decompensated heart failure. Patients with acute decompensated heart failure with hypotension or persistent pulmonary edema despite initial measures may benefit from intravenous inotropic support with Dobutamine or Milrinone. An intra-aortic balloon pump, extracorporeal membrane oxygenation, and LV assist devices have been used successfully as

a bridge for recovery or transplantation in patients with PPCM and should be considered in rapidly deteriorating patients who are not responding to medical therapy, including inotropic medications.

Anticoagulation with heparin should be considered if EF is significantly reduced, that is, less than 35% due to the high risk of thrombus formation and thromboembolism in the context of pregnancy-related hypercoagulability and stasis due to LV dysfunction.

Early delivery may be necessary if persistent hemodynamic instability is present, but if the mother is stabilized the goal is delivery at term. Cesarean delivery is reserved for obstetric indications. Early pain control is a key in patients with peripartum cardiomyopathy during labor as pain increases cardiac work and causes tachycardia. A carefully dosed epidural that provides adequate pain control and avoids hypotension is vital.

OBSTETRIC HEMORRHAGE

Background

Obstetric hemorrhage is the leading cause of maternal morbidity and mortality worldwide. It is defined as greater than 500 ml blood loss at the time of a vaginal delivery or greater than 1000 ml of blood loss at the time of cesarean birth. Massive hemorrhage is defined as greater than 1500 ml of blood loss. Rates of massive hemorrhage are increasing as the age and comorbidities of the pregnant population increases. Most obstetric ICU admissions will be due to hemorrhage. The most common causes of obstetric hemorrhage are uterine atony, placental abruption, and abnormal placentation (previa/accreta). Less common causes include genital tract lacerations, uterine inversion and coagulopathy.

Clinical Features/Management

1. Uterine atony

- a. Signs and symptoms include a boggy, soft uterus after delivery with the lower uterine segment often filled with clot.
- b. Risk factors include precipitous or prolonged labor, labor augmentation, overdistended uterus, grand multiparity, prior history of postpartum hemorrhage from uterine atony.

- c. Management include fundal massage and evacuation of the uterus are the first line in treatment of uterine atony. Retained products of conception can prolong the hemorrhage.

Uterotonic drugs are administered during the fundal massage including intravenous oxytocin (10-40 units in 500-1000 ml normal saline), methylergonovine (0.2 mg intramuscularly), carboprost tromethamine (0.25 mg intramuscularly), or misoprostol (1000 mcg/rectum).

Methylergonovine may be associated with increases in maternal blood pressure and therefore cannot be used in women with hypertension or preeclampsia. Prostaglandins can cause bronchospasm and therefore should be avoided in asthmatics.

Obstetric balloon devices can also be used temporarily to tamponade uterine bleeding and slow postpartum hemorrhage. Patients may be observed for up to 24 hours with the balloon in situ before deflating and closely observing for recurrent bleeding.

Surgical management options, including uterine compression sutures and uterine artery ligation, can also be pursued prior to hysterectomy.

Additionally, in certain centers angiographic embolization can be performed, however this should not be considered first line therapy to control active obstetric hemorrhage.

2. Placental abruption

- a. Signs and symptoms include severe persistent abdominal pain differing from the classic crescendo-decrescendo labor pattern; \pm vaginal bleeding; retroplacental clot on ultrasound; abnormal fetal heart rate tracing; coagulopathy; bluish “Couvelier’s” uterus at the time of cesarean delivery.
- b. Risk factors include severe hypertension, preeclampsia, cocaine use, trauma, and rapid decompression of the

uterus (ruptured membranes with polyhydramnios, delivery of the first twin).

- c. Management include the most important steps in the management of placental abruption are identifying the cause of the abruption, treating the underlying disorder and correction of coagulopathy. In the case of significant abruption, delivery should be affected as soon maternal hemodynamic stability is achieved.

3. Abnormal placentation (previa/accreta)

- a. Signs and Symptoms include placenta previa (placenta overlying the internal cervical os) often presents with painless third trimester bleeding and is usually diagnosed antepartum if adequate prenatal care is received. Placenta accreta occurs when the placenta invades the myometrium and fails to separate following delivery.
- b. Risk factors are similar for previa and accreta and include multiparity and prior uterine procedures (cesarean and curettage). Serial cesarean birth is the single greatest risk factor for abnormal placentation and all women with a prior cesarean delivery should undergo ultrasonographic evaluation for placenta accreta. Often the diagnosis of accreta is suspected on ultrasound based on the lack of integrity in the placenta myometrial border and/or placenta lakes. In cases where the suspicion is high, MRI may help further characterize the extent of invasion.
- c. Management include all cases of abnormal placentation should be delivered by cesarean with a skilled pelvic surgeon available. Early notification of the blood bank is imperative as massive transfusion may be required. Some literature has also described preoperative placement of embolization or balloon catheters prophylactically in the highest risk patients.

General Considerations

Obstetric hemorrhage is often underestimated. A stable airway and adequate intravenous access should be established early. Maternal hemodynamic collapse often does not occur until blood loss is greater than 2000 cc and coagulopathy is common. Hemorrhagic shock should be treated early and aggressively with 2:1 replacement with crystalloid and aggressive resuscitation with blood products is imperative. Most academic institutions have created an obstetric hemorrhage protocol to improve communication with the blood bank for release of products. When the hemorrhage protocol is activated packed red cells, fresh frozen plasma and platelets are released together, usually in a 6:4:1 or 4:4:1 ratio. Cryoprecipitate is often added after the first hemorrhage pack is transfused. Identification and correction of bleeding must be accomplished promptly. Newer therapies exist, with limited data regarding safety and effectiveness, which may be advocated for in intractable life-threatening hemorrhage include activated factor VII, prothrombin complex concentrate and tranexamic acid.

When a patient has endured a significant obstetric hemorrhage, she is at risk for significant comorbidities and complications related to the acute blood loss, massive transfusion and indicated therapies. By being aware of these risks, the critical care team can ensure proper posthemorrhage care, with early recognition and appropriate treatment of complications should they arise. Priorities in posthemorrhage management in the ICU include close observation of laboratory parameters (including CBC and coagulation profile) to assure adequate replacement once equilibration has occurred and avoidance of coagulopathy. Close observation is required for evidence of ongoing or recurrent bleeding. Infection is another risk that should be closely monitored for. Recognition of potential hypoperfusion injury to the brain, heart, kidneys and pituitary must be ensured. Additionally, risk for transfusion-related lung injury should be recognized and ventilatory status should be optimized. Aggressive venous thromboembolism prophylaxis must be initiated with sequential compression devices until hemostasis assured, and subsequently pharmacoprophylaxis added.

CRITICAL MEDICAL CONDITIONS IN PREGNANCY

Thromboembolic Disease in Pregnancy

Background

Changes during normal pregnancy promote coagulation, decrease anticoagulation, and inhibit fibrinolysis. Venous thromboembolism (VTE) is the leading cause of maternal death in developed countries. The risk of VTE is increased 4× to 5× in pregnancy and the puerperium with an overall incidence of 1 in 1600 pregnancies. Most (~66%) of deep vein thromboses (DVT) occur during gestation while over half of pulmonary emboli (PE) occur postpartum. The mortality from VTE is higher in black pregnant patient compared with white ones.

Diagnosis

DVT and PE can present with a wide variety of signs and symptoms, many of which can be confused with normal pregnancy-related complaints including shortness of breath and lower extremity edema. Pregnant patients were excluded from the Prospective Investigation of Pulmonary Embolism Diagnosis II (PIOPED II) study that described signs and symptoms of PE in nonpregnant patients. There are no validated clinical prediction guidelines for determining the pretest probability of PE in this population.

Significant clinical debate surrounds the decision between ventilation perfusion scans, computed tomography pulmonary angiography and magnetic resonance angiography for the diagnosis of PE in pregnancy. Every effort should be made to avoid unnecessary radiation exposure to the fetus while providing an accurate and timely diagnosis for the mother. In emergent situations, CT angiography is considered the gold standard for diagnosis of a PE in pregnancy.

American Congress of Obstetricians and Gynecologists (ACOG) committee guidelines state that fetal risks from radiation exposure are negligible when doses are less than 0.05 Gy. CTA delivers slightly lower fetal radiation doses and higher maternal doses of radiation (7.3 vs 0.9 mS) than V/Q scanning (0.003-0.131 mGy vs 0.32-0.74 mGy),

in the first through third trimester. Using V/Q scans as the initial diagnostic approach may necessitate a second diagnostic scan using CTA, which results in more overall radiation.

1. A normal arterial blood gas or alveolar-arterial difference is common with PE. Nonetheless, the presence of hypoxemia with normal chest radiograph should increase the clinical suspicion for PE.
2. D-dimer testing in pregnancy has limited value as no pregnancy-related normal values have been established and validated. Kovac and colleagues, proposed new values for D-dimer thresholds in pregnancy that should vary with trimesters: 286, 457, and 644 ng/mL in the first, second, and third trimesters, respectively, but these are not yet validated.
3. Compression ultrasound (CUS) is a noninvasive test with a sensitivity of 97% and a specificity of 94% for diagnosing symptomatic, proximal DVT in the general population. CUS appears to have a similar diagnostic accuracy in pregnant patients, with a false-negative rate of approximately 0.7%.⁷ The diagnosis of DVT during pregnancy is most often made by demonstrating poor compressibility of the proximal veins with the patient in the left lateral decubitus position. It is important to note that CUS may miss pelvic vein thromboses which are more common in pregnant and postpartum women.
4. Ventilation/perfusion (V/Q scan)—For those with a normal chest radiograph, V/Q scanning can be used for the diagnosis of PE in pregnancy. Very low probability scans are associated with a 0% to 6% chance of having a PE. High probability scans are associated with a 56% to 96% chance of having a PE. Small studies describe perfusion (Q) scanning alone with decreases the radiation exposure to mother and fetus, for the diagnosis of PE in pregnancy. In such studies, Q scanning alone had a negative predictive value of 100% and only 7% of scans were nondiagnostic. An abnormal chest radiograph increases the probability of a moderate probability V/Q scan

result and should prompt the clinician to avoid V/Q scan and directly proceed to CTPA.⁵

5. CT pulmonary angiograph (CTA) is considered the preferred tool for evaluating respiratory complaints and diagnosing PE in pregnancy due to better interobserver agreement for radiologists reading CT than nuclear scans and better imaging of other pulmonary pathology.
6. Magnetic resonance pulmonary angiography (MRPA) sensitivity and specificity for the diagnosis of PE during pregnancy has not been evaluated. Although no fetal teratogenicity of gadolinium has been observed in human studies, teratogenicity for high doses or prolonged exposures to gadolinium has been observed in animals, so that gadolinium is classified as a category C agent by the FDA.

Management

Adequate treatment of highly suspected or diagnosed VTE can be achieved using subcutaneous low-molecular-weight heparin (SC LMWH), intravenous unfractionated heparin (IV UFH), or subcutaneous unfractionated heparin (SC UFH). Neither UFH nor LMWH cross the placenta. Warfarin crosses the placenta and is not used for treatment of VTE in pregnancy because of the increased risk of birth defects if used during organogenesis and increased risk of fetal hemorrhage at delivery if used in the third trimester. Direct thrombin inhibitors have been demonstrated to cross the placenta in animal models and are not used in pregnant humans.

Subcutaneous LMWH, half-life of 6 hours, is preferred over IV UFH or SC UFH because it is easier to use and more efficacious with a better safety profile, findings extrapolated from clinical trials in nonpregnant patients. Initial doses of SC LMWH include dalteparin 200 units/kg once daily, tinzaparin 175 units/kg once daily, dalteparin 100 units/kg every 12 hours, or enoxaparin 1 mg/kg every 12 hours. While data is limited, many recommend the use of twice daily dosing of LMWH especially after the second trimester due to changes in volume of distribution and increased GFR rate. The dose can be titrated to an anti-Xa level of 0.6 to 1.0 IU/mL for twice daily administration. Controversy exists about monitoring anti-Xa activity in anticipation of the

need for dose-escalation as pregnancy progresses. Once a therapeutic dose is achieved, some advocate the performance of periodic anti-Xa levels, particularly in patients at the extremes of body weight or those with altered renal function. The first anti-Xa level is generally measured 6 hours after the third or fourth dose if the dosing is every 12 hours, or 6 hours after the second or third dose if the dosing is once daily. Most adjustments should be an increase or decrease of 10% to 25%.

IV UFH is preferred in critically ill patients and those likely to need delivery due to short half-life (1.5 hours) and easy reversibility with protamine. The impact of protamine on the fetus has not been widely studied, so the use of protamine should be reserved for cases of significant bleeding.

The dose consists of bolus of 80 units/kg, followed by a continuous infusion of 18 units/kg/h. The infusion is titrated every 6 hours to achieve a therapeutic activated partial thromboplastin time (aPTT), that corresponds to an anti-Xa level of 0.3 to 0.7 IU/mL. Once the target aPTT level is achieved, it should be rechecked once or twice daily.

Indications for insertion of an IVC filter are the same in pregnant and nonpregnant patients.

Women diagnosed with VTE within 4 weeks of expected delivery, who have high rate of mortality if therapeutic anticoagulation is stopped are transitioned from LMWH to UFH at approximately 36 weeks' gestation. The IV UFH can be stopped 4 hours before delivery or when the patient goes into labor, with the PTT and anti-Xa levels used to monitor the coagulation status. In patients with extensive DVT or PE, scheduled induction of labor or cesarean delivery should be considered to minimize the duration of time without anticoagulation and a temporary IVC filter can be inserted. Neuraxial anesthesia is contraindicated in a therapeutically anticoagulated patient; timing delivery can allow patients to receive adequate anesthesia. After uncomplicated delivery heparin may be restarted 12 hours after a cesarean delivery or 6 hours after a vaginal birth.

Thrombolytic therapy. Despite the concern that thrombolytic therapy could lead to placental abruption, this complication has not been reported. Cesarean birth within 10 days is considered a relative contraindication to thrombolytic therapy; however, successful thrombolysis has been reported within an

hour after vaginal and 12 hours after cesarean birth. In a review of 28 cases using thrombolysis in pregnancy, the complication rate was similar to that in nonpregnant patients.

There are case reports of successful use of thrombolytic therapy for massive PE during labor. Cesarean delivery in a patient with massive PE carries a high risk of maternal death and should be performed only in cases where the risks and benefits have been weighed and the mother is stable or perimortem.

In centers with interventional radiology expertise, pulmonary angiography with percutaneous mechanical clot fragmentation and placement of an IV filter may be attempted. Should mechanical and iv thrombolysis not be feasible or fail, ECMO with or without surgical embolectomy followed by cesarean delivery and placement of an IVC filter should be considered.

Severe Sepsis, Septic Shock, and Multiorgan Failure

Background

Severe sepsis and septic shock are not very common conditions, reported to occur in 0.002% to 0.01% of deliveries, but they do carry a high maternal morbidity and mortality with rates between 20% to 30% in pregnant patients with septic shock and multiple organ failure. Pregnancies complicated by severe sepsis are associated with increased rates of preterm labor, fetal infection, and preterm delivery.

Pregnancy predisposes women to specific infectious complications. The most common prenatal infections are chorioamnionitis, septic abortion, pyelonephritis, and pneumonia. The most common postpartum infections are endometritis, wound infection, necrotizing fasciitis, pelvic abscess, septic pelvic thrombophlebitis, and pyogenic sacroiliitis.

The outcome in severe sepsis is improved with early detection, prompt recognition of the infectious source, and early antibiotic therapy. However, there are no pregnancy-specific criteria for sepsis and sepsis criteria are affected by pregnancy physiology.

Diagnosis

Chorioamnionitis—Chorioamnionitis (CA) is an infection of the amniotic fluid, membranes, placenta, and/or decidua. It results from ascending

polymicrobial infection in the setting of rupture of membranes or advanced cervical dilatation, rarely from hematogenous spread or invasive procedures such as amniocentesis, chorionic villus sampling or fetal surgery. Length of labor and ruptured membranes appear to be important risk factors. Signs include typical signs of sepsis associated with uterine tenderness \pm foul or purulent amniotic fluid or vaginal discharge. Amniocentesis for amniotic fluid culture, gram stain, glucose concentration, WBC concentration, and leukocyte esterase level can be used to establish a microbiologic diagnosis of intra-amniotic infection.

Early treatment with antibiotics covering gram-negative and anaerobic flora and evacuation of the uterus are imperative. The most commonly used antibiotics are ampicillin and gentamicin. Patients who undergo cesarean delivery in the presence of CA, are at increased risk of wound infection, endomyometritis, and venous thrombosis and usually require additional anaerobic antibiotic coverage.

Endometritis—Endometritis occurs postpartum, usually in the first week. It originates from bacterial ascension from the lower genital tract during labor. Symptoms are similar to chorioamnionitis. If there is no improvement within 24 to 48 hours, with broad-spectrum intravenous antibiotic therapy, imaging studies should be undertaken to search for a fluid collection or surgical site infection. The most common antibiotic regimens used to treat endometritis are single agent unasyn or combination ampicillin/gentamicin/clindamycin.

Septic Abortion—Septic abortion is now rare in the United States. Historically, septic abortions commonly occurred prior to national legalization of abortion. After the diagnosis of septic abortion is established, treatment with broad-spectrum antibiotics should be immediately instituted with evaluation for and removal of any retained products of conception. Surgical management should be pursued if the patient becomes hemodynamically unstable or shows no improvement with 24 to 48 hours of broad spectrum antibiotics. Hysterectomy and oophorectomy may be required if a dusky, devitalized uterus or pelvic tissue crepitus is encountered intraoperatively and/or clostridial infection is suspected.

Puerperal Mastitis—Puerperal mastitis is usually unilateral, presents in the first week postpartum,

with septic symptoms, marked breast engorgement, erythema, and severe pain. Cases of toxic shock syndrome secondary to mastitis have been described and recently concern exists over the appearance of community-acquired methicillin-resistant *S aureus* (CA-MRSA). Milk from the affected breast should be aspirated and sent for culture and sensitivity before antibiotic treatment. Breast abscess may require surgical incision and drainage or aspiration. Breast feeding is safe and recommended during episodes of mastitis.

Acute Pyelonephritis—Acute pyelonephritis is common in pregnant patients due to pregnancy physiology; dilation of the ureters secondary to progesterone, lack of protective peristalsis, mechanical compression of the urinary system by the gravid uterus and bacteriuria. It manifests with sepsis symptoms, flank pain, nausea/vomiting, and/or costovertebral angle tenderness in the presence or absence of cystitis symptoms. Microscopic bacteriuria and pyuria on urinalysis are verified by a positive urine culture. Bacteriuria during pregnancy has a greater propensity to progress to pyelonephritis and therefore should be treated. *E. coli*, *Klebsiella*, *Enterobacter*, *Proteus*, and gram-positive organisms, including group B *Streptococcus* account for approximately 70% of cases. Empiric treatment with a cephalosporin or broad-spectrum penicillin is recommended when pyelonephritis is suspected before a positive culture is confirmed. Failure to improve with first-line antibiotic treatment within 24 to 48 hours should prompt evaluation with ultrasound for obstructive urinary tract lesions, such as urinary calculi or perinephric abscess.

Pneumonia—Pneumonia (PNA) has increased morbidity and mortality in pregnancy. The most common pathogens are the same as those found in nonpregnant patients. Community-acquired MRSA can cause a necrotizing pneumonia or can be a super infection with influenza pneumonia. Standard antibiotics for treatment of PNA can be used in pregnancy with the exception of fluoroquinolones.

Influenza—Influenza in pregnant women is associated with a higher rate of morbidity and mortality. A rapid test can detect Influenza A and B, but the sensitivities differ seasonally. If suspicion is strong, culture should be performed. Oxygen, hydration, and neuraminidase inhibitors zanamivir (Relenza) and

oseltamivir (Tamiflu) should be started immediately. Women with suspected or confirmed influenza who are pregnant or who have delivered within the previous 2 weeks should receive aggressive antiviral treatment and undergo close monitoring regardless of the results of rapid antigen tests.

Management

Interventions that improve maternal hemodynamic stability and oxygen delivery to the fetus result in improved maternal and fetal outcomes. Operative intervention on behalf of the fetus in an unstable mother increases maternal morbidity and mortality. To date, no “evidence-based” recommendations are specific to the pregnant patient with septic shock.

1. Vasopressors can vasoconstrict uterine blood vessels, reducing fetal blood flow. First line in the management of hypotension is administration of intravenous fluids (normal saline 20 mg/kg) and placing the patient in the left lateral decubitus position to prevent compression of the IVC by the gravid uterus. Hypotension that persists requires vasopressor therapy. Although norepinephrine can reduce uterine blood flow, there is no data to suggest that norepinephrine has an adverse effect on fetal well-being, therefore it is often the first line therapy. Vasopressin may be added in patients with refractory shock at a rate of 0.01 to 0.04 UI/min
2. Bedside critical care ultrasound is emerging as a useful tool in the assessment of the hypotensive critically ill patient. Transthoracic echocardiography (TTE) may assist in the differentiation of life-threatening hypotension in the critically ill obstetric patient by allowing the rapid identification of right ventricular versus left ventricular heart failure, pericardial effusion and fluid status.
3. Little evidence exists regarding the management of ARDS specifically in pregnancy, and thus, treatment approaches must be drawn from studies performed in a general patient population. Initial management is the same regardless of the cause of the acute respiratory failure with supplemental oxygen with goal is to maintain the oxyhemoglobin

saturation 95% or more and arterial oxygen tension (PaO_2) more than 70 mm Hg, to maintain fetal oxygenation. Mechanical ventilation may be required. Ventilatory goals are different in pregnant patients. The target PaCO_2 is 30 to 32 mm Hg, since this is the normal level during pregnancy; more respiratory alkalosis should be avoided because it may decrease uterine blood flow. Maternal permissive hypercapnia may also be deleterious to the fetus because of resultant fetal respiratory acidosis.

4. Sedation is required to tolerate mechanical ventilation. The literature suggests that use of benzodiazepines and narcotics are safe in pregnancy. Transient neurologic deficits and respiratory depression have been reported in neonates born to mothers medicated in the later stages of pregnancy. Propofol classified as a pregnancy category B agent, crosses the placenta and may be associated with neonatal respiratory depression. Data on the clinical use of propofol for pregnant critically ill patients is limited to case reports, so its use should be limited until more prospective data is available.
5. Extracorporeal membrane oxygenation (ECMO) is a technique that provides support to selected patients with severe respiratory failure. Little data exists regarding the long term outcomes for infants born after the use of ECMO during pregnancy. However during the 2009 H1N1 influenza epidemic, ECMO was used with a good impact on survival for pregnant women.
6. Acute Kidney Injury is often reversible in pregnancy. Ischemic ATN is usually precipitated by abruptio placentae or postpartum hemorrhage and, less commonly, by AFE and sepsis. The diagnosis of postrenal AKI in the pregnant patient is particularly challenging due to the physiologic dilatation of the collecting system that normally occurs in the second and third trimesters and determining the presence of abnormal findings on renal ultrasonography is more difficult.

Pulmonary Edema

Historically, approximately 50% of the cases of pulmonary edema were attributed to tocolytic therapy or cardiac disease, peripartum cardiomyopathy, mitral stenosis, with the rest due to preeclampsia, eclampsia or iatrogenic volume overload.

The use of tocolytics including calcium channel blockers, to inhibit preterm labor is associated with the pulmonary edema in 0.25% to 5% of treated patients. It is more common among multiple gestations and use of multiple tocolytic agents simultaneously.

The standard therapeutic approach includes discontinuation of potentially contributing tocolytics, supplemental oxygen, fluid restriction, and diuresis. Diuretics should be used with caution in the setting of preeclampsia due to intravascular volume depletion.

Arrhythmia

Arrhythmias are more common in women with heart disease. Arrhythmia with significant hemodynamic effect should be treated urgently and aggressively. If the mother's own perfusion is compromised significantly, uterine vascular constriction will occur. ECG should be done to document the rhythm before treatment and secondary causes for arrhythmia should be ruled out (dehydration, hyperthyroidism, drugs, sepsis, pulmonary emboli).

Paroxysmal supraventricular tachycardia is the most common nonsinus tachycardia in women of childbearing age. Adenosine, verapamil or metoprolol intravenous are highly effective in terminating the rhythm. Paroxysmal Atrial Fibrillation and Atrial flutter with rapid ventricular response occur more frequently in young women mostly due to successful congenital heart disease treatment. The treatment should be the same as in nonpregnant women, although with a heightened sense of urgency. Intravenous verapamil, metoprolol or diltiazem are usually successful at slowing the ventricular rate. If this is not achieved, cardioversion should be performed.

Ventricular tachycardia does occur in pregnancy especially in patients with history of structural heart disease. Acute treatment should include the usual medications or cardioversion as needed to protect the mother.

All drugs used to treat an arrhythmia cross the placenta resulting in fetal exposure, and most are categorized as Food and Drug Administration (FDA) class C. All beta-blockers have the potential for influencing fetal and newborn size, but only atenolol is singled out as being FDA class D. Digoxin, verapamil, diltiazem, and adenosine have their usual efficacy without adversely affecting the fetus. Experience during pregnancy is greater with quinidine than with all the other antiarrhythmic drugs. Lidocaine has been used without any recognized teratogenic effects, although there has been some concern about fetal bradycardia. A reported series, used Amiodarone in 26 women to treat fetal arrhythmias and also for maternal arrhythmias had no recognized adverse fetal effects. Cardioversion preceded by moderate sedation has been used in pregnancy without any reported adverse fetal effects.

Symptomatic bradycardia is rare in pregnancy. Temporary and permanent pacing can be performed during pregnancy if required with minimizing irradiation, for maternal and fetal benefit.

Diabetic Ketoacidosis

Diabetic ketoacidosis (DKA) occurs in approximately 1% to 3% of diabetic women who become pregnant and represents a medical emergency with high maternal and fetal mortality. Prompt recognition and resuscitative therapy markedly improves outcome. It can occur in the newly diagnosed diabetic patient, and the hormonal changes of pregnancy, a state of relative insulin resistance may become the background for this phenomenon. The blood glucose levels in pregnant women with DKA are usually lower than those in nonpregnant women with DKA.

The presentation of DKA is similar in pregnant and nonpregnant women, with symptoms of nausea, vomiting, thirst, polyuria, polydipsia, tachypnea, change in mental status.

Maternal hyperglycemia results in fetal hyperglycemia and fetal osmotic diuresis. Maternal acidemia decreases uterine blood flow with a resultant decrease in placental perfusion leading to decreased oxygen delivery to the fetus. Fetal acidosis and fetal volume depletion may occur, which jeopardizes the viability of the fetus. Other than fetal heart rate

monitoring, which is used to assess and monitor the fetus, DKA is treated similarly in pregnant and non-pregnant patients.

STATUS ASTHMATICUS

Asthma affects 3% to 8% of pregnant women. Clinical severity of asthma in pregnancy seems to follow the severity before the pregnancy with exacerbations 20% to 36% of pregnancies, most frequently between weeks 14 and 24.

The diagnosis and treatment of acute asthma during pregnancy does not differ from the management in nonpregnant patients. Intensive monitoring of both mother and fetus is essential. Pregnant patients with acute asthma should rest in a seated, rather than supine, position. A severe asthma attack presents more of a risk to the fetus than the use of asthma medications because of the potential for fetal hypoxia, so therapy β 2-agonists, anticholinergics, and systemic corticosteroids should be used as indicated to treat exacerbations.

Evidence based data about the management of refractory status asthmaticus in obstetric patients is minimal. Review of 3 case reports with a total of 10 cases, 2 of which were past 32 weeks, revealed 2 patients who underwent cesarean delivery and improved dramatically after the procedure.

SUMMARY

Critical illness in obstetrics may occur due to pregnancy-specific conditions, rarely encountered by the intensivist physician, or due to commonly seen critical care diagnoses with unique-management considerations in pregnancy. A multidisciplinary collaborative approach will help to optimize maternal and fetal outcomes in these high-risk pregnancies.

Critical Care of Burn Patients

Edward Pellerano Guzman, MD and
John M. Oropello, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 Care of the severely burned patient requires prompt resuscitation and definitive surgical management.
- 2 Patients with major burns ($\geq 25\%$ total body surface area) require management in an intensive care unit.
- 3 Burn survival correlates with 3 major factors: patient age, burn size, and presence of inhalation injury.
- 4 Acute renal failure may result from severe hemodynamic instability, delayed or inadequate resuscitation during the initial burn treatment, or later as a result of sepsis or rhabdomyolysis.
- 5 Compartment syndrome in the extremities, torso, or abdomen have been linked to the presence of deep, full-thickness circumferential burns and to the volume resuscitation.

INTRODUCTION

Caring for critically ill patients is even more challenging when the largest organ, the first barrier against any external insult, is damaged by a burn injury. Care of the severely burned patient requires prompt resuscitation and definitive surgical management to reduce morbidity and mortality. The approach is multidisciplinary and involves intensivists, surgeons, and skilled nursing teams among others. The need for psychologic and social support is considerable.

Mortality rates from severe burn injuries have steadily declined over the last 30 years attributed in part to a multidisciplinary approach and specialized care delivered in burn centers. Most burns are the result of fire or scalding and involve less than 10% of the total body surface area (TBSA) with a mortality of close to 0.5%. Patients with major burns ($\geq 25\%$ TBSA) require management in an intensive care unit.

Burn survival correlates with 3 major factors: patient age, burn size, and the presence of inhalational injury.

CLASSIFICATION OF BURNS

Burns are classified as thermal, electrical, chemical, friction, or radiation injuries that result in coagulative necrosis of tissues. The clinical severity is determined by the depth and extent of injury. Depending on the depth of injury, burns are further classified as superficial (first degree), partial thickness (second degree), and full thickness (third degree) when all skin layers are affected ([Figure 61–1](#)). A fourth degree burn signifies deeper tissue involvement down to bone or muscle.

Burns affecting the epidermis are usually red with mild pain and no blisters. Burns extending beyond the epidermis tend to be erythematous, painful and with blisters; a dry aspect is seen on deeper dermal burns due to the effect of coagulative

FIGURE 61–1 Classification of burn depth. (Reproduced with permission from Tintinalli JE, Stapczynski JS, Ma OJ, et al: *Tintinalli's Emergency Medicine: A Comprehensive Study Guide*, 8th edition. New York: McGraw-Hill Companies, Inc; 2011.)

necrosis sealing the tissues. Full thickness burns are always dry and in the vast majority insensible, as there is destruction of the entire dermis.

A thermal injury triggers responses in every major organ system. Immediately after a burn, intense inflammation and systemic manifestations are generated; inflammatory mediators cause loss of capillary integrity with edema formation mainly in the first hours extending up to 24 hours or more, postburn. The same cascade causes volume depletion, depressed cardiac contractility, and systemic hypoperfusion producing a shock state. Contributing to this process is leukocyte and endothelial activation with cytokine production, complement activation, histamine release, xanthine oxidase, and lysosomal enzyme activation that augment microvascular permeability and wound edema, similar to the cascade that causes acute respiratory distress syndrome (ARDS).

Cortisol, epinephrine, glucagon are also persistently secreted generating glucose intolerance and a hypermetabolic or catabolic state that extends beyond the initial recovery.

INITIAL MANAGEMENT

The initial management is triage and acute resuscitation in the first 24 to 48 hours. Prehospital care and stopping the burning process is the most important component for first responders. Clothes that are burning, smoldering, or soaked with chemicals

should be removed. The patient should be removed away from an electrical source. In chemical injuries copious water lavage should be performed. A sequential assessment (primary survey) to avoid missing serious associated injuries as described by the American College of Surgeons in Advanced Trauma Life Support should be followed.

Estimating the total burned body surface area is a key component for resuscitation. Fluid resuscitation by formula is recommended if the TBSA is more than 15%. All current formulas and methods for resuscitation in burned patients are based on body weight and the percentage of TBSA burned. The initial history and physical exam should also include the body weight and an estimate of the second and third degree burn areas used to calculate resuscitation. The “rule of nines” allows a simple, rapid estimate of TBSA: (in an adult [units = % TBSA]): entire head & neck = 9; each arm = 9; upper 1/2 torso front = 9; lower 1/2 torso front = 9; upper 1/2 torso back = 9; lower 1/2 torso back = 9; each leg = 18—anterior leg = 9; and posterior leg = 9.

AIRWAY AND MECHANICAL VENTILATION

In burn patients a reevaluation of the airways and breathing should be done upon hospital arrival. Inhalational injury should be suspected in all patients exposed to smoke, flames, or steam, especially those trapped in a closed environment or rescued in an

FIGURE 61–2 Edema associated with inhalation injury and resuscitation. Nasotracheal intubation was performed early to prevent accidental loss of airway. (Reproduced with permission from Kasten KR, Makley AT, Kagan RJ: Update on the critical care management of severe burns, *J Intensive Care Med.* 2011 Jul-Aug;26(4):223-236.)

unconscious state. Early intubation should be performed in the presence of distinct features: deep facial burns, full thickness neck burns, oropharyngeal edema, hypoxemia, stridor, hypercapnia, or a Glasgow Coma Scale less than 8. In the early stages intubation is technically easier if there is minimal or no airway edema. If intubation is performed the internal diameter of the endotracheal tube should be at least 7.5 mm or greater (eg, 8.0–9.0 mm) if possible, in anticipation of the need for later bronchoscopy. Emergency tracheostomy or cricothyroidotomy is rarely needed if intubation is performed early; tissue edema in the head and neck can make these procedures complicated ([Figure 61–2](#)).

Pulmonary insufficiency and failure in severely burned patients is multifactorial, due to direct pulmonary and upper airways injury, indirect or secondary injury due to systemic inflammatory response, and delayed injury due to sepsis and pneumonia. Ventilation can also be impaired due to edema within the torso and abdomen; torso escharotomy can avoid laparotomy and improve ventilation.

LUNG INJURY AND ACUTE RESPIRATORY DISTRESS SYNDROME

Severe inflammation and endothelial activation can lead to significant pulmonary capillary leak and

ARDS which is common in burn patients with an incidence as high as 30%.¹ It can be exacerbated by sepsis and over resuscitation.

Reduced lung compliance and chest wall rigidity can lead to higher airway pressures. Lung injury may not be a result of higher airway pressures because there is also less stretch on the alveoli as is also seen in other situations where compliance is reduced such as abdominal hypertension. Ventilator strategies may include low tidal volume ventilation with permissive hypercapnia with conventional ventilator modes, airway pressure-release ventilation or high-frequency oscillation in selected patients with inhalational or chest wall injuries. Inhaled nitric oxide may be used for the treatment of hypoxic vasoconstriction improving ventilation/perfusion mismatching and tissue oxygenation. Extracorporeal membrane oxygenation, used more often in pediatrics, may be helpful in selected adults with severe refractory ARDS.²

TRACHEOSTOMY

The indications and timing of tracheostomy (either open or percutaneous) after burns are similar to critically ill patients in general, however, caution is needed in the selection of patients with severe facial and neck burns or upper airway edema for tracheostomy because of the increased potential for loss of the airway and local skin complications. Tracheostomy in a burned neck tends to be a difficult procedure due to anatomy disruption, with increased complications such as bleeding, infection, and poor wound site healing.

RESUSCITATION

As in other critical illnesses such as septic shock, prompt and adequate resuscitation is of great importance. However due to external burn injuries, the degree of systemic inflammation and tissue edema, fluid losses are much more prominent. The main focus on resuscitation strategies is to minimize resuscitation complications of under or over resuscitation. Protocols unique to the burned patient take into account fluid losses via the skin.

Two large-bore peripheral intravenous catheters should be inserted through unburned skin if

possible and baseline laboratories sent. Frequently unusual peripheral venous sites or central venous access is required. The groins are often spared; so femoral venous cannulation is usually possible. Burns are usually the immediate cause of hypovolemia, however, bleeding from other injuries should also be ruled out.

Fluid resuscitation should be individualized based on age, comorbidities, organ function, burn area and hemodynamics. Fluid resuscitation guidelines are often based on the Parkland burn formula. Typically a lactated Ringer's solution is infused at an initial volume of $4 \text{ mL/kg body weight} \times \% \text{ burn area}$ in 24 hours with 50% given in the first 8 hours and the remainder over the next 16 hours. However, balanced isotonic crystalloids such as plasmalyte containing acetate, a bicarbonate precursor, may also be used; either Ringer's lactate or plasmalyte will result in less hyperchloremic metabolic acidosis than normal saline. Continuing fluid administration may be based on the formula $0.3 \text{ to } 0.5 \text{ mL/kg} \times \% \text{ burn area}$ over 24 hours, but fluid resuscitation must be modified depending on organ function and hemodynamics. In adults, a urine output of at least 30 to 50 mL/h is commonly targeted. Under resuscitation results in reduced cardiac output (CO), inadequate tissue/organ perfusion, oliguria and increasing lactate trends; over resuscitation can result in a constellation of complications including worsening of upper airway edema, pulmonary edema, prolongation of mechanical ventilation, cerebral edema and compartment syndromes (CS) (abdomen, extremities, ocular).³ Elevated lactate appears to be a biomarker for increased mortality in burn patients but a normal lactate alone does not mean that fluid resuscitation is adequate.

Fluid resuscitation with hypertonic saline (eg, 7.5% NaCl) or colloids (eg, albumin) has not been demonstrated to improve outcomes, although as expected the total resuscitation volume is usually less with colloid administration.

HEMODYNAMICS

Almost immediately after a major thermal injury, CO tends to decrease within an hour. This is, in part, due to myocardial depression from tumor necrosis factor (TNF)-alpha and endotoxin. After adequate

resuscitation, the CO tends to normalize and is often followed by a hyperdynamic circulation with vasodilation. Evaluation of hemodynamic parameters typically involves invasive or noninvasive blood pressure measurement and some form of cardiac monitoring. Pulmonary artery catheters are less commonly used, being supplanted by transpulmonary thermodilution devices and noninvasive techniques such as ultrasound of the heart, inferior vena cava (IVC), and lung that can provide accurate information in monitoring resuscitation of the acute burn patient.

BLOOD TRANSFUSION

Restrictive strategies of red blood cell transfusion (hemoglobin 7.0-9.0 g/dL) may be superior or at least equivalent to the liberal strategy (hemoglobin 10.0-12.0 g/dL) in critically ill patients. This appears to also be applicable in burn patients as increased mortality is associated with blood transfusion. The use of erythropoietin is not helpful to prevent or improve anemia in burn patients due to blunting of erythropoietic response.

ACUTE RENAL FAILURE AND ELECTROLYTE DERANGEMENTS

Acute renal failure may result from severe hemodynamic instability, delayed or inadequate resuscitation during the initial burn treatment or later as a result of sepsis or rhabdomyolysis. Patients who have sustained high-voltage electrical injuries are at increased risk of acute tubular necrosis, as the large myoglobin molecules released after such an injury can damage the renal tubules. Patients with evidence of myonecrosis or rhabdomyolysis have a reported mortality of more than 70% in severe burns.⁴ Intravenous fluid rates should be increased for a target urine output of 1 mL/kg/h, commonly between 75 and 100 mL/h. In difficult cases, diuresis with mannitol or furosemide may be instituted but may result in hypovolemia and invalidates urine output as a reliable measure of resuscitation. Although nothing has been proved to be superior to saline administration, alkalization of the urine with sodium bicarbonate is advocated to prevent precipitation of myoglobin in the renal tubules.

Acute burn patients are at risk for electrolyte derangements, especially hyperkalemia, due to renal failure and rhabdomyolysis. Serum electrolytes—sodium, potassium, calcium, and phosphorus—and creatinine kinase (CK) must be monitored frequently with initial treatment aiming for intravenous (IV) fluid administration and electrolyte management until CK is less than 5000 U/L. In cases that do not respond and develop oliguric or anuric renal failure, fluid resuscitation will no longer be beneficial and if continued will exacerbate volume overload. In this setting with volume overload and/or persistent hyperkalemic acidosis, renal replacement therapy should be initiated.

POSTBURN EDEMA

Edema is almost always present in the burn patient, even in the absence of excessive fluid administration. Edema is seen in tissues affected by the thermal injury and also in unburned areas related to systemic inflammation and resuscitation. Complications due to the edema can be cumbersome; facial and neck swelling create more difficult airway management, requiring prophylactic intubation in some instances.

COMPARTMENT SYNDROME

Compartment syndrome (CS) in the extremities, torso, or abdomen have been linked to the presence of deep, full-thickness circumferential burns and the volume resuscitation.

Limb CS: Clinical suspicion is increased in the presence of delayed capillary refill, cyanosis, paresthesias, and diminished pulses. Compartment pressures can be measured by placement of an 18-gauge needle connected to an arterial pressure transducer under the eschar into the subfascial tissue. Pressures above 25 to 30 mm Hg in any compartment are considered diagnostic of CS, but the clinical exam is important in diagnosis regardless of pressure measurements that can be inaccurate or misleading. The diagnosis of CS mandates decompression via escharotomy and/or fasciotomy. Escharotomy includes incision along the full length of eschar with extension into viable unburned tissue, typically using electrocautery. Fasciotomies involve the surgical opening of the full length of fascial compartments.

In both cases, a tissue bulge is often noted indicating adequate release of compartment pressure. Escharotomies are commonly performed at the bedside using mild sedation; fasciotomies may need to be performed in an operating room under general anesthesia. Failure to diagnose and promptly treat CS can lead to ischemia, myonecrosis, and limb loss.

Abdominal CS: Abdominal distention, oliguria, and high airway pressures on mechanical ventilation may signal the development of an abdominal compartment syndrome (ACS). ACS significantly decreases perfusion to vital organs including the small and large bowel, liver, and kidneys, contributing to the development of multisystem organ failure. Early recognition of abdominal hypertension through serial bladder pressure measurement can allow for timely decompressive laparotomy and avoidance of the sequelae caused by prolonged tissue ischemia. In many centers, caring for burned patients there are institutionalized protocols to monitor for abdominal hypertension, especially in patients with greater TBSA percentages, large torso burns, and those who require large volume resuscitation (> 500 mL/h).

Another complication of postburn edema is elevated ocular pressure. Measuring intraocular pressure (IOP) is required in some patients with large facial burns and eyelid edema; when the IOP is persistently high, decompression is indicated to avoid optic nerve damage and visual loss.

INFECTION AND SEPSIS

Sepsis is an independent risk factor for mortality following thermal injury, especially when multiorgan system failure is present. Open wounds, injured lungs, central venous catheters and urinary catheters place the burn patient at increased risk of infection and sepsis, in that order. Signs of systemic inflammatory syndrome (SIRS) are all normal findings induced by burn injury, leading to diagnostic uncertainty. Laboratory markers including peripheral white blood cell (WBC) levels, procalcitonin, C-reactive protein, human leukocyte antigen D-related (DR) expression and others have been proposed as early indicators of sepsis in the burn patient, all with mixed results. Absolute values and trends in WBC, neutrophil percentage and body

temperature are unable to predict bloodstream infection in the burn patient. The promise of early markers is to provide earlier diagnosis and treatment of infection. Although controversial, the use of procalcitonin levels has been advocated due to its sensitivity, specificity and mortality correlation in patients with burns having sepsis. However there is insufficient evidence to support the use of procalcitonin as a single diagnostic marker for sepsis in patients with burn injury.

The largest entrance of infection in burns is the breakdown of the skin barrier. The monitoring of wounds and the use of topical and surgical therapies is the first line for prevention of burn wound infection.

Ventilator associated pneumonia (VAP) in severe burn patients is associated with increased mortality but the diagnosis of VAP is nebulous. Due to severe underlying inflammatory pulmonary pathology, accurate clinical diagnosis of VAP can be very difficult in burn patients and infiltrates may be due to noncardiogenic pulmonary edema (ie, ARDS) from SIRS. The emergence of multidrug resistant bacteria is a major problem as is the use of prolonged antibiotherapy.

Bloodstream and urinary tract infections are also of concern. Timing of central access exchange in the patient with burns is determined by the risk of colonization, need for placement through burned versus unburned tissue, and physician preference. The use of peripherally inserted central catheters lines may not decrease the risk of central-line-related bloodstream infections.³ Prompt removal of all indwelling catheters when no longer warranted provides the best balance between benefit and risk in the patient with burns. Blood and urinary tract infections are treated with removal of the catheter whenever possible and appropriately tailored antibiotic therapy. The use of systemic antibiotic prophylaxis has not been shown to decrease wound infection or any others in the burned patient and may promote infection with multidrug resistant organisms and fungal infections. Protocols vary in when surveillance cultures of burn wounds are performed. Burn wounds often become colonized but may or may not be causing sepsis. Systemic antibiotics are added to standard local wound care if infection is suspected (see Sec. "Wound Care").

Less Common Infections

Acute infective endocarditis has a low prevalence in burn patients, but adds considerable morbidity and mortality. A common pathogen is *Staphylococcus aureus* and persistent bacteremia should prompt investigation for endocarditis. Other less frequent infections in burn patients include parotitis, sinusitis, chondritis of the ear and ocular infections.

Wound Care

Although wound sepsis in burns has steadily decreased, it remains a factor that adds morbidity and mortality. Cleansing and debridement of the wound is accomplished with mild soap and water or with chlorhexadine/normal saline washes. Most burn experts recommend debridement of all blisters larger than 0.5 cm to reduce the risk of bacterial colonization or infection. Burn wounds become colonized in the first few hours with gram-positive bacteria including *S aureus* and *epidermidis*, and by 5 days are predominantly colonized with gut flora such as *Pseudomonas aeruginosa*, *Enterobacter cloacae*, and *Escherichia coli*.

Health care workers must be vigilant in hand washing and maintenance of a clean environment around the wounds for prevention of cross-contamination in these immunocompromised patients. Culture swabs of all wound beds should be obtained upon admission and repeated serially to monitor for changes in colonization or if there is a clinical suspicion of wound sepsis. Quantitative cultures of the burn to diagnose wound invasion are best obtained by tissue biopsy, either in the operating room or at bedside. Bacterial colonization of burn wounds does not require systemic antibiotics but should be managed with early debridement and/or excision, together with appropriate topical and/or biologic dressings.

Cleansing and debridement is followed by application of a topical antimicrobial agent intended to control colonization, not sterilize the burn wound. Several layers of absorptive gauze and Kerlix cover the wound to decrease evaporative water losses. Minor burns can be managed with biologic dressings, silver-coated dressings, or tribiotic ointment covered with nonadherent gauze. Commonly utilized topical agents include silver sulfadiazine

(silvadene), mafenide acetate (sulfamylon), and silver nitrate. Silvadene continues to demonstrate effective control of burn wound colonization, while remaining inexpensive and easy to apply. However, eschar penetration is minimal and complications related to leukopenia and hemolysis have been reported. Mafenide acetate cream (sulfamylon) is painful when applied to superficial partial thickness burns. Eschar penetration is greatest with sulfamylon, making it the topical agent of choice in burns where the eschar will not be excised immediately or when control of *P. aeruginosa* is required. Metabolic acidosis may occur, as sulfamylon is a carbonic anhydrase inhibitor. Silver nitrate 0.5% solution has fallen out of favor due to electrolyte abnormalities and poor tissue penetration but may be used as a reasonably effective agent for treatment of gram-negative or fungal colonization. Other alternatives for topical treatment are available especially when patients are allergic to sulfas, such as bacitracin, neosporin, mupirocin (mainly gram-positive coverage), and polymyxin B.

Complications directly related to topical agents, frequent dressing changes often result in traumatized epithelialization and delayed wound healing. Silvadene has been shown to delay wound healing due to a direct toxic effect on keratinocytes. To avoid this silver impregnated dressings have been developed to provide antimicrobial coverage, adequate humidity, and decreased trauma, all with less frequent dressing changes. Biosynthetic products designed as epidermal substitutes are also used, allowing for faster reepithelialization, although their use is limited due to increased infection.

SURGICAL MANAGEMENT

In addition to topical wound care, a great deal of wound care relies on the surgical management. Deep burns are managed with surgical excision and placement of xenograft, allograft, autograft, or cultured skin substitutes.

Most experienced burn centers advocate for an early wound excision within the first 1 to 7 days following thermal injury to attenuate the systemic inflammatory effects of burns and reduce the risk of sepsis. No significant difference in infection or mortality rates was found when burn excision

was performed at any point between 2 and 7 days of management. The appropriate timing for burn wound excision and grafting involves a number of important factors including the age of the patient, extent and depth of burn, comorbidities, hospital resources, and physician preference. Mortality and length of stay is decreased in young populations of burn patients (< 30 years and children) with a TBSA more than 30% when early excision is performed.

After the wound is excised, bleeding is controlled and grafting occurs as per institution protocol, after the procedure a proper wound dressing, topical antibiotics are a must to avoid graft failure and infections. Skin substitutes and replacements require adequate wound bed preparation to ensure minimal graft loss.

NUTRITIONAL SUPPORT

Burns are associated with a hypermetabolic state. The increase in metabolic rate is proportional to the extent of the burn and the coexistence of infection; the metabolic rate peaks at 7 to 10 days and can persist for many months postinjury. Overfeeding excess carbohydrate or lipid calories can result in metabolic complications such as hyperglycemia and fatty liver.

Caloric requirements may be estimated using 120% to 150% of the Harris–Benedict formula calculation or 20 to 30 kcal/kg body weight/day, trending toward the higher 30 kcal/kg due to the increased metabolic rate. Supplying 1.5 to 2.0 gram of protein/kg body weight will help in maintaining the nitrogen balance due to excess protein losses via the burn wounds. Enteral nutrition is preferred and early enteral nutrition is beneficial. In patients with gastrointestinal complications (see the following section), unable to tolerate enteral feeding, TPN may be initiated.

MODULATING HORMONAL AND ENDOCRINE RESPONSES

Hyperactive metabolic response in the thermal injury is due to the increased levels of catecholamines and catabolic hormones. The use of beta-blockers is very common in burn units to attenuate the catabolic state reducing oxygen demand, resting

energy expenditure and heart rate. Randomized prospective trials will be needed to assess the impact of beta-blockade after burn injuries.

GASTROINTESTINAL COMPLICATIONS

Multiple complications affecting the gastrointestinal tract arise after the occurrence of severe burns, usually in patients with a Total Body Surface Burn (TBSB) more than 25%. Dysmotility problems vary from diarrhea (very common), mainly while using enteral feeds, high osmotic loads, overfeeding, and infection (*Clostridium difficile*, Cytomegalovirus). Ileus may develop due to hypovolemia, use of narcotics, infection, prompting nasogastric decompression and bowel rest.

Within hours of a severe burn injury, the stomach and the duodenal mucosa can develop focal injuries, progressing to larger and multiples lesions and even gastrointestinal bleeding (Curling's ulcers). Rapid resuscitation, the use of proton-pump inhibitors or H-2 blockers and early enteral feeding has decreased this complication to less than 2% in the critically ill population.

The liver seems to be affected immediately following severe burn injury most likely related to severe systemic inflammation, shock, and hemolysis. There is a mild to moderate increase of aminotransferases that should resolve within a few days, the presence of early jaundice is associated with a poor prognosis.

The proposed etiology of hemolysis is the induction of morphologic changes in red cells. Schistocytes and spherocytes are identified due to direct effect of heat on the cells, hemolysis generally takes place during the first 24 to 48 hours and it correlates with the TBSA.

The incidence of pancreatitis has increased in patients with severe burns as more patients survive. Standard diagnostic and therapeutic modalities are used when clinically indicated (amylase, lipase levels) with temporary bowel rest. Acute cholecystitis (mostly acalculous, intestinal necrosis) can occur in any critically ill patient and is increased in patients receiving TPN. Acute cholecystitis is less commonly seen, possibly due to more effective resuscitation and enteral nutrition.

ANALGESIA IN BURNS

Pain as the result of an acute burn is usually a mixed picture (procedural pain and pain directly caused by the injury), multiple procedures from wound dressings changes, debridement, grafting, and physiotherapy will add severe pain to the patient, poor pain management will impede proper patient cooperation and ultimately good rehabilitation. In intubated patients the usual approach is continuous sedation and opiate infusion, in awake patients needing multiple procedures conscious sedation is ideal. Long-acting opiates and patient control analgesia are useful. Evaluation and follow up by an acute pain team can be beneficial by recommending other therapies, anxiolytics, nonopiate medications, and nonpharmaceutical strategies.

DEEP VEIN THROMBOSIS

The incidence of deep vein thrombosis and pulmonary embolism in the burn patient is increased; unless contraindicated all critically ill burn patients should receive both mechanical (intermittent compression devices) and pharmacologic prophylaxis (fractionated or unfractionated heparin) until mobile.

PSYCHOSOCIAL CARE

Psychologic and psychiatric support is often not needed in the acute ICU setting; however, an assessment and treatment should be addressed as soon as needed, taking into account that most of every severe burned patient will live with not only physical sequels from their misfortune but also with a pronounced posttraumatic stress disorder. Caregivers should start a clear and honest conversation with the patient and family when feasible, for a better understanding of the implications of the injuries sustained.

REHABILITATION

A multidisciplinary approach including nurses, physiotherapists, counselors, occupational therapists, and social workers is fundamental to aid rehabilitation and reduce long-term disability. It should start at the time of injury and during the acute care

and continue postdischarge. Physical therapy can decrease muscle mass loss and bone mineralization, and improve mobility and function in the burned patient.

Critical Care of Disaster Victims

Carla Venegas-Borsellino, MD; Sharon Leung, MD, MS and Vladimir Kvetan, MD

KEY POINTS

- 1 Major natural and manmade disasters have always occurred, but their increasing frequency over the past decade has elevated awareness of the importance of planning and preparing for catastrophic events.
- 2 The responses of different healthcare systems to major disasters in the past have demonstrated the continued need for a more clearly identified planning process in order to effectively respond to multi-hazard events.
- 3 The CCM physician should be prepared to provide triage, stabilization, clinical management, teamwork leadership and managing of hospital resources.
- 4 The goal in mass casualty scenarios is to minimize mortality and morbidity, but an effective response during a disaster situation depends on multiple variables: nature of the incident, number of victims, resources, and the coordination of efforts, among others.
- 5 Understanding the characteristics of different disasters and predicting their impact on the healthcare system, integrating the principles of the command center, and participating in the local disaster planning process will improve the appropriate response by the critical care physician to disaster situations.
- 6 Educational efforts are crucial before and after a disaster. Simulation sessions and mock outbreak/disaster exercises must be instituted on a regular base to understand our current level of preparedness, teach personnel how to respond appropriately to these unique situations, predict and be prepared for unexpected events.

INTRODUCTION

Major natural and manmade disasters have always occurred, but their increasing frequency over the past decade has elevated awareness of the importance of planning and preparing for catastrophic events. Over the past 2 decades, more than 3 million lives have been lost worldwide due to major disasters. In 2008 alone, the total number of deaths caused by disasters with a natural and/or technologic trigger was a staggering 242,662.¹ As populations grow and occupy spaces

that are vulnerable to different hazards, it is expected that disasters will increase in severity and impact. The New York City Panel on Climate Change 2013 states in its executive summary that “Climate change poses significant risks to New York City’s communities and infrastructure.”² Analyses of the response of different healthcare systems to major disasters in the past have demonstrated the continued need for a more clearly identified planning process in order to effectively respond to multihazard events.³

In general, the US Critical Care Medicine System receives massive resources in terms of gross national product expenditure when compared with other developed countries, giving it the capacity to provide care to critically ill patients resulting from these disasters. But the question is whether the US critical care system and the intensivists are ready to handle the challenges such events present.⁴ The expected percentage of critically injured can vary depending on the nature of the event, but it is estimated to be approximately 16% of the overall number of survivors (range 2.5%-34%).^{5,6} However, published experience has shown that in mass casualty situations, the ICU is also commonly utilized as an overflow area for primary triage, as well as initial and overflow postoperative management.⁷ Therefore, the CCM physician should be prepared to provide triage, stabilization, clinical management, teamwork leadership and managing of hospital resources.

The responsibility of caring for the most serious salvageable casualties in natural and manmade disasters will ultimately involve the critical care physician.⁸ To provide an appropriate response the intensivist should be part of the institutional disaster-planning effort, understand what the resources and capabilities are for the community, hospital, and its ICU on a continual basis, and be able to plan a modular expansion of the critical care services for any successful emergency response.⁹

The goal in mass casualty scenarios is to minimize mortality and morbidity, but an effective response during a disaster situation depends on multiple variables: nature of the incident, number of victims, resources, the coordination of efforts, among others. So one of the most important concepts to guarantee a successful management of disaster victims is understanding the layers of command and control related to which organizations that are responding to any unique event and how to participate within the disaster incident command system.

Through this chapter we want to initially review basic concepts of the nature of the disaster and expected medical complications, and then review the most recent recommendations for critical care providers about disaster medical management and preparedness for local mass casualty situations, based on the 2 most recent publications offering illumination on this topic: the Critical Care Collaborative

Initiative's January 2007 Mass Critical Care Summit¹⁰ and the 2007 US Department of Homeland Security National Preparedness Guidelines.¹¹ The former contains 5 articles which include an executive summary¹⁰ and individual papers on current capabilities,¹² a framework to optimize surge capacity,³ medical resource guidance,¹³ and recommendations for allocating scarce critical care resources in a mass critical care setting.¹⁴ The latter highlights 15 national disaster scenarios, 12 of which have the potential to produce large numbers of critically injured or ill patients.

IMPORTANT DEFINITIONS¹⁵

Disaster—Currently there is no uniformly accepted definition for the word disaster as it implies individual and local perspective. From a healthcare standpoint, the most important variable that defines a disaster is its functional impact on the healthcare facility.

Hazard—An event with the potential to cause catastrophic damage. It may be a “naturally” or “manmade” occurring phenomena.

Emergency—A natural or manmade event that significantly disrupts the environment of patient care resulting in disrupted care and treatment.

Casualty—Any person suffering physical and/or psychologic damage by outside violence leading to death, injuries, or material losses.

Multicasualty incident—A hazardous event that regardless of its size is containable by local emergency medical services.

Mass casualty incident: A hazardous event that overwhelms local response capability. It is likely to impose a sustained demand for health services rather than a short, intense peak typical of many smaller-scale events.

NATURE OF THE DISASTER

The nature of the disaster is widely variable and can include a terrorist attack, infectious pandemic, mass transit accidents, or natural disaster and all of them can exhaust regional or national critical care

systems. As highlighted by the 2007 US Homeland Security Task Force,¹¹ the scenarios which can generate massive amounts of critically ill victims are broadly divided into 3 general categories: terrorist attacks, epidemic disease, and natural disaster.

Natural disasters arise from forces of nature and include earthquakes, volcanic eruptions, hurricanes, floods, fire, and tornadoes.

Infectious disasters can be classified as epidemic or pandemic.

Manmade disasters are due to identifiable human causes and may be further classified as complex emergencies (eg, wars, terrorist attacks) and technologic disasters (eg, industrial accidents, explosions from hazardous material).

Regardless of the type of classification used to categorize disasters, certain unique features are associated with each type of disaster. It is important to understand the common effects of different natural and manmade disasters to predict their impact and plan effectively.¹⁵

Natural Disasters

Earthquakes

Earthquakes are common and even predictably frequent especially in many earthquake prone areas of the world and result in significant mortality.¹¹ Availability of health care providers well trained in basic and advanced trauma and life support and the architectural design and build quality of the stricken area's housing and public facilities are 2 major determinants of outcomes for earthquake victims. Earthquakes also commonly result in damage to health infrastructures and water systems and create disruptions to communication and transportation networks.¹¹

Volcanic Eruptions

Different types of eruptive events occur, including pyroclastic explosions, hot ash releases, lava flows, gas emissions, and glowing avalanches (gas and ash releases). Although lava flows tend not to result in high casualties, the "composite" type of volcano is associated with a more violent eruption which is associated with air shock waves, rock projectiles (some with high thermal energy), release of noxious

gases, pyroclastic flows, and mud flows (lahars). The morbidity and mortality are related to respiratory-related syndromes and conjunctival and corneal injury, topical irritation of skin and other mucosal surfaces.¹⁵

Hurricanes, Cyclones, and Typhoons

These are large rotating weather systems that form seasonally over tropical oceans. They are among the most destructive natural phenomena. Many complications are the result of widespread flooding and most hurricane-related deaths occur from storm surge-related drowning. The most common injuries include lacerations, blunt trauma, and puncture wounds. Late morbidity can be due to postdisaster cleanup accidents (eg, electrocution), dehydration, wound infection, and outbreaks of communicable disease.¹¹

Floods

There are 3 major types of floods: flash floods (caused by heavy rain and dam failures), coastal floods, and river floods. Together, they are the most common type of disasters and account for at least half of all disaster-related deaths. The primary causes of death are drowning, hypothermia and injury due to floating debris. The impact on the health infrastructures and lifeline systems can be massive and may result in food shortages. Interruption of basic public services (eg, sanitation, drinking water, electricity) may result in outbreaks of communicable disease. Another concern is the increase in both vector-borne diseases and displacement of wildlife.¹⁵

Landslides

They are defined as downslope transport of soil and rock resulting from natural phenomena or manmade actions and are more widespread than any other geologic event. Landslides cause high mortality but relatively few injuries. Trauma and suffocation by entrapment are common. Pending an assessment needs can be anticipated, such as search and rescue, mass casualty management, and emergency shelter for the homeless.¹⁵

Other Natural Disasters

Tornadoes occur most commonly in the North American Midwest. They cause widespread destruction of community infrastructure. Injuries most

commonly seen are complex contaminated soft-tissue injury, fractures, head injury, and blunt trauma to the chest and abdomen.

Infectious Disasters

Pandemic Respiratory Infections

Pandemic H1N1 2009 was caused by a new strain of influenza A virus that within weeks spread worldwide through human-to-human transmission. During the first month of the emergency, the CDC's Strategic National Stockpile released 25% of the supplies in the stockpile for the treatment and protection from influenza.⁶ At the third month the World Health Organization (WHO) declared the 2009 H1N1 influenza a global pandemic, generating the first influenza pandemic of the 21st century. The initial data show that about 8% of H1N1 patients were hospitalized (23 per 100,000 population); 6.5% to 25% of these required being in the ICU (28.7 per million inhabitants) for a median of 7 to 12 days, with a peak bed occupancy of 6.3 to 10.6 per million inhabitants; 65% to 97% of ICU patients required mechanical ventilation, with median ventilator duration in survivors of 7 to 15 days; 5% to 22% required renal replacement therapy; and 28-day ICU mortality was 14% to 40%.⁶

Judicious planning and adoption of protocols for surge capacity and infrastructure considerations are necessary to optimize outcomes during a pandemic.^{16,17} Safe practices and respiratory equipment are needed to minimize aerosol generation when caring for patients with influenza. These measures include hand-washing, gloves and gowns, and the use of N95 mask.^{16,17}

Manmade Disasters

Transportation Disasters

Transportation accidents can produce injuries and death similar to those seen in major natural disasters. Some of the largest civilian disasters in North America have been related to transportation of hazardous materials, but more commonly they are related to motor vehicle accidents, railway accidents, airplane crashes, and shipwrecks. They cause a wide range of injuries including multiple trauma, fractures, burns, chemical injuries, hypothermia, dehydration, asphyxiation, and CO inhalation.¹⁵

Weapons of Mass Destruction

Weapons of mass destructions (WMDs) are those nuclear, biological, chemical, incendiary, or conventional explosive agents that pose a potential threat to health, safety, food supply, property, or the environment. Since the terrorist attacks in September 2001 and subsequent intentional release of anthrax spores in the United States, there is growing concern around the world about the possible threat of chemical, biological, or nuclear weapons used against a civilian population. In response to a WMD incident, healthcare personnel should be prepared to manage casualties in an environment of panic, fear, and paranoia.⁴ Because most attacks occur without warning, the local healthcare system will be the first and most critical interface for detection, notification, rapid diagnosis, and treatment.¹¹

Biological Weapons

Biological weapons can be either pathogens (disease-causing organisms such as viruses or bacteria) or toxins (poisons of biological origin). Compared with other WMDs, biological weapons are characterized by ease of accessibility and dissemination, difficulty in detection because of their slow onset of action, and their ability to cause widespread panic through the fear of contagion.^{11,18} Based on these characteristics they require special action for public health preparedness. In the event of a suspected bioterrorist attack, the CDC has issued protocols for early notification of local and state public health department agencies.

Chemical Weapons

Chemical incidents are events that threaten to or do expose responders and members of the public to a chemical hazard. Agents commonly used as chemical weapons are also used in industrial processes. These agents, however, pose serious problems for emergency care providers because of their potential to cause a large number of casualties rapidly and their potential for secondary contamination. Any emergency medical or public health response to a major incident involving a chemical warfare agent will require coordination among local, state, and federal organizations. First responders should be aware of access to specialized local and federal response teams, basic triage and demarcation of

the contaminated area, use of handheld devices for agent detection and identification, use of personal protective equipment, and knowledge of appropriate medical treatment and antidotes.¹¹

Nuclear Weapons and Radiation Accidents

A variety of terrorist applications of radiation exist that could produce varying degrees of damage to public infrastructure and operations, human casualties and illnesses, and most importantly, fear. Approximately 50% of the energy released from a nuclear bomb is due to the blast and shock waves, giving a majority of the survivors blast-related injuries as well as creating extensive infrastructure damage. About 35% of the energy released is thermal radiation (in orders of tens of millions of degrees), giving rise to high-degree skin lesions. However, the most likely terrorist threat using radiation is the so called “dirty bomb” in which some type of radioactive material is added to a conventional explosive bomb. Among experts in this field it is thought such a bomb would most likely involve the use of more easily accessible but less dangerous forms of radioactive material; thus the likelihood of mass casualties with acute radiation poisoning at this point is not high.¹¹

Hazardous Materials Disasters

A hazardous material is a substance potentially toxic to the environment or living organisms. Full-scale disasters from hazardous materials disasters (HazMat) are relatively rare, but isolated incidents are among the most common in the community and are not limited to chemicals but can include various biological and radiologic materials as well. Knowledge of the types of industries present in the community would be helpful in developing a potential plan to deal with likely HazMat situations. Injuries secondary to release of hazardous materials can present as chemical burns, inhalational injury, and a variety of systemic injuries.¹¹

Armed Conflict

Armed conflict continues to be the most preventable and destructive of manmade disasters. Specific healthcare issues during these conflicts include trauma from blast injuries and projectiles, crush-related injuries, communicable diseases due to the breakdown of public infrastructure, mass

displacement of populations, burns, and radiation-related injury.¹⁵

PRINCIPLES IN DISASTER PLANNING

Disaster Plan Development

Most of the logistical problems faced in disaster situations are not caused by shortages of medical resources but rather from failure to effectively coordinate their distribution. Planning requires the participation of leaders with clear responsibilities and corresponding skill to coordinate efforts and develop policies to contain the disease; to coordinate resource allocation and manpower; to advise and share information regarding infection control and treatment; to share data and research endeavors; to maintain staff morale; and to provide information to various levels of government, health care institutions, front-line workers and the public.⁸

Existing Preparedness Requirements

In developing disaster plans, hospitals must take into account the national and local requirements imposed by governmental agencies like the Centers for Medicare and Medicaid Services (CMS) and The Joint Commission (TJC). The CMS's conditions for emergency preparedness and services establish minimum requirements for hospitals that participate in Medicare or Medicaid programs. Similarly, TJC standards apply to a full range of hospitals from small rural to large urban academic centers and are focused on 4 main areas: (1) emergency preparedness management plan, (2) security management plan, (3) hazardous materials and waste management plan, and (4) emergency preparedness drills.¹⁹

Hazard Vulnerability Analysis

Any disaster plan should start with a thorough analysis of potential hazardous events that can occur in or around the healthcare facility. TJC requires a formal documented hazard vulnerability analysis that is integrated with the emergency management plan, setting priorities among potential emergencies and also defining the hospital's role in the local community-wide emergency plan.¹⁹

Incident Command System

The incident command system (ICS) is designed to provide the basic response in emergency management to avoid the lack of coordination among various public and healthcare agencies and from the lack of operational integration of various medical specialties. The ICS specifies a common terminology and a command structure with 5 functional sections:

Command—Unified command staff responsible for overall management of the incident. This includes a designated person who will have the authority to declare an emergency. All personnel involved in the command system should be aware of the exact predetermined location of the command center.

Operations—Performs the actual response work under the directives of the command center.

Planning—Gathers relevant information and develops response strategies as the situation progresses. The plan should provide protocols that guide notification and the sequence of mobilization of the personnel in a disaster situation.

Logistics—Responsible for facility-wide supplies, equipment, personnel, and services. The command system must have independent telephone lines to ensure uninterrupted communication with the external world in a disaster situation.

Finance—Authorizes expenditures, maintains records, and provides documentation of the incident.

Once initiated, the ICS has a built-in chain of command that would be responsible for triage of patients and allocation of personnel and resources.¹⁹

TRIAGE

Triage is a dynamic process that includes not only the disaster site or the emergency department but is carried through several levels of the medical response pathway in disaster response. Triage of critically ill patients in the mass casualty situation is challenging, because the medical critical care is provided not necessarily to the sickest patient, but

the one who has the best opportunity for long-term survival. Although less applicable in disasters with a gradual onset, patient triaging is extremely important in sudden events like explosions or natural disasters. Frykberg⁴ established a direct linear relationship between over-triage (delivery of immediate care to disaster victims who are not critically ill or injured) and higher critical mortality rate.

Problems commonly encountered in the triage process include the following:

Lack of medical direction at the scene—During a mass casualty event, triage is approximately 70% accurate with a tendency to underestimate injury severity.²⁰ The most important strategy to prevent under or over triage includes the use of an experienced triage officer, usually a senior physician/surgeon, with outstanding leadership and communications skills, who has a clear understanding of the medical resources at hand and the ability to recognize and, if necessary, perform immediate lifesaving measures.

Lack of interorganizational planning—Dynamic management of the triage process requires constant assessment of medical resources and communication between the command center, the scene, and the triage site. This will allow for rational and appropriate triage based on the availability of resources.

Regarding triaging admissions to the ICU, the triage officer will review all patients for inclusion and exclusion criteria (recommended by sequential organ failure assessment [SOFA] scoring system)²¹ and facilitate discharge from critical care for patients no longer requiring it. The triage officer will evaluate daily all patients receiving critical care, and evaluate those requested to be considered for critical care as they arise.

Another challenging issue is how to provide critical care management during a prolonged period of time if resources can be limited. In these cases it is important to provide essential rather than limitless critical care to allow many additional community members to have access to key life-sustaining interventions during disasters. The concept of emergency mass critical care (EMCC) involves planning and provision of essential interventions to maximize the

number of individuals who receive sufficient critical care.³ Medical resource planning recommendations for EMCC can be divided into 3 categories: treatment materials, hospital personnel, and facilities; or staff, staff, and space. Resources include mechanical ventilators, intravenous fluids, vasopressors, antidotes, antimicrobial for specific diseases, sedatives and analgesics, specific therapeutics, and intervention materials (such as those needed in renal replacement therapy and parenteral nutrition). The EMCC recommendations should be used only in overwhelming events, meaning after calls for assistance from local, regional, state, interstate, and federal authorities have been exhausted.¹⁰ The Task Force recommends that hospitals with ICUs should be prepared to provide EMCC for at least 3 times the usual number of critically ill patients and to maintain such care for 10 days without “sufficient external assistance.” The panel also offers a progressive list of changes in resource use for coping with shortages. It starts with substitution and runs through adaptation, conservation, reuse, and finally reallocation, the last meaning taking a resource from 1 patient and giving it to another with a better prognosis or greater need.¹⁴

While the initial triage during a disaster focuses on the patients, the disaster critical care triage focuses on the resources (tertiary triage). Decisions to reallocate critical care resources among patients will require a high degree of transparency and regular reviews to ensure that established processes are being followed.¹⁴ The SOFA score, though not validated, has been proposed to determine qualification for ICU admission during mass critical care.²¹ Patients who are excluded from critical care should receive palliative care.²² It is mandatory that mass disaster preparation anticipates palliation for large numbers of individuals.¹⁰

The EMCC, to date, is untested, and the real benefits of implementation remain uncertain. Nonetheless, EMCC currently remains the only comprehensive construct for mass critical care preparedness and response.²³

SURGE CAPACITY

Critical care service and supplies should be assessed and prepared for possible expansion during a major disaster.^{7,8} The plan should have a current inventory of all supplies and capabilities of the facility: number

of ventilators in use and its absolute capacity, inventory of various ICU supplies; and vendor lists should be readily available if there is sudden demand for supplies. The disaster plan should allow for at least 2 days’ worth of supplies. Available computer-based systems can help to predict surge capacity and design the disaster plan response.²⁴

Disaster plans should also consider the possibility of internal and external power outages and related disruptions (such as communications), loss of utilities such as power, water, or telephones due to floods, civil disturbances, accidents, or emergencies within the organization or in its community.¹⁰

Stuff (Medical Equipment and Supplies)

The recommendations focus on the surge-capacity on ventilators because there is little guidance in the medical literature and the anticipation is that most patients who will require mechanical ventilation in a mass critical care event will probably require several days of ventilation.

Ventilators

All predictions are that the need for ventilators in a major pandemic will far exceed the supply.²⁵ Currently there is an estimated total of 105,000 ventilators in the United States and the US national stockpile has about 4600 ventilators, making them likely insufficient to deal with a pandemic influenza outbreak or lung injury following a widespread terrorist attack.^{26,27} Most hospitals cannot afford to stockpile ventilators, and in a catastrophic disaster, transportation and communication disruption may limit the ability to draw from regional and national stockpiles. The guidance includes suggestions on short-term strategies to boost ventilator capacity, such as repurposing other types of ventilators (anesthesia machines, noninvasive devices, and transport devices), and borrowing from other hospitals that are not having critical care shortages. In a surge setting, ventilators should be able to operate without high-pressure medical gas, be able to oxygenate and ventilate pediatric and adult patients with significant airflow obstruction, accurately deliver the prescribed minute ventilation, and have a standard alarms system. Modifying a ventilator to be used for multiple patients is no longer acceptable.¹⁰

Oxygen Tanks

Oxygen remains the critical consumable resource in disaster management²⁸ and may run short in a disaster situation due to consumption by large numbers of patients in respiratory failure, or due to damage of oxygen storage and delivery systems. Strategic management of oxygen supplies in disaster scenarios remains a priority because in the case of a shortage, the Strategic National Stockpile will not supply oxygen, and delivery by contracted vendors can be delayed. Medical oxygen sources include bulk and portable liquid systems, compressed gas cylinders, and oxygen concentrators. Most hospitals have sufficient stores of bulk liquid oxygen to support patient needs for the short term. Potential areas of concern include damage to reserve systems that are contiguous with the main system and ventilator models that require a high-pressure gas supply and cannot be supported by small oxygen concentrators.²⁹

Medications

The Task Force recommends planning how to optimize availability of medications and safe administration thereof during a disaster response. Planning should include rules for medication substitutions, safe dose or drug frequency reduction, conversion from parenteral administration to oral/enteral when possible, medication restriction, and guidelines for medication shelf-life extension.¹³

Staff

The current shortage of critical care trained personnel is well documented³⁰ and staffing issues may be further complicated if the crisis is prolonged or affects employees personally (also possible due to staff absenteeism).⁸ Staff resources may also be reduced by illness during an influenza epidemic or bioterrorist attack, especially in the critical care setting where the personnel have direct contact with the airway secretions and there can be significant pathogen aerosolization. Strategies for infection control include early identification and triage of at-risk populations, and ensuring adequate supply and strict use of personal protective equipment. Hospitals should also fit-test all staff with negative pressure respirators, such as the n95 mask.³¹ Other concerning issues are the exposure to critical care staff at significant risk of sleep deprivation and

exhaustion, the feeling of being isolated working in difficult and demanding conditions, and the worrisome event of them falling ill (like during the Severe Acute Respiratory Syndrome by coronavirus[SARS] SARS epidemic).³¹

A complete disaster management plan should include a regimented shift schedule that balances available staff and skills with current clinical abilities, constant moral support for the team members, a frequent feedback system that allows the personal to get congratulations for their efforts, and the possibility to start a cases group support with help from psychiatric or the emergency response crisis team; treatment for posttraumatic stress disorder that cause long-term disability in the healthcare providers should also be considered.²³

To extend their ability to provide direct critical care to large numbers of patients, the Task Force guidelines recommend that critical-care-trained physicians and nurses oversee noncritical care staff supported by guidelines of standardize interventions to reduce care variability.¹³ The Task Force recommends that any nonintensivist physicians willing to serve in intensivist roles could be encouraged to join critical care teams. These physicians could be assigned to care for up to 6 critically ill patients each with intensivists overseeing 4 to 8 of these nonintensivist clinicians (up to 48 patients), depending on their experience. Noncritical care nurses and pharmacists could become responsible for medication delivery to all of the critical care patients; paramedics could help maintain airways of critical care patients; respiratory therapists (RT) who specialize in critical care could oversee groups of their noncritical care colleagues (1 critical care RT and 1 noncritical care RT to care for perhaps 12-14 patients); and pharmacists could help redistribute scarce pharmaceutical resources.¹³

Space

Hospitals can expand critical care to other areas, but shortages of equipment and staff can limit that option due to the fact that most critical care interventions need specialized machines and equipment which only can be performed in locations with electricity and oxygen.²³ Intensive care units,

postanesthesia care units, and emergency rooms are best outfitted to provide mechanical ventilation and close monitoring; step-down units, large procedure suites, telemetry units, and hospital wards may be used for EMCC when capacity in these spaces is exceeded.¹³ Facility planning for both backup systems and expansion of services (ie, generator availability) is essential to maximize critical care capacity.

Also because care of noncritical patient requires less infrastructure, strong consideration should be given to the transfer of stable patients to “surge facilities” to maximize dedicated hospital space for critical care delivery in an overflow situation. Finally, another resource is evacuating critical patients to another facility when the hospital exceeds its capacity or is directly affected by the disaster to maximize survival in a mass casualty event⁶; but this is not likely to be a good immediate option while the disaster is in the early stages of its evolution.

Point of Care

There is a constant concern about the delay in identification of complex pathologies which require medical testing and their significant associated mortality and morbidity (eg, myocardial infarctions, acute kidney injury, and sepsis). So, new recommendations are focusing on point-of-care (POC) testing³² that allows medical testing, early patient stabilization and transfer to a critical care setting for comprehensive critical care management.

Palliative Care

During a catastrophic mass casualty event, there is an important role for palliative care services in the support of individuals not expected to survive and their relatives. These services should be included in the state and local disaster plan to minimize the suffering of the victims, and free up resources to optimize survival of others. In a recent publication,²² the investigators provide guidance about the role of palliative care in a mass casualty event, stating that even in the context of scarce resources during these events, support and training for healthcare personnel deciding treatment for those “likely to die” should be in place.

OTHER CHALLENGES IN DISASTER PLANNING

Planning

It has even been reported that less than 10% of casualties actually require hospital admission^{4,5}; in large scale casualty event it is known that field triage stations are often bypassed, causing hospital nearest to the disaster site to receive the bulk of the casualties. This makes it remarkably important to conduct a careful survey of potential sites and types of hazardous events specific to the local area while designing a disaster plan, and include transfer agreements between hospitals and nearby ICUs to meet possible bed shortages.⁸

Communication Devices

The failure of communications systems in major disasters due to excessive demand or possible disruption has been well documented.¹⁰ It is considered the responsibility of local and regional health officers to identify medical disaster communication needs and establish primary and backup systems linking response providers, health care facilities, and emergency operations centers. The Trust for America's Health sponsored by the Robert Wood Johnson Foundation, include streamlined and effective communication channels as 1 of the 8 core goals of a public health emergency response to enhance rapid and accurate transfer of information between health care workers, frontline responders, and the public.³³

Legal Issues

Resource triage is arguably the most problematic issue in disaster medicine because it inevitably raises the concern of health care rationing that will potentially impact individual survival. The ethical, legal, and social ramifications of resource triage can be quite significant, compelling us to first to make all efforts to obtain scarce resources, transfer patients, or increase surge capacity through EMCC before considering the “rationing” of resources.¹⁴ To ensure appropriate legal and societal support, resource triage should be done in collaboration with regional and federal public health authorities

using objective, fair, and transparent criteria for provision of care.¹⁴

In contemplation of the ethical implications of resource triage, more work is needed to develop a system that is effective, rational, and amenable to society. Several groups, including the Task Force have favored employing the SOFA score to stratify patients with respiratory failure and/or shock with end-organ damage in terms of short-term survival, because it relies on objective data that are relatively easy to obtain and has been validated in a variety of critical illnesses^{10,21}; yet, considering finite and potentially dwindling resources consideration must be given to excluding those patients with overall poor prognosis caused by end-organ failure such as end-stage liver disease, end-stage heart failure, or end-stage pulmonary disease.

Education and Simulation Training

Scheduling regular training and exercises in disaster management at different scales is important to enhance preparedness. Regular drills will help identify difficulties and provide knowledge of the absolute capacity of devices, equipment, and services in a disaster situation.³⁴ Plans to evacuate critically ill patients to nearby hospitals in the event of failure of backup systems should also be addressed in the process. Even though there is no perfect educational tool which exactly replicates a disaster, educational efforts in preparedness are still useful and necessary. Simulation training provides opportunities for teaching, observing and analyzing performance in order to find ways to improve.

Training our staff and our future ICU trainees for such eventualities through the use of simulators and mock disaster codes has become necessary to build on our successes and learn from to avoid the problems we encountered in the past. Educational tools include table exercises, standardize patients, and robotic patient simulators among others. A recent study showed that all critical actions took longer to perform on simulator patients compared to actor patients (standardize patient), and the time required to perform procedures on simulators were similar to published results on real-world patients.³⁴

Critical Care in Unconventional Situations

There have been numerous examples in medical literature describing extended critical care through mobile ICU teams, not necessarily restricted to disaster settings. Some of the special factors to consider in the formation of ICU teams are: (1) choosing personnel that are flexible in terms of their availability, (2) having flexible staffing strategies to respond appropriately to each unique situation, (3) providing special training that allows innovative interventions adapted to local needs, and (4) assessing if the mobile ICU team can be implemented quickly enough. The preparation of mobile ICU teams should include review of the overall effort and adequacy of the ICU teams, outcome of victims, operational costs, and analysis of the structure and process of the ICU in the field.³⁵

CONCLUSIONS

Critical care is an indispensable part of the medical disaster response not only because intensivists provide care for the sickest of the salvageable patients but also because they can share their clinical expertise in triage, resuscitation, and complex medical care. Understanding the characteristics of different disasters and predicting their impact on the healthcare system, integrating the principles of the command center, and participating in the local disaster-planning process will improve the appropriate response by the critical care physician to disaster situations. Also appropriate interventions for medical syndromes that require specific therapies are critical to minimizing morbidity and mortality during disaster events and their aftermaths.

Educational efforts are crucial before and after a disaster. Simulation sessions and mock outbreak/disaster exercises must be instituted on a regular base to understand our current level of preparedness, teach personnel how to respond appropriately to these unique situations, predict and be prepared for unexpected events. Learning from the successes and failures of past local and global disasters is necessary to prepare our health system for a successful emergency response which can mitigate the inevitable suffer that a mass causally event brings to the community.

Controversies: Scoring Systems in Critical Care

Michael Elias, MD and John M. Oropello, MD, FACP, FCCP, FCCM

INTRODUCTION

Management of the critically ill patient is complex. The acuity of illness, multiple organ system derangements, patient heterogeneities such as age, comorbidities, uncharted genomic and epigenetic variability, and the availability of evolving treatments and systems of health care delivery make the prediction of prognosis an elusive, moving target.

Originally created in response to limited ICU resources, an aging population and rising healthcare costs, scoring systems¹⁻³ (also called scoring models) are intended to provide objective predictions or probabilities of mortality and long-term outcome to aid clinical decision making and planning. Their role has been expanded to benchmark or compare the performance of ICUs and assess the quality of care provided (eg, observed mortality vs predicted mortality), to predict the resources needed or the appropriateness of ICU admission depending on the severity of illness and finally to assess patients for inclusion in research studies or to compare severity of illness and assess case-mix dissimilarities between patients in various study groups.

Although intensivists will increasingly encounter assessments of their ICU patient population, ICU structure and process and physician performance via scoring systems, the application of scoring systems is not without significant controversy. This chapter discusses the main ICU scoring systems in use today,⁴⁻⁷ how their performance is assessed, how they are utilized, the limitations and the controversial issues surrounding their use.

ICU SCORING SYSTEMS

The type, timing, and quantity of data collected vary significantly among the numerous scoring systems. Some scores, such as the sequential organ failure

assessment, measure the organ dysfunction and thus the severity of the disease at any point of time to monitor the clinical evolution. Others, known as general risk prediction scores focus primarily on survival. These systems were developed on the assumption that the severity of illness and mortality are related to acute physiologic derangements that appear early in the course of the disease.⁸ The most prevalent are acute physiology score chronic health evaluation (APACHE), mortality probability model (MPM), and simplified acute physiology score (SAPS). They were developed approximately 30 years ago and have since undergone 3 to 4 revisions ([Table 63-1](#)). APACHE IV combines a total of 27 variables collected within the first 24 hours of ICU admission, MPM₀ III and SAPS III combines, respectively, 16 and 20 variables collected within 1 hour of ICU admission. They all depend on acute physiologic variables collected on admission such as vital signs, electrolytes, cell count, blood gas, etc, in addition to chronic health variables and admission diagnosis.

Scoring systems provide a numerical estimation (score) to quantify the severity of illness, which is correlated to mortality, length of stay (LOS), morbidity, and long-term functional outcome (ie, quality of life). Prognostic models are constructed using prospective cohorts of patients with predefined candidate variables, outcomes and time points. Candidate variables are preselected variables, such as any patient characteristics, lab values or risk factors that are thought to play a role in the prediction of the model. A statistical analysis method, called logistic regression, will then identify and weight the variables that can predict the outcome. Although the original versions of the APACHE and SAPS scoring systems used expert opinions to determine the predictive variables, more recent versions use multiple logistic regression techniques (logistic and Cox regression) to also select and weight the variables.

TABLE 63–1 General risk prediction scoring systems and revisions.

Scoring System (Year Introduced)	Number of Variables	Selection of Variables and Weights	Variables	Comments
Acute Physiology Chronic Health Evaluation (APACHE)				
APACHE I (1981)	34	Panel of expert clinicians	Worst acute physiology variables within the first 32 hours + preadmission chronic health status 3-6 months prior to admission.	The first iteration of the APACHE system. No longer in use.
APACHE II (1985)	12	Panel of expert clinicians	Worst acute physiology variables within the first 24 hours (APS score) + preadmission chronic health status 3-6 months prior to admission	Used for a group of patients, in public domain, limited number of variables, most frequently used system for risk stratification in clinical trials
APACHE III (1991)	17	Multiple logistic regression	See above	Not in public domain, proprietary, available at cost
APACHE IV (2006)	27	Multiple logistic regression (110,518 patients in 104 US ICUs)	Data collected within the first 24 hours Acute physiology variables, age, chronic health variables, ICU admission diagnosis, ICU admission source, length of stay prior to ICU admission, emergency surgery, thrombolytic therapy, FiO ₂ , mechanical ventilation.	Most accurate for hospital mortality and ICU length of stay, requires considerable data and training. Specific algorithm for mortality prediction after Coronary Artery Bypass Graft (CABG) surgery. Calculator of raw score: in public domain. Real time validation, updated probabilities: proprietary
Mortality Probability Model (MPM)				
MPM I (1985)	11	Multiple logistic regression	First hour and 24 hours of admission	Probability of death
MPM II (1993)	15	Multiple logistic regression	First 24, 48, and 72 hours of admission	Probability of death
MPM ₀ III (2007)	16	Multiple logistic regression (124,885 patients in 135 ICUs—mainly US)	Worst values prior to and within 1 hour of ICU admission: Acute physiologic variables, age, chronic health variables, acute diagnoses, admission type (medical, surgical), emergency surgery, CPR within 1 hour of ICU admission, mechanical ventilation, code status	Predicts hospital mortality and ICU length of stay. Least amount of data collection, does not require a diagnosis at ICU admission, collected at lower cost and least time compared to APACHE IV and SAPS III. Predicts ICU LOS
Simplified Acute Physiology Score (SAPS)				
SAPS I (1984)	15	Panel of expert clinicians	Worst values within the first 24 hours	Simple to use, for stratification, not for mortality prediction
SAPS II (1993)	17	Multiple logistic regression	Worst values within the first 24 hours	Simple to use, most widely used in Europe
SAPS III (2005)	20	19,577 patients in 307 ICUs from 35 countries; multiple logistic regression	Worst values prior to and within 1 hour of ICU admission: Acute physiologic variables, age, chronic health variables, ICU admission diagnosis, ICU admission source, length of stay prior to ICU admission, emergency surgery, infection on admission, type of surgery	Simple to use (easy and quick), no cost, wide range of diagnosis represented, worldwide population represented

SCORING SYSTEM PERFORMANCE ASSESSMENT

The performance or ability to predict the outcome, is assessed by comparing the model predictions of mortality risk to the actual mortality in the studied patient populations across different ICUs. The measures used to evaluate outcome prediction include discrimination and calibration. Discrimination is the capability to distinguish between patients who will develop the event of interest (eg, death) versus those who will not (eg, survival).⁹ Discrimination is represented by the area under the receiver operating characteristic curve (AUROC) (Figure 63–1), where the true positive rate is plotted against the false positive rate. The greater the area under the curve, the more accurate the system is able to discriminate between a given outcome, for example, alive or dead. Calibration depicts how the model performs over a wide range of predicted mortality; it estimates the scoring system's accuracy in mortality prediction over a wide spectrum of severity of illness, usually in

FIGURE 63–1 Discrimination is the ability to distinguish between patients who will and will not develop the event of interest, in this case death. The AUROC represents the accuracy of a scoring system. The true positive rate represents the patients predicted correctly to die. The false positive rate represents the patients predicted to die but survive. AUROC (Area Under the Receiver Operating Characteristic Curve) Sensitivity = true positive rate; 100-Specificity = false positive rate. (Reproduced with permission from Strand K, Flaatten H: Severity scoring in the ICU: a review. *Acta Anaesthesiol Scand*. 2008 Apr;52(4):467-478.)

FIGURE 63–2 Legend: Calibration compares the expected and observed death at different deciles of mortality risk. (Reproduced with permission from Strand K, Flaatten H: Severity scoring in the ICU: a review. *Acta Anaesthesiol Scand*. 2008 Apr;52(4):467-478.)

deciles from low to high (Figure 63–2).⁹ For example, scoring systems tend to underestimate mortality in patients with a high severity of illness and underestimate mortality in patients with a low severity of illness.

The predictive performance of models must be validated.¹⁰ Internal validation refers to the analysis of the performance of the model in the ICU dataset population from which the model is derived; this is the population in which it will perform the best because the variables were adjusted to optimize the model. This is followed by a process called external validation in which the performance of the model is assessed in patients from ICUs that were not part of the original dataset used to develop the model. The ICUs used for external validation should be of the same type (eg, general ICU vs general ICU not general ICU vs specialty ICU [eg, cardiac]) as those used in the internal validation.

UTILIZATION OF SCORING SYSTEMS

Although they were introduced more than 30 years ago, scoring systems have been used in only 10% to 15% of the total yearly ICU admissions in the United

States.¹¹ The lack of clinical utility at the bedside can be explained by the lack of predictive applicability in the individual patient, the limited practical utility of the models (too complex or cumbersome to implement) and the costs. To be used in clinical practice, the model should be simple, readily available and not expensive. The least expensive and simplest scoring systems to implement have been the most prevalent. For example, the APACHE II system—no cost, in the public domain—is today the most used system to assess patients for inclusion in research studies based on severity of illness or to compare severity of illness between control and treatment groups and assess case mix dissimilarities between patients in various study groups. APACHE II is also used in many ICUs to assess predicted mortality compared to observed mortality, thus as a quality measure of ICU performance to national norms. However, the APACHE II system was created and validated 30 years ago. Ultimately, prognostic scoring systems become obsolete over time if they are not updated to follow the advancement of medical sciences. Due to improvements in medical care and in population health, the mortality predictions of older systems tend to overestimate the current mortality rate. This trend is obvious in inexpensive systems which are almost guaranteed to provide a good result—most ICUs, using APACHE II, will have a lower than predicted mortality and thus favorable benchmarking.

It is important to understand the different components of APACHE IV, which is the paradigm of a more modern system that allows predictions of both hospital mortality and expected ICU LOS. APACHE IV is characterized by an internal validation on a very large database with selected variables determined by multiple logistic regression—a more rigorous statistical method than arbitrary expert opinions. There are 2 versions, 1 in the public domain that is essentially a web-based calculator; 1 enters the patient variables and quickly generates a score that correlates to a predicted mortality. The other version is managed by a company, Cerner (Vienna, VA), which maintains the database and analyzes the APACHE IV data across different hospitals, providing updated and repeated analysis over time with better resolution and potential value. Because the accuracy of the prediction is highly dependent upon the quality

of data collected, this elaborate system is associated with significant costs to avoid any deviation from the precise data-collection methodology that may result in errors in predictions. The cumbersome computer-based data entry requires considerable training, and often, a full time specialist dedicated to collect data on site. Because of the cost, the online “calculator” version of APACHE IV is more commonly used.

Once a scoring system is found to be accurate, one must assess if the prediction obtained has any influence on the management; it becomes beneficial to use in clinical practice if an impact study demonstrates decisional power.^{12,13} To date, the impact of APACHE IV (or any other general ICU scoring system for that matter) on patient outcome, on clinical decision-making or cost has not been addressed in any prospective study or a randomized controlled trial.

LIMITATIONS OF SCORING SYSTEMS

Despite the existence of many prognostic models and their attractive potential utility, scoring systems have a limited clinical value at the bedside and are seldom used in clinical practice. There are a number of reasons for this.

Prognostic models should closely follow the advancement of medical sciences and be updated in a timely fashion to avoid becoming obsolete. There may be limitations of the predictive ability after modification of a variable. As diagnosis and treatment evolve scoring systems require repeated recalibration and validation, although this is difficult and time consuming to achieve. Also the lack of collaboration between researchers that might improve upon a single model leads to the multiplication of redundant, often competing and nonvalidated models.^{10,13-15}

Most of the available information on scoring systems is based on internal validation, less studies report external validation and almost none report the impact on clinical decision-making and outcome.¹⁶ After the external validation process is completed, the impact of the scoring system on clinical decision-making, patient outcome, or costs should be assessed in a management study or randomized controlled trial^{12,13} before being used in clinical practice.

Scoring systems designed for general medical or surgical ICUs would be inappropriate if used in specialized units such as coronary, burn or pediatric where patients differ from the populations of the original and external validation samples from which the system was derived. Clinical judgment remains fundamental because not all relevant variables are included in the models.

The outcome and the time points might be different than those for which the scoring system was designed. For example, changes in hospital practices resulting in earlier discharge of patients to long-term acute care facilities thus reducing the hospital mortality or calculating scores outside of the intended and validated ranges, for example, daily versus within the first hour or first 24 hours.

To be used in clinical practice, the user should understand the existing models, be convinced of their utility and trained in their application. The barriers for the effective use of scoring systems may be related to the limited practical utility of the models. Some models such as APACHE IV are complex and require dedicated personnel and a specific training; they can be expensive to use, therefore, limiting their spread across the health-care community.

The more data required by the scoring system, both in amount and complexity, the greater the opportunity for errors and missing data. In theory, different users with similar backgrounds in critical care should obtain similar scores for the same patient population, however, low interobserver reliability resulting in dissimilar scoring values by different users can occur.

Scoring systems provide only probabilities, not certainties. It would be inappropriate to deny or withdraw care based solely on a probability derived from any existing scoring system. The course of illness over time is important. Clinical variables may not be included in these models and clinical judgment and ethical principles need to be employed when making decisions regarding prognosis in an individual patient. For example, the physiologic response of sepsis which is linked to unknown genomic factors is not taken into account in any scoring system. Human physiology is complex and clinical assessment prevails over scoring system predictions.

Benchmarking Intensive Care Units Based on Scoring Systems

The ranking of intensive care units and institutions based on severity of illness versus mortality rate is controversial. Different populations of patients in different ICUs are not always comparable even when their severity of illness scores is identical. For example, a hospital with the same mean prognostic score but a higher mortality does not necessarily underperform when compared to another hospital as there may be other elements that are not represented in the dataset captured by these systems. For instance, as the lack of health insurance is associated with increased 30-day mortality and decreased use of common procedures for the critically ill, the insurance status may be an indicator of mortality not picked up by patient and clinical characteristic variables.¹⁷ In elective surgical admissions, there is an association between the socioeconomic status and hospital mortality that is not explained by case mix or the withdrawal of active treatment.¹⁸ Finally, among trauma patients, the uninsured receive less trauma-related care and have a higher mortality rate.¹⁹ These examples illustrate the fact that 2 different populations of patients can have similar severity of illness scores with very different mortality rates.

CONCLUSION

Although scoring systems are numerous and potentially useful, they are not commonly used in clinical practice in part because many flaws exist in their development, validation, and maintenance. The obstacles to the implementation of scoring systems are significant. However, the strategies to overcome many of these barriers are becoming available as clinical information systems become electronic and more sophisticated. In the future, systems may be able to parse notes in the medical record to form alerts in real time and the costs and errors involved with specialized and redundant data entry may be avoided.

Controversies: Patient-Controlled Sedation— Ready for Prime Time?

Annie Lynn Penaco, MD and Jay Berger, MD, PhD

KEY POINTS

- 1 Depth of sedation exists as a continuum from minimal sedation where the patient is able to interact during the sedation to deep sedation which is just short of general anesthesia.
- 2 Patient-controlled sedation is an extension of patient-controlled analgesia, where the patient is able to control the depth of sedation that is comfortable for them during an invasive procedure.
- 3 Primary focus on the use of patient-controlled sedation is in the setting of ambulatory procedures that are typically performed under local or regional anesthesia.
- 4 The highly titratable nature of sedation requires the use of medications that are highly potent with rapid onsets of action.
- 5 The use of target-controlled infusion allows for more stable plasma concentrations of the sedative medication during the procedure.
- 6 Patient-maintained sedation utilizing target-controlled infusions produces more stable plasma concentrations; however, the time to reach adequate sedation is relatively slower as compared to patient-controlled sedation.
- 7 Most common adverse event encountered during sedation is respiratory depression, manifested as hypoxemia and decreased respiratory rate.

SEDATION

Sedation is an induced altered state of consciousness following the administration of a sedative agent. According to the American Society of Anesthesiologists, depth of sedation exists as a continuum¹ ranging from minimal sedation to deep sedation, just prior to achieving general anesthesia (Table 64–1). With minimal sedation, patients are in a state of anxiolysis and may have impaired cognitive function, but retain

protective airway reflexes and the ability to respond normally to verbal commands. Moderate sedation, previously referred to as conscious sedation, refers to a state of depressed consciousness with a purposeful response to verbal commands and light tactile stimulation, such as glabellar tap. In a state of deep sedation, patients are not easily arousable but are able to purposefully respond to repeated or painful stimuli. In cases where the level of sedation becomes deeper

TABLE 64–1 Continuum of depth of sedation.

	Minimal Sedation	Moderate Sedation	Deep Sedation	General Anesthesia
Responsiveness	Normal response to verbal stimulation	Purposeful response to verbal and tactile stimulation	Purposeful response following repeated or painful stimulation	Unarousable to painful stimulation
Spontaneous Ventilation and Airway	Unaffected	Adequate, no intervention required	May be inadequate, may require intervention	Frequently inadequate, intervention required
Cardiovascular Function	Unaffected	Usually maintained	Usually maintained	May be impaired

Reproduced with permission from American Society of Anesthesiologist (ASA): Continuum of depth of sedation: Definition of general anesthesia and levels of sedation/analgesia. ASA House of Delegates, October 30, 1991.

than initially intended, interventions in airway management or hemodynamic support may become necessary. Other similar measures of sedation such as the Observer Assessment of Alertness and Sedation Scale² are also commonly used (Table 64–2).

BACKGROUND

Historically, sedation has been widely administered in a clinician-controlled manner as a means of facilitating invasive interventions or making intolerable procedures appropriately acceptable. However, patients often have varying expectations and degrees of anxiety and discomfort as well as different sensitivities to sedative agents. This causes sedation requirements to vary widely, making it clinically challenging to predict and achieve the optimum level of sedation for each individual patient. Clinicians must rely on subjective determinants of adequate sedation with the constant concern for enhancing safety and preventing adverse

events. The technique of patient-controlled sedation (PCS) may circumvent these challenges by offering patients the ability to control and titrate their desired levels of sedation.

PATIENT-CONTROLLED ANALGESIA VERSUS PATIENT-CONTROLLED SEDATION

Patient-controlled drug administration is a well-established concept. The more commonly encountered, patient-controlled analgesia (PCA), has been effectively and safely utilized for several decades as a means of providing pain relief especially in the acute postoperative setting. PCA consists of a delivery system with which patients are able to self-administer predetermined doses of analgesic medications as required for pain management. With advances in PCA pump technology, this technique operates safely with the ability to program parameters with respect to bolus dosages and lockout intervals. A similar technique and logical extension of the PCA concept using related technology is PCS.

Initial reports of PCS began independently with investigations by Rudkin et al³ and Park and Watkins⁴ in 1991. Rudkin et al reported a high level of patient satisfaction with PCS using self-administration of propofol during dental extraction surgery under local anesthesia. Meanwhile, Park, and Watkins studied the use of PCS using a combination of midazolam and fentanyl during surgical procedures under epidural anesthesia and compared this to anesthesiologist-administered sedation using the same drugs. The results of the study indicated

TABLE 64–2 Observer assessment of alertness and sedation scale.

Rating	Sedation Level
5	Responds readily to name
4	Lethargic, responds to name
3	Responds if name called loudly
2	Responds after mild shaking
1	Only responds to noxious stimulus
0	Does not respond to noxious stimulus

that PCS is not only a safe and effective technique, but it also leads to higher levels of patient comfort and satisfaction. Subsequent investigations under various clinical conditions have led to similar results using different combinations of medications.⁵

Although seemingly identical in design, PCA and PCS have fundamental differences that limit the similarities in clinical application and associated adverse events. PCA primarily acts on postoperative pain, which tends to be uniform and predictable for each individual. PCA typically utilizes medications with slower onsets of action but with prolonged duration, such as morphine. In this way, PCA is designed to operate safely in the absence of continuous monitoring from an anesthetic-care provider. In contrast, PCS especially in the intraoperative setting requires the flexibility to respond rapidly to constantly changing levels of stimulation. PCS typically utilizes easily titratable medications that have rapid onsets of action that are conducive to the rapidly changing environment in which it is required. Although PCS has been often shown to be generally as safe as conventional anesthetist-administered sedation, experience with PCS in the absence of an anesthetic-care provider has generally not been supported due to the potential for adverse events that are uncommonly seen with PCA.⁵ For instance, adverse events such as respiratory depression and excessively deep levels of sedation have been reported to occur in association with PCS, similar to anesthetist-administered sedation.⁶ Due to inherent differences, PCA and PCS must differ in the delicate balance between efficacy and safety. Ultimately, with regard to patient safety, as the requirement for effective sedation increases, patient monitoring must also become more intense so that complications can be easily detected and managed expeditiously.

CLINICAL APPLICATIONS

Interest in the use of PCS has generally been focused on a variety of ambulatory procedures which are performed under local or regional anesthesia. Common surgical applications include ambulatory surgery procedures of short duration, dental procedures, ophthalmic surgery, gynecologic or lower abdominal surgery, neurologic surgery, and orthopedic surgery.⁵ PCS is also beneficial for nonoperative procedures associated with discomfort such as endoscopy, colonoscopy, and lithotripsy. Furthermore, PCS may be utilized for perioperative anxiolysis in select patients.

PHARMACOLOGIC AGENTS

PCS typically requires highly potent medications with rapid onsets of action in order to provide effective and reliable sedation in the rapidly changing environment associated with the operating room or procedure room. Several medications such as propofol, benzodiazepines, and opioids have been extensively studied either alone or in various combinations. Each of the agents has been found to be equally safe and effective,⁷ but present with varying advantages and disadvantages ([Table 64–3](#)).

Propofol (Diprivan)

Propofol has the ideal pharmacokinetic properties for PCS as it has rapid onset, short time to peak effect as well as a short context sensitive half-life that makes it easily titratable. However, its main disadvantage is the high incidence of pain on injection that may make intravenous injection uncomfortable.⁵ Propofol in high doses is also associated with apnea and cardiovascular depression. Propofol is often

TABLE 64–3 Commonly used pharmacologic agents for PCS.

	Mechanism of Action	Onset (min)	Duration (min)	Disadvantages
Propofol	Potential of GABA receptor activity	< 1	3-10	Causes pain on injection
Benzodiazepines	Enhances GABA receptor function	1-2	30-60	May cause memory impairment
Opioids	Various effects on opioid receptors	1-2	30-60	May cause arterial oxygen desaturation

used successfully as a sole sedative agent but may be supplemented with other agents.

Benzodiazepines

Benzodiazepines, particularly midazolam, are effective sedative agents with the additional effects of amnesia and anxiolysis. However, midazolam has the disadvantage of relatively prolonged recovery.⁸ It appears to be associated with the greatest degree of memory impairment, intraoperatively and postoperatively.

Opioids

Opioids, such as fentanyl, alfentanil, and remifentanyl, are also commonly used as adjunctive agents in PCS. Opioids are suggested to be useful in treating the discomfort and restlessness from prolonged immobilization⁷ during longer procedures, or generally those lasting greater than 2 to 3 hours. The main disadvantages of opioids are transient intraoperative pulse oximetric desaturations and the potential for respiratory depression, especially when given in combination with benzodiazepines. It is also associated with a high incidence of postoperative nausea and vomiting.

PATIENT-CONTROLLED SEDATION

In PCS, patients are clearly instructed preoperatively on the proper use of the infusion device as well as the purpose of sedation. Sedation is carried out via an infusion pump with a reservoir, which is connected to a handheld button that only the patient can control. When the button is pressed, the pump delivers a bolus of a predetermined dosage of medication. A lockout period, or a time interval in which another dose cannot be administered, may or may not be programmed. When present, it appears to offer a safety mechanism by preventing excessive drug administration and subsequent oversedation and loss of consciousness.⁷ The patients are instructed to press the button until they reach the desired level of sedation to allow them to be able to tolerate the procedure. In this way, the patients themselves can control and determine the end point of sedation.

In a prospective, randomized, controlled study, Mazanikov et al compared PCS using propofol and remifentanyl with anesthesiologist-controlled

patient sedation using propofol for ERCP procedures.⁹ Between the 2 groups, patient and endoscopist satisfaction were comparable. However, the study found markedly less propofol consumption and faster recovery in the PCS group. Similar results were obtained in a study conducted by Girdler et al on dental patients, with the PCS group requiring a lighter level of sedation compared to a clinician-controlled group.¹⁰ This suggests that anesthesiologist-controlled sedation may result in unnecessary deep sedation while PCS is well-accepted because patients appreciate the ability to maintain control of their sedation.

Target-Controlled Sedation

Due to the short duration of action of sedative agents, particularly propofol, a potential drawback of self-administration in bolus increments is the volatility of plasma concentrations and subsequent varying levels of sedation. Target-controlled infusion (TCI) overcomes this problem of varying blood concentrations. This method of administration utilizes a computer-controlled infusion system that can calculate and maintain target blood concentrations of propofol with great accuracy. TCI uses a pharmacokinetic model to predict the initial bolus dose and infusion rates necessary to achieve and maintain a given target concentration, avoiding peaks and troughs in plasma concentration. The target concentration can then be adjusted accordingly by the patient to achieve the optimal level of sedation.

In a study by Irwin et al, the benefits of TCI were used in combination with patient-controlled feedback¹¹ in a technique referred to as patient-maintained sedation (PMS). Based on each patient's age and weight, a TCI system calculated the dose necessary to achieve and maintain a selected target concentration of propofol. In this case, an initial target concentration of 1 mcg/mL was chosen. The patient also had control of a handset that when pressed, increased the target concentration by 0.2 mcg/mL increments with a lockout interval of 2 minutes. When no demand boluses were required for several minutes, the system gradually decreased until a baseline target concentration of 0.2 mcg/mL was reached. Although there was wide variability amongst individuals in total consumption of propofol, optimal sedation was found to be achieved

at median target concentrations of 0.8 to 0.9 mcg/mL. Following cessation of the infusion at the end of the procedure, recovery was rapid and no delays were reported in meeting discharge criteria from the recovery room. Patients expressed overall satisfaction with the technique and reported interest in using the technique again in the future.

Rodrigo et al performed a randomized study comparing outcomes between PCS and PMS using a TCI of propofol.¹² The study found no significant differences in depth of sedation, operating conditions and patient satisfaction. However, a majority of patients preferred PMS likely because it produces more stable blood concentrations and possibly less oversedation. The main disadvantage of PMS is relatively slower onset in achieving adequate sedation. The time required for adequate sedation was 8.6 minutes in the PMS group, compared to 5.7 minutes in the PCS group.

EFFECT-SITE-CONTROLLED SEDATION

When variable rate infusions of propofol target the plasma concentration, the clinical effect lags behind the plasma concentration, reflecting the fact that the

site of action of propofol is the brain rather than the plasma. Because of the inability to measure the concentration of propofol in the brain, or the effect site, it is assumed that the clinical effect of propofol reaches a plateau when the plasma and brain concentrations have equilibrated. This mathematically derived term, the effect-site concentration, therefore, corresponds to the clinical effect of propofol. In an alternative PMS system, where the effect-site compartment is targeted, sedation may be achieved rapidly and safely.

To assess both the efficacy and safety of effect-site-targeted PMS, Anderson et al recruited 20 healthy volunteers and gave them the task of attempting to oversedate themselves using this system.¹³ The initial target effect-site concentration was set at 1 mcg/mL. The system was able to overshoot, or increase the target plasma concentration up to 100% over the target effect-site concentration. The predicted plasma concentration was reduced as the target effect-site was approached (Figure 64-1). When the plasma concentration decreased to within 10% of the target effect-site concentration, the patient's demand button was activated. Pressing the button led to an increase in the target effect-site concentration by increments of 0.2 mcg/mL. Although there was no traditional lockout time, further increases

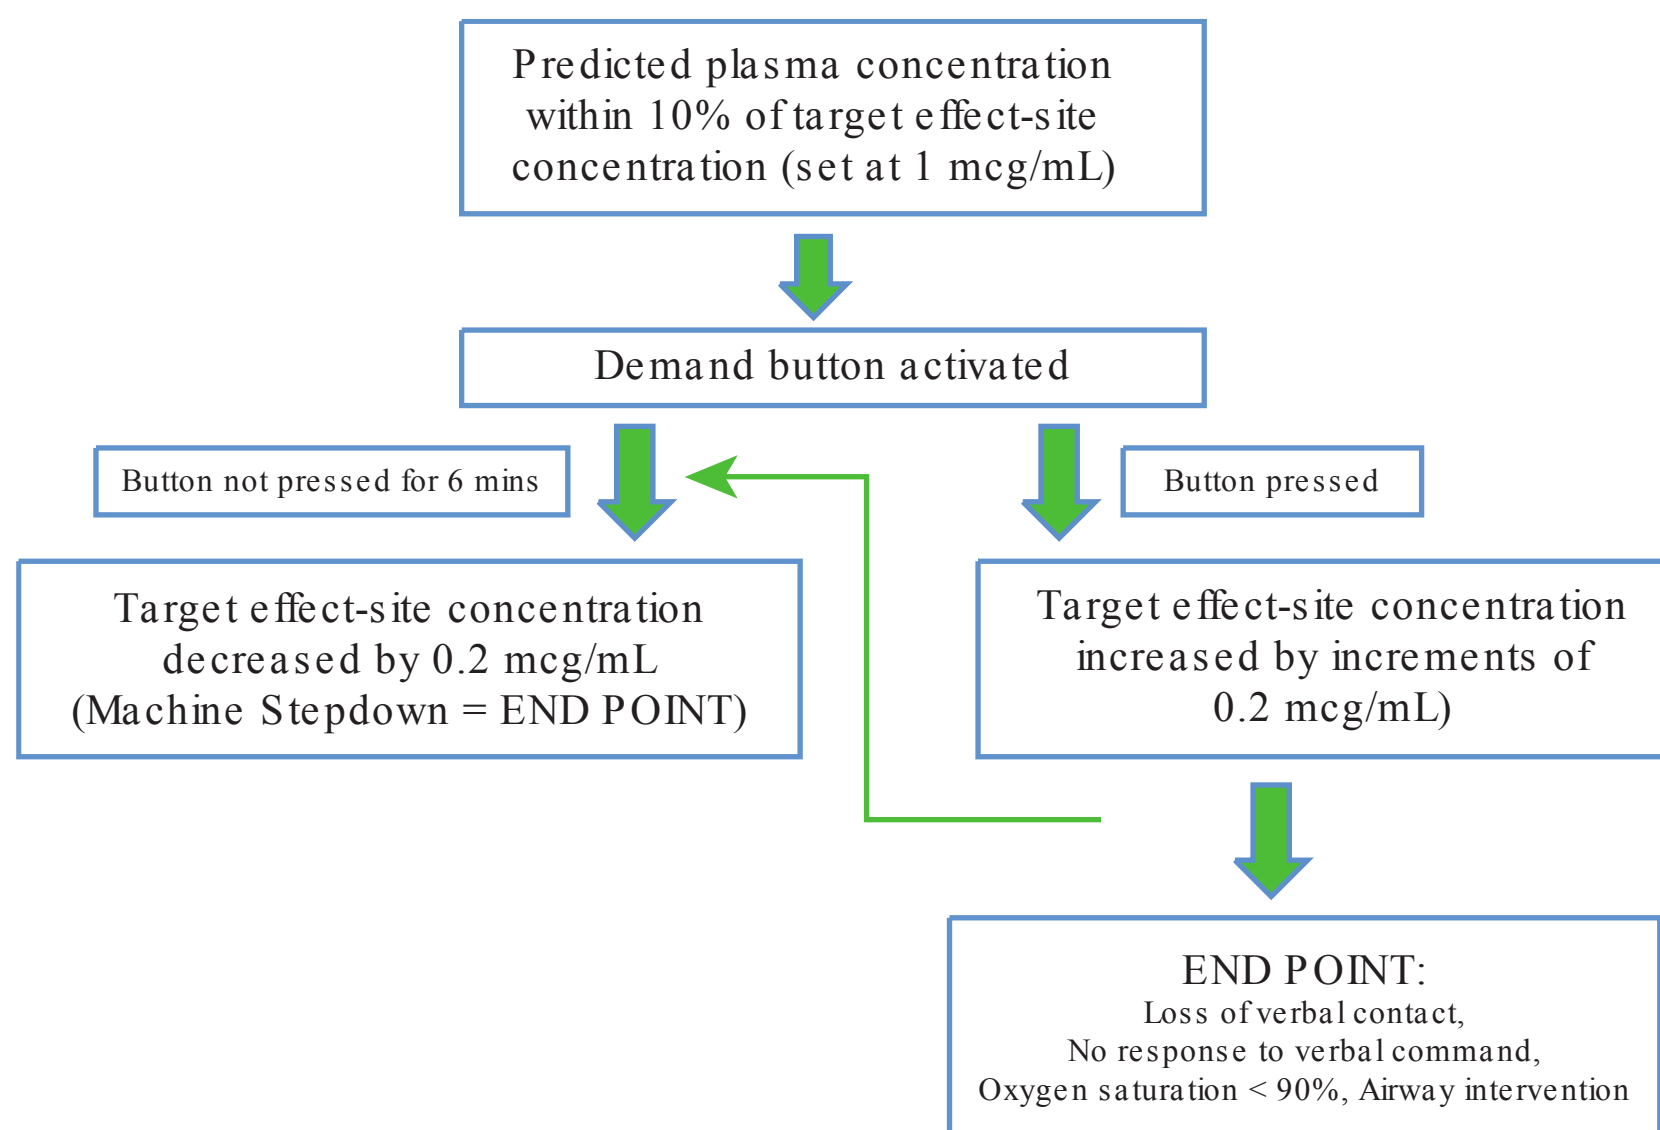

FIGURE 64-1 Effect-site controlled patient-maintained sedation with propofol, study design.¹³ To assess PCS safety, study volunteers were instructed to attempt to oversedate themselves using a demand button.

in effect-site concentration could not be requested until plasma concentration fell to within 10% of the target effect-site concentration. The system was programmed with a means of machine stepdown, in which lack of a successful press of the control button after 6 minutes led to a 0.2 mcg/mL reduction in effect-site concentration. Under continuous monitoring, volunteers were instructed to try to make themselves unconscious. End-points of the study included loss of verbal contact, no response to verbal command, machine stepdown, oxygen saturation less than 90% or the requirement for airway intervention. Of the 20 subjects enrolled in the study, 15 terminated the study through machine stepdown, 4 developed oxygen saturation less than 90%, and 1 lost verbal contact. Although the system appeared to function successfully in achieving sedation, when the safety of the system was stressed in the artificial conditions of the study, a significant number reached potentially unsafe end-points. This suggests that anesthetic supervision may be required for safe administration.

Stonell et al studied the use of effect-site PMS with propofol compared to anesthetist-administered sedation with propofol boluses in patients undergoing colonoscopy.¹⁴ Patients in the effect-site PMS group underwent sedation more slowly (13 minutes vs 3 minutes) and less deeply as determined with BIS monitoring. The more rapid induction of sedation in the anesthetist-administered sedation group resulted in a higher incidence of hypotension and oversedation, but overall did not lead to negative outcomes. Between the 2 groups, patient and endoscopist satisfaction was similar. All patients also had similar recall of events. These results suggested that although effect-site-steered PMS may be comparable to anesthetist-controlled sedation in quality, it lacks the efficiency in induction time.

POSSIBLE ADVERSE EVENTS

The most common issue encountered during PCS is respiratory depression, manifested by a decrease in arterial oxygen saturation and respiratory rate. Oxygen supplementation, routinely via nasal cannula, is the standard of care although it may not be necessary especially in young, healthy patients.

Propofol is a known cardiovascular depressant, which may precipitate hypotension especially in elderly patients who are already mildly dehydrated from NPO status.

The potential for respiratory depression and cardiovascular complications highlights the need for close monitoring during PCS. Resuscitation equipment should be made readily available in areas where PCS is practiced and practitioners should be certified in CPR and ACLS.

SPECIAL CONSIDERATIONS

Although PCS has been shown to be safe and effective, most randomized controlled trials have often involved relatively young patients. PCS investigations in elderly patients, while limited, have also resulted in similar outcomes. Herrick et al found that between elderly patients with no intraoperative sedation and those receiving PCS for cataract surgery, satisfaction was higher in the PCS group, whether or not the device was actually used.¹⁵ Many of the patients felt comfortable enough not to need sedation but appreciated the availability of intraoperative sedation, should they desire it. In a prospective, randomized, controlled trial, Lee et al compared conventional clinician-controlled sedation with PCS in elderly patients undergoing outpatient colonoscopy.¹⁶ PCS appeared to be safer with comparable effectiveness and acceptance. PCS must be used cautiously in elderly people, however, as the effect of bolus doses may not be as predictable. Therefore, smaller dosages with longer lockout periods are recommended.

Another application of PCS which may warrant further investigation is the self-administration of sedative medications in critically ill, mechanically ventilated ICU patients. In an investigation by Chlan et al, dexmedetomidine was administered via a basal infusion as well as with patient-triggered boluses.¹⁷ PCS was rated favorably for its ability to safely and adequately relieve anxiety and attain a satisfactory level of comfort.

CLINICAL PRACTICE

PCS has been widely investigated for several years but has yet to achieve widespread clinical application. Reasons for hesitancy in use may involve

various factors.⁵ Conceptually, the technique of PCS contradicts the traditional tenet of monitored-anesthesia care where an anesthetist proactively administers sedation based on the anticipation for intraoperative events. Also, although many investigators have reported superior outcomes with PCS, others report no difference. With this lack of consistency or definitive benefit, there is a lack of incentive to change current practice and invest in new equipment. Furthermore, not all patients desire control. As patient satisfaction may be associated with degree of control, this may not provide a benefit for all patients.

CONCLUSION

PCS is a technique which allows patients to control and titrate their own level of sedation based on anxiety or perceived discomfort from noxious stimulation during a procedure. Ample evidence has suggested the safety and efficacy of PCS when compared with conventional anesthetist-administered sedation. PCS is also associated with high levels of patient satisfaction which may be related to an increased feeling of control in being able to self-administer sedation as it is required in the rapidly changing environment of the operating room or procedure room. More technologically advanced, alternative techniques of PMS, such as target-controlled sedation or effect-site-controlled sedation, have the added benefit of being able to provide a stable level of sedation uncomplicated by variability of plasma concentration. Despite these perceived advantages, however, PCS has not gained wide acceptance in clinical practice due to a lack of consistent and definitive evidence of superior outcomes compared to the currently utilized sedation techniques. It merits further interest and evaluation because it empowers patients to participate in their own care and challenges anesthetic-care providers to reevaluate sedation practices.

Controversies: Ventilator Weaning—Which Strategy is Better? RT-RN Versus Physician Driven

Ilde Manuel Lee, MD and Louis P. Voigt, MD

INTRODUCTION

The advent of invasive mechanical ventilation (IMV) has been one of the greatest achievements in the field of respiratory and critical care medicine. In the United States alone, there were 790,257 hospitalizations involving IMV in 2005, and that number is expected to steadily increase, outpacing population growth by 2026.^{1,2} Although advances in medical technology have facilitated the management of patients who require ventilatory support, mechanical ventilation remains associated with risks and complications.³ Thus, once clinical improvement occurs, significant emphasis is placed on rapidly weaning the patient from IMV. Over the past 25 years, numerous trials have evaluated the most effective approach to liberate patients from IMV, including the use of protocol-based weaning (PBW). Compared to physician-directed weaning, protocolized strategies driven by nurses and/or respiratory therapists (RTs) have gained general acceptance in many intensive care units (ICUs) because of reduction in morbidity, mortality, and health-care costs ([Table 65–1](#)).^{4–6}

PAST AND PRESENT WEANING APPROACHES

Prior to the adoption of protocols, conventional weaning was at the sole discretion of the ICU physician(s) overseeing the patient's care.⁷ Conventional weaning (ie, no protocol) was highly based on clinical experiences and institutional practices. Thus, the weaning of a particular patient varied

considerably among physicians and across institutions. This broad range of traditions and practice patterns underscored an imperfect process of IMV termination. Data from the mid-to-late 1990s highlighted that clinical judgment alone was not always accurate in predicting successful extubation and that physicians were more likely to keep patients on IMV for longer periods than necessary.^{6,8,9}

The availability of registered nurses (RNs), RTs, and ancillary staff at the bedside in the ICU coupled with their intimate knowledge of patient's characteristics offered an alternative pathway to liberation from IMV. Subsequent efforts focused on developing conventional, structured, reproducible, and safe methods of liberating patients from IMV, not only to improve patient outcomes but also to decrease existing variations in practice among healthcare providers. Protocol-driven weaning was thus born.⁴

WEANING AND COMPONENTS OF A PROTOCOL

Liberation from IMV is a process composed of several steps including readiness testing (or screening), weaning (itself), and extubation.

Readiness testing (or daily screening)—The process uses several criteria to determine if a patient is ready to begin weaning or to undergo a so-called spontaneous breathing trial (SBT). The most frequent criteria include: (1) reversal of the condition(s) that prompted IMV; (2) acceptable PaO₂/FiO₂ ratio; (3) relatively low positive end-expiratory pressure (PEEP);

TABLE 65–1 Benefits of protocolized weaning.

Summary of Benefits of Protocolized Weaning	
Decreased duration of weaning	Reduced costs
Decreased duration of mechanical ventilation	Decreased barotrauma/volutrauma
Decreased ICU LOS	Decreased incidence of VILI
Decreased hospital length of stay	Decreased rates of tracheostomy
Decreased incidence of VAP	Reduced incidence of diaphragmatic dysfunction
Decreased extubation failure rates	Reduced incidence of CIPN/CIPM
Decreased mortality	Reduced incidence of delirium

ICU = intensive care unit; LOS = length of stay; VAP = ventilator-associated pneumonia; VILI = ventilator-induced lung injury; CIPN = critical illness polyneuropathy; CIPM = critical illness polymyopathy.^{3,4,6,11,18,27,37}

(4) ability of the patient to initiate spontaneous breaths; and (5) stable hemodynamic parameters (Table 65–2).^{7,9-11}

Weaning—It is the practice of either a gradual or total reduction in ventilator support during a SBT, thereby allowing patients to incrementally participate in the work of breathing.^{6,8} Weaning a patient from IMV may take up to 40% of the total duration on the ventilator.⁶ A SBT is often performed concurrently with daily interruption of sedation.¹² The most popular weaning models are T-piece and continuous positive airway pressure (CPAP) trials, and pressure support ventilation (PSV) either alone or in combination with synchronized intermittent mandatory ventilation (SIMV). These strategies are largely institution-dependent and currently there is no general consensus as to which particular weaning mode leads to faster extubation rates.^{6,8}

Extubation—It is the physical act of removing the artificial airway (ie, endotracheal tube) from the patient. Regardless of the weaning model

TABLE 65–2 Commonly used daily screen criteria.^{7,10,11}

Criteria for Screening	
(1) Reversal or improvement of clinical conditions that prompted IMV	Yes
(2) Ability to initiate spontaneous breaths	Yes
(3) PaO ₂ /FiO ₂ ratio	> 200
(4) Respiratory rate	≤ 30-35
(5) PEEP	≤ 5-8 cm H ₂ O
(6) Mental status	Awake, oriented
(7) Hemodynamic stability	HR ≤ 110/min and either of or on low-dose VP agents

PEEP = positive end-expiratory pressure; HR = heart rate; VP = vasopressor.

chosen, extubation is considered once the patient demonstrates the ability to breathe with little or no support from the ventilator and both airway patency and protection have been established. Liberation and discontinuation of mechanical ventilation are terms used interchangeably to describe the process of weaning and extubation.¹³

A weaning protocol is an algorithm applied to the components of the traditional weaning process highlighted above, with the purpose of consistently identifying and determining the most appropriate time for extubation.¹⁴ A successful protocol usually incorporates the 3 basic components mentioned (ie, daily screening, weaning and criteria for extubation) but 2-step models have also been proposed. A protocol is usually driven by a RN and/or a RT.

Finally, weaning is a fastidious process with sometimes unpredictable outcomes that are dependent on several variables. Patient-specific factors include underlying illness severity, functional status before ICU admission, and comorbid conditions. The application of evidence-based practice by healthcare providers (eg, low tidal volume ventilation strategy for acute respiratory distress syndrome, promotion of sleep hygiene, avoidance of delirium-generating medications and interventions,

and early ICU mobilization) has a definite impact on weaning. In reality, some patients are easily and promptly extubated while others linger on the ventilator for long periods of time. To improve standardization, patients who undergo weaning can be classified as simple, difficult and prolonged.¹⁵ The “simple weaning” group incorporates patients that are successfully liberated from IMV after 1 SBT. Patients in the “difficult weaning” group require up to 3 SBTs or up to 7 days on IMV (after failing the first SBT) prior to successful liberation. Those in the “prolonged weaning” group fail at least 3 SBTs and require more than 7 days of weaning before they can be successfully disconnected from the ventilator.^{15,16}

EVIDENCE SUPPORTING PROTOCOL-BASED WEANING

The evidence for PBW dates back to the early 1990s. One of the earliest trials was a computer-based protocol that was compared to conventional or physician-controlled weaning. The study reported fewer arterial blood gas samples, shorter weaning times, and less time spent outside acceptable respiratory rate and tidal volume parameters in the group assigned to the computer-based protocol.¹⁷ In 1996, Ely et al demonstrated that, compared to a physician’s judgment alone, a protocol executed by nurses and RTs was superior in decreasing the total duration of IMV, associated complications, and costs.⁴ Subsequent studies have shown substantial evidence in favor of nursing and/or RT-directed PBW to expedite liberation from IMV.

A 2011 Cochrane systematic review and meta-analysis of 11 randomized and quasi-randomized controlled trials (primarily RN/RT and computerized protocols) concluded that PBW resulted in a decrease in the duration of mechanical ventilation, weaning and ICU length of stay (LOS), without adverse outcomes.¹⁸ A retrospective study of patients mechanically ventilated for more than 24 hours (at an institution with PBW) corroborated a decrease in duration of IMV and a 12.7% reintubation rate, well within the standard of 5% to 15% proposed by the multisociety task force guidelines in 2001.^{9,19} Similarly, a multicenter prospective

cohort study by Teixeira et al concluded that incorporating a protocol in difficult-to-wean patients (ie, patients failing their first SBT) led to significantly higher extubation rates and improved mortality.²⁰ Extubation failure in the protocol group was 13.3% compared to 30.4% in the nonprotocol group.²⁰ Another prospective randomized controlled trial in a coronary care unit demonstrated significantly faster times to extubation and lower reintubation rates (16.7%), once protocol weaning was initiated.²¹

The majority of the early PBW trials were primarily RT/RN- or RT-driven. Recent evidence from solely RN-driven weaning has emerged ([Table 65–3](#)). Danckers et al showed that a protocol for liberation from IMV driven by ICU nurses decreased the duration of IMV and ICU LOS in patients mechanically ventilated for more than 24 hours without adverse effects and was well accepted by ICU physicians.²²

EVIDENCE AGAINST PROTOCOL-BASED WEANING

In 2001, a study looking at a neurosurgical population found no benefit to an RT-driven protocol (compared to physician judgment alone) in terms of duration of IMV, mortality, reintubation rates, and development of ventilator-associated pneumonia (VAP).²³ Similarly, another study looking at an RT-driven protocol (vs physician judgment) in a trauma ICU also concluded no difference in outcomes (ie, self-extubation rates, ventilator days, ICU LOS, and costs).²⁴ Krishnan et al studied the outcomes of 2 groups of patients who required mechanical ventilation for more than 24 hours: the experimental group underwent a weaning protocol driven by RTs and/or nursing staff; weaning in the control group was managed by various physicians at different levels of training who staffed a closed ICU.²⁵ Reported outcomes were successful extubation, duration of mechanical ventilation, hospital mortality, ICU-LOS, and rates of reintubation. The authors reported no difference in outcomes between the 2 groups. Finally, Rose et al found no reduction in duration of IMV in surgical and trauma ICUs that compared Smartcare automated weaning versus usual care.²⁶

TABLE 65–3 Summary of various studies on protocol-based weaning.

Author (Date)	Method	Protocol	Conclusions
Strickland (1993) ¹⁷	RCT	Computerized protocol vs physician judgment	Fewer ABGs, ↓ duration MV, less variation in RR and VT parameters
Ely (1996) ⁴	RCT	RN-RT driven protocol vs physician judgment	↓ duration MV, ↓ complications* ↓ cost
Kollef (1997) ⁵	RCT	RN-RT driven protocol vs physician judgment	Safe; ↓ duration MV
Horst (1998) ³⁷	Quasi-RCT	RT driven protocol vs physician judgment	↓ duration MV, ↓ cost
Marelich (2000) ³⁸	RCT	RN-RT driven protocol vs physician judgment and a standardized approach	Safe; ↓ duration MV
Namen (2001) ²³	RCT	RT driven protocol vs physician judgment	No difference in outcomes
Duane (2002) ²⁴	Retrospective review	RT driven protocol vs physician judgment	No difference in outcomes ^a
Simeone (2002) ³⁹	RCT	Protocol vs physician judgment	↓ duration MV
Dries (2003) ⁴⁰	Quasi-RCT	RN-RT driven protocol vs physician judgment	↓ duration MV, ↓ VAP, ↓ unplanned extubations
Krishnan (2004) ²⁵	RCT	RN-RT driven protocol vs physician judgment	No difference in outcomes
Tonnelier (2005) ⁴¹	Prospective vs retrospective cohort	RN driven protocol vs physician judgment	↓ duration MV
Navalesi (2008) ⁴²	RCT	RN-RT driven protocol vs physician judgment	↓ reintubation rates; no effect on duration of duration of MV
Piotto (2008) ²¹	RCT	RT-driven protocol vs physician judgment	↓ duration MV, ↓ reintubation rates

Danckers (2013) ²²	Prospective vs retrospective cohort	RN driven protocol vs physician judgment	↓ duration MV, no adverse effects

^aMortality was not measured.
*Complications included: re-intubation, self-extubations, tracheostomy, mechanical ventilation > 21 days.
Note: RCT= randomized controlled trials; RN= registered nurse; RT= respiratory therapist; ABG= arterial blood gas; MV= mechanical ventilation; RR= respiratory rate; VT= tidal volume; VAP= ventilator-associated pneumonia; ICU= intensive care unit; LOS= length of stay.

DISCUSSION—WHICH STRATEGY IS BETTER?

The study by Krishnan et al highlighted the importance of the “organizational context,” which relates to factors such as staffing, “usual care,” type of

ICU (surgical, medical, neurosurgical, etc), bed availability, and even an open versus a closed ICU model. It points to redundancies in hospitals and medical centers where a high staffing level is likely to promote early recognition and transition to weaning and extubation without the need for a

choreographed structure.^{25,26} Usual care refers to the customary practices performed at a particular ICU. At Johns Hopkins Hospital where the Krishnan study was conducted, high-level, evidence-based practice with 24-hour ICU physician coverage (ie, usual care) may explain the lack of difference in outcomes and the apparent ineffectiveness of PBW.²⁷ Protocolized weaning may be more suitable to hospitals that lack 24-hour coverage by intensivists or other physicians versed in the weaning cultures.

The type of ICU can play an important role in the weaning process. For example, a postanesthesia care unit (PACU) or a surgical ICU may not embrace the time-consuming and restrictive PBW. The daily screen is often disregarded in favor of an expeditious SBT in the majority of patients in the PACU or surgical ICU, thereby avoiding the burden of fulfilling stringent weaning criteria. No benefits were demonstrated when PBW was tried in neurosurgical and trauma ICUs, reinforcing the limitations associated with certain types of ICU.^{23,24} Although safe and effective, PBW may miss many patients that could be extubated sooner than what is predicted by established protocol criteria. As previously reported, half of the patients who self-extubate prematurely, do not require reintubation within a 24-hour period.^{28,29}

Another major concern regarding PBW lies in the heterogeneity of the published studies and their conflicting and inconsistent results. Hospital and ICU cultures, resources and settings heavily influence the methodology and protocol designs of these trials, resulting in a vast array of treatment algorithms. In the meta-analysis of 11 randomized controlled trials (RCTs) by Blackwood et al, readiness to wean criteria (daily screen) differed in every single study.¹⁸ Likewise, there was variability in the staff members (RTs, RNs, or physicians) involved in the application of the study protocols. Of the 11 studies, only 2 employed the same weaning protocol while the remainder used different combinations of weaning methods for liberation from IMV. The weaning modality (eg, PSV, T-piece trials, SIMV, or CPAP) also differed between the studies but did not impact the process of adequately identifying prospective candidates for liberation from IMV.^{10,20} The results of these studies are hardly reproducible and centers should be mindful and perform careful assessment of a protocol before its implementation.

Despite these limitations, a large body of evidence argues in favor of an RN/RT-led approach to weaning when compared to conventional (ie, no protocol) weaning by physicians (Table 65–3). Indeed, RN- and RT-directed protocols appear to be safe, beneficial and cost-effective. Certainly, healthcare providers who spend a lot of time with patients are well equipped to recognize the best time for extubation. PBW is relatively easy to incorporate into the culture of an ICU because RNs and RTs are widely available in many ICUs and they are consistently present at a patient's bedside.

RN/RT-led PBW appears ideal for patients in the “simple weaning” category and for most patients in the “difficult weaning” group. Patients in the “prolonged weaning” group and a few patients in the “difficult weaning” category should undergo further workup to identify barriers to successful liberation from IMV. Imaging studies, electromyography and nerve conduction testing, serologic markers for vasculitides, myopathies and endocrinopathies, esophageal manometry, etc may be necessary to diagnose medical conditions that impede weaning and to develop appropriate plans of treatment.^{30,31}

In the past few years, a new paradigm has emerged with the concepts of limited/no sedation and early ICU mobilization (early rehabilitation therapy) as adjuncts in liberating patients faster from IMV.^{32–36} A small number of RCTs and prospective studies have demonstrated that early mobilization of patients requiring mechanical ventilation was not only safe and feasible but also associated with increased ventilator-free days, shorter return time to baseline functional capacity, and reduced ICU and hospital LOS, mortality and costs.^{33–35} In the majority of cases, early mobilization was possible at a median of 1.5 days (range of 1–2.1 days) after initiation of IMV.³⁵

SUMMARY

Ventilator weaning protocols can aid ICU staff (physicians, RNs, and RTs) in identifying patients ready to be liberated from IMV. However, protocols have limitations. Notwithstanding, protocols are safe and, for the majority of patients, they yield real benefits that reduce morbidity, mortality and costs. RNs and RTs play an instrumental role in successful

PBW strategies but the appropriate weaning strategy is likely dependent on the available resources at a specific institution. We advocate RN/RT PBW for patients in the “simple” and “difficult” to wean groups in hospitals that have limited human and financial resources. At our institution, we use a wide-ranging integrative approach of limited sedation and early mobilization that involves physicians at different levels of experience (ie, residents, fellows, and full-time intensivists), critical care RNs, nurse practitioners, physician assistants, RTs, and physical and occupational therapists to determine readiness to wean and achieve liberation from IMV. We have achieved great success without the need for a specific weaning protocol.

Controversies: Invasive Versus Noninvasive Strategy for Diagnosing Respiratory Failure

Anil Singh, MD and Stephen M. Pastores, MD, FACP, FCCP, FCCM

INTRODUCTION

The etiology of acute respiratory failure (ARF) among different patient populations is highly variable.¹ In general, pulmonary infections are the leading cause of ARF followed by heart failure, exacerbation of chronic obstructive pulmonary disease (COPD), and sepsis.² Early and appropriate diagnostic strategies are vital for the initial choice of therapy and subsequent treatment decisions. With advances in medicine, aggressive treatments have been introduced to achieve the highest possible cure which in turn, has resulted in the concomitant rise in the incidence of life-threatening toxic and infectious complications, particularly involving the lungs.

There are many practical questions surrounding the diagnostic work-up of critically ill patients with ARF. What is the utility of noninvasive testing? Is empiric treatment enough? What are the risks and benefits of invasive diagnostic procedures? Does invasive testing result in improved outcomes? To answer these questions, a review of the literature has produced mixed results. The apparent dilemma between the need to identify the cause of ARF and complications associated with invasive procedures may have created this uncertainty. To this end, there is some data in hematology and oncology patients which can only be extrapolated to other groups of immunocompromised hosts for whom further testing guided by clinical and epidemiologic data may reveal unsuspected diagnoses. In this chapter, we discuss the utility of noninvasive and invasive testing for diagnosing ARF and provide a diagnostic algorithm based on the best available data ([Figure 66–1](#)).

NONINVASIVE STRATEGY

This approach consists of obtaining chest imaging studies, cardiac biomarkers (eg, B-type natriuretic peptide) and echocardiography to exclude cardiogenic pulmonary edema, and serologic and microbiologic studies of sputum, nasopharyngeal (NP) aspirates, blood, and urine to diagnose infection. In addition, newer molecular techniques are being implemented along with conventional methods in order to identify specific pathogens not only faster but more accurately without exposing patients to additional risks.

The most commonly performed noninvasive tests for diagnosing ARF are shown in [Table 66–1](#).

Important causes of ARF such as sepsis, aspiration pneumonia, diffuse alveolar hemorrhage, eosinophilic pneumonia, transfusion-related lung injuries and respiratory failure associated with cancer and other immunocompromised states are diagnosed clinically using a constellation of radiographic and other ancillary investigations.

The clinical presentation of suspected pulmonary infections is usually nonspecific. This is particularly important in immunocompromised patients who are prone to develop pulmonary infections with certain pathogens such as herpes simplex virus, Cytomegalovirus (CMV), *Pneumocystis jirovecii* (PCP), *Mycobacterium tuberculosis*, and *Aspergillus* species and hence require specific diagnosis and treatment as opposed to empiric therapy.

Gram stain of respiratory secretions, available within a few hours, may help in narrowing or broadening the antimicrobial spectrum but lacks

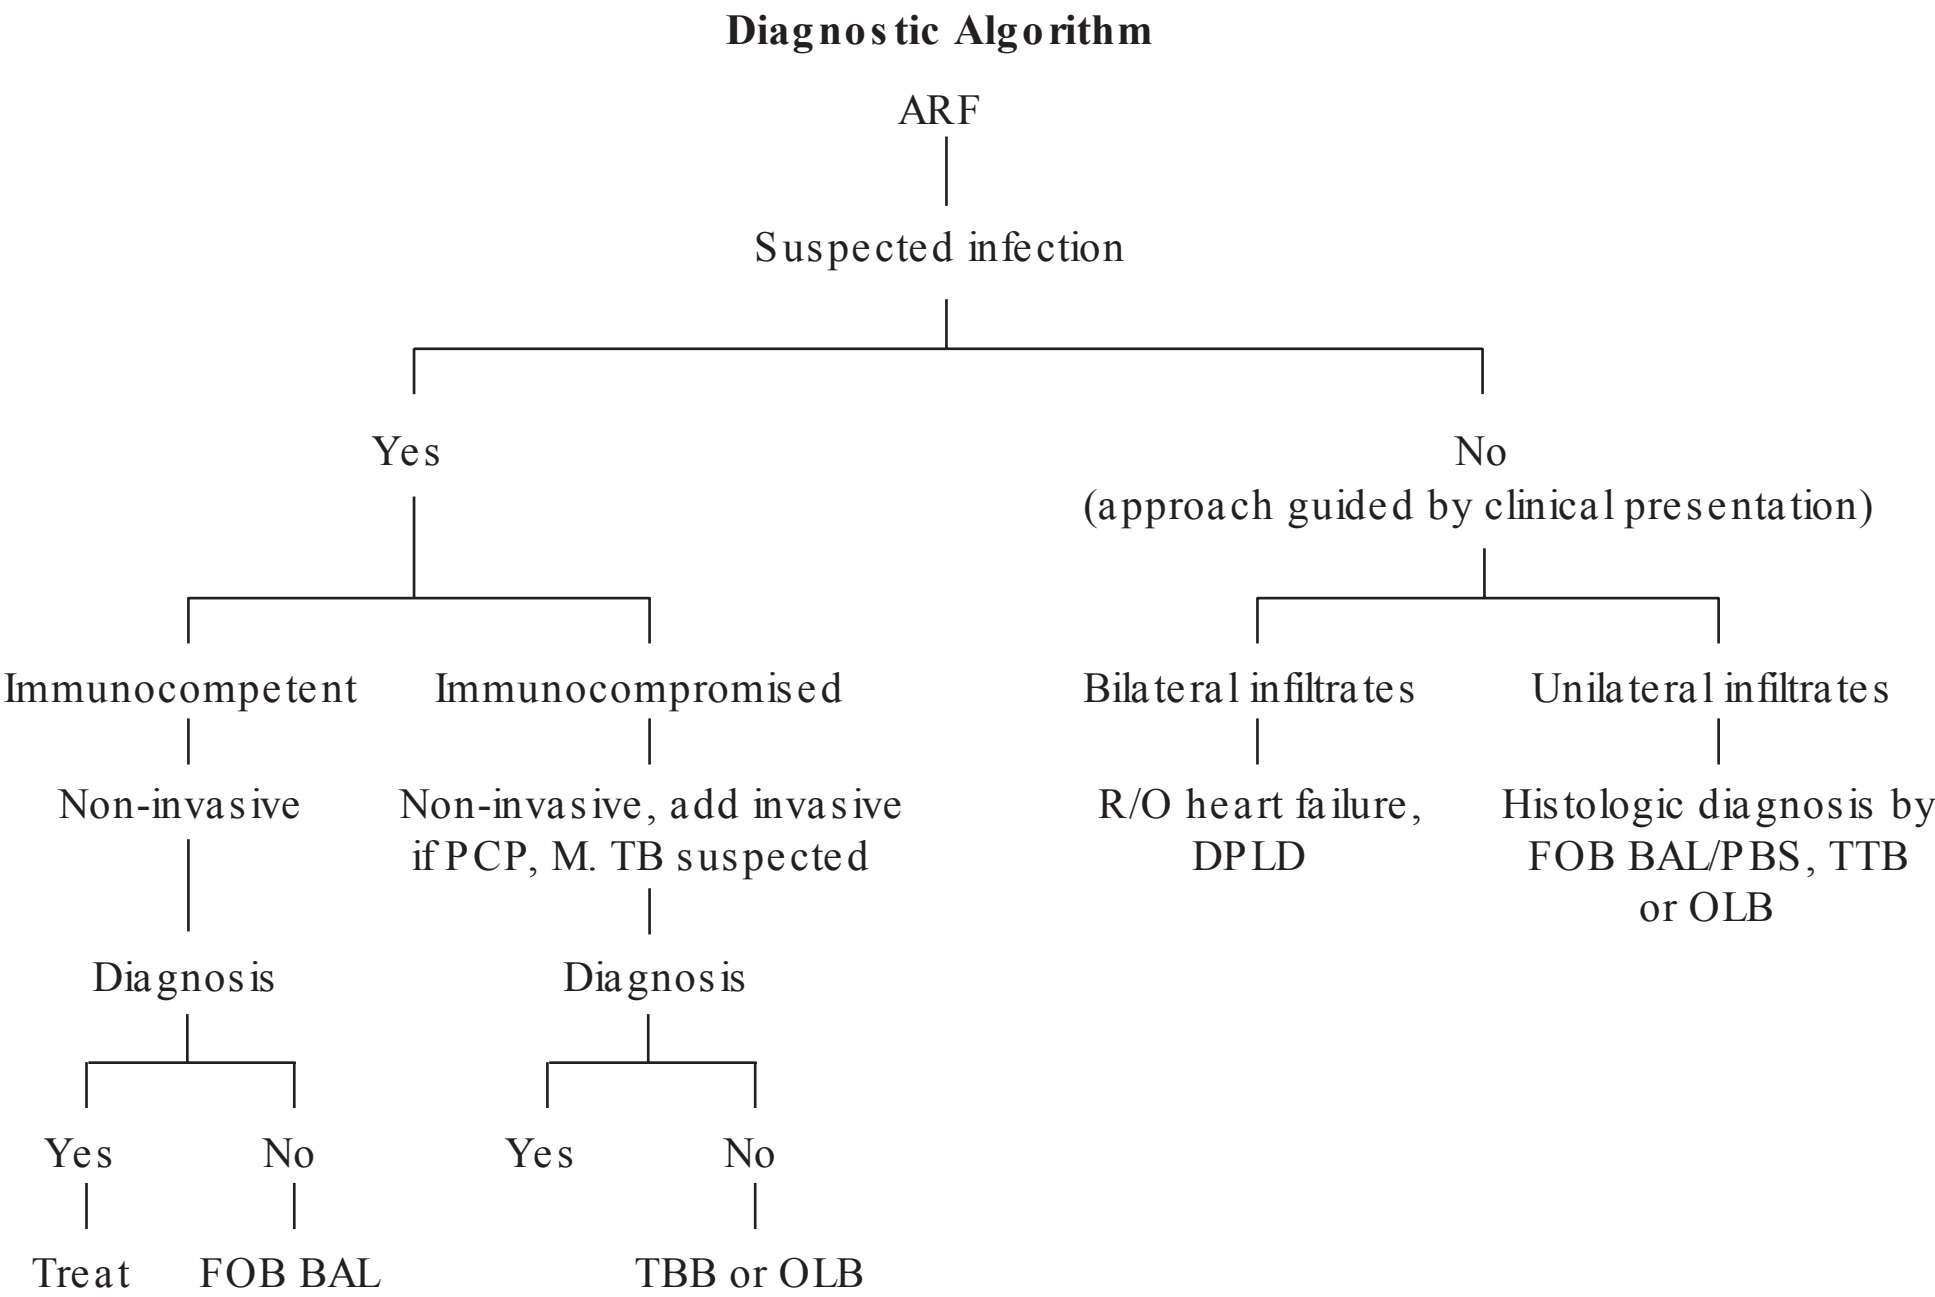

FIGURE 66–1 Diagnostic algorithm for diagnosing acute respiratory failure. (ARF = acute respiratory failure; FOB= fiberoptic bronchoscopy; BAL= bronchoalveolar lavage; PCP = Pneumocystis jiroveci; MTB= Mycobacterium tuberculosis; TBB= transbronchial biopsy; PBS = protected brush specimen; OLB= open lung biopsy; DPLD = diffuse parenchymal lung disease)

TABLE 66–1 Noninvasive tests for diagnosing acute respiratory failure.

Investigation	Diagnosis/Specific Pathogen
Imaging (chest radiograph, high-resolution CT, chest ultrasound)	Pattern of different radiologic findings may help in narrowing differential diagnosis
Transthoracic echocardiogram	Congestive heart failure, cardiac tamponade, pulmonary embolism
Expectorated sputum	Bacteria (Spneumoniae, Staphylococcus aureus, Hemophilus influenza, Enterobacteriaceae, Pseudomonas), Candida, other fungi (Histoplasma, Coccidioides) and Mtuberculosis
Induced sputum (smear and cultures)	P jiroveci, Mtuberculosis
Nasopharyngeal aspirates	Respiratory viruses, Spneumoniae
Blood cultures	Various pulmonary infections
Polymerase chain reaction	Herpes, Cytomegalovirus, P. jiroveci, M. tuberculosis
Circulating antigens	Aspergillus, P. jirovecii
Serum immunoglobulins	Chlamydia, Mycoplasma, Legionella
Urine antigens	Legionella, Spneumoniae
Pleural fluid analysis (chemistry, microbiology, cytology and other ancillary tests)	Malignancy, pulmonary embolism, collagen vascular disease, pancreatitis, uremia, yellow nail syndrome, sarcoidosis

sensitivity and specificity. Similarly, the yield of conventional stains for the diagnosis of other infections such as yeast, other fungi, *Aspergillus*, *M. tuberculosis*, and PCP pneumonia have been disappointing and slow, which has led to a greater reliance on polymerase chain reaction (PCR)-based techniques. The latter has provided improved insight into the biology and genomic structure of the pathogens.

Azoulay et al³ performed a multicenter randomized controlled trial (RCT) comparing noninvasive testing (of sputum, induced sputum, NP aspirates, serum and urine as well as chest imaging and echocardiography) with an invasive strategy involving fiberoptic bronchoscopy with bronchoalveolar lavage (FOB-BAL) in 219 hematology and oncology patients with ARF. Bacterial infection was the primary etiology of ARF followed by infections with viruses, yeasts and molds, or *Pneumocystis*. Noninvasive testing provided the diagnosis in 71% of cases and resulted in a change in management in 44% of patients compared to only 34% in those who underwent FOB-BAL. In 20% of cases, no diagnosis was made with either strategy. Additionally, the time to diagnosis of bacterial, non-*Aspergillus*, and viral infection was shorter and available quicker with noninvasive testing as compared to invasive testing. However, the diagnosis of PCP took longer in the noninvasive group (3 [-7] days vs 1 [0-1] day). In both groups, a specific diagnosis was established in 80% of cases. These diagnostic rates were significantly higher than those reported in the earlier observational study conducted by the same authors suggesting the improved utility and advances in noninvasive testing in recent years.⁴

The sensitivity of nasal swab and NP aspirate is comparable for all respiratory viruses except for the detection of respiratory syncytial virus due to the inherent lability and relatively lower viral load present in the nasopharynx.⁵ Although serologic testing for CMV IgM and IgG may be used to screen for primary CMV infection or exposure, this is not used for the diagnosis of active CMV infection. Viral load testing in serum, tissue specimens, or BAL fluid using both quantitative nucleic acid amplification testing (QNAT) and antigenemia testing are currently the cornerstone for diagnosis and monitoring for CMV infection and disease.⁶ Real-time QNAT testing for CMV is now the standard of care given

its better precision, broader linear range, faster turnaround time, higher throughput, and less risk of contamination compared with conventional PCR tests. In contrast, the antigenemia test is labor intensive, lacks a standardized cutoff value, and the assay performance diminishes when the absolute neutrophil count is less than 1000/mm³.⁶

Streptococcus pneumoniae urinary antigen has sensitivity of up to 78% in nonbacteremic patients and 80% in bacteremic cases and a specificity of more than 90% in adults. However, there have been false-positive reports of pneumococcal infection rates ranging from 21% to 54% in children with NP carriage and no evidence of disease.⁷ This limitation may be overcome with quantitative real-time PCR testing of NP swab samples to estimate NP colonization density and using cutoff values more than or equal to 8000 copies/mL, which improved the sensitivity to 82% and specificity to 92% for distinguishing pneumococcal pneumonia from asymptomatic colonization.⁸ Similarly, detection of *Legionella pneumophila* antigen in urine is rapidly available and requires no specialized laboratory equipment. Sensitivity rates of 73% and 77%, respectively, were reported for the new Meridian TRU *Legionella* assay and BINAX urinary antigen test. Additionally, the sensitivity of the Meridian TRU *Legionella* test increased to 81% after 60 minutes of incubation.⁹

PCP cannot be cultured and hence diagnosis relies on visualization of the fungus on microscopic examination of respiratory specimens. The sensitivity of microscopy varies according to the staining technique and type of respiratory sample used. In one study, the sensitivity and specificity of Grocott-Gomori methenamine silver stain for PCP were 79.4% and 99.2%, respectively.¹⁰ A serum assay for beta glucan, a cell wall component of most pathogenic fungi, is currently being used for PCP diagnosis with sensitivity and specificity rates of 100% and 96.4%, respectively, using a cutoff value of 100 pg/mL.¹¹ In a select group of patients the yield of induced sputum-PCR assay for detection of PCP has been shown to be excellent with sensitivity of 100% and specificity of 90% which would make FOB-BAL or lung biopsy practically unnecessary.¹² Of note, respiratory specimens should be collected before or immediately after initiation of therapy because the

sputum-PCR assay for detection of PCP may turn negative quickly. A negative PCR may allow for the discontinuation of anti-PCP therapy.¹²

Both direct microscopy and cultures are insensitive methods to diagnose aspergillosis. Galactomannan is an *Aspergillus*-specific polysaccharide which is released during *Aspergillus* growth at the site of infection. This antigen can be detected by quantitative serum galactomannan index and is used as a biomarker of the disease. In addition, galactomannan antigen has a strong correlation with clinical outcome; thus the test is currently repeated frequently during the course of treatment. In contrast, the presence and magnitude of the galactomannan index in BAL fluid does not have any mortality implication.¹³ In a study of 500 patients, the diagnostic yield of acid-fast bacilli (AFB) smear, cultures and PCR of induced sputum for *M. tuberculosis* was increased consistently with repeated induction from 64%, 70%, and 89% for AFB smear, and from cultures and PCR, respectively, to 98%, 100%, and 100% on fourth induction.¹⁴ Current amplification techniques can detect *M. tuberculosis* and rifampin resistance directly from clinical specimens in approximately 2 hours with high sensitivity compared to the standard method.¹⁵

Early molecular detection methods are currently under development. With regards to bacterial pathogens, multiplex amplification assays might include frequently involved microorganisms. Despite the obvious advantages of PCR-based methods (rapidity, sensitivity, convenience), several limitations including the need of cut-off levels to distinguish between colonization and infection, the inability to detect living viruses from prolonged harmless shedding, lack of information about the antibiotic susceptibility and the high cost of these tests still limits their widespread use in clinical decision making. Moreover, studies measuring clinical outcomes and mortality benefits are lacking at this time. These limitations in diagnostic testing with noninvasive strategies have led to the development of antimicrobial guidelines for empiric treatment.¹⁶ At this time, PCR-based testing can supplement rather than replace culture-based methods for pathogens where antibiotic resistance is a concern.

INVASIVE STRATEGY

This approach relies on FOB-BAL and/or protected brush specimens (PBS), transbronchial biopsy (TBB) and lung biopsy (open or video assisted). FOB-BAL and/or PBS permit collection of distal airway secretions with minimal oropharyngeal contamination which is inevitable during specimen collection.

The reported diagnostic yield of FOB in different studies has been variable. This is attributed to the heterogeneity of the patient population, severity of illnesses, regional differences, timing, and techniques of FOB-BAL and/or PBS.^{17,18} A summary of these studies is shown in [Table 66–2](#).

In a prospective study of 101 immunocompromised patients with suspected pneumonia, 80% of whom had human immunodeficiency virus infection and/or acquired immunodeficiency syndrome, hematologic and solid organ malignancies, chronic steroid use and neutropenia, FOB-BAL/TBB had a general diagnostic yield of 52% but 76% in infectious diseases.¹⁹ Mycobacterial infections accounted for one third of infections followed by bacterial pathogens and PCP. In contrast, the diagnostic yield of FOB in immunocompetent patients is lower. In one study of nonselected patients, the diagnostic yield of FOB was 53% in immunocompromised patients versus only 19% in immunocompetent patients suggesting that the need of invasive testing in the latter group must be established based on clinical importance and risks of the procedure.²⁰ The yield was further decreased if patients received antibiotics prior to bronchoscopy. Complications were seen in 5 patients (12%) with a higher proportion of minor self-limited bleeding ($n = 3$), pulmonary edema ($n = 1$), and cardiac arrhythmias ($n = 1$).²⁰

In a retrospective study of 501 patients who underwent hematopoietic stem cell transplantation, the mortality rate was lower in the early (< 4 days) FOB-BAL group (6%) versus 14% to the late FOB group (> 5 days). The overall diagnostic yield for clinically significant pathogens was 55% and was highest (75%) if the FOB-BAL was performed within 24 hours.²¹ Similarly, a multicenter RCT in patients with suspected hospital-acquired pneumonia (HAP) where an invasive strategy (direct examination of FOB-BAL or PSB samples and quantitative cultures)

TABLE 66–2 Summary of studies comparing noninvasive versus invasive strategy for diagnosing acute respiratory failure.

Authors	Study Design	Patient Population	Results
Jain P, et al¹⁸	Observational study	Non-HIV infected immunocompromised patients (n = 104)	Overall diagnostic yield of FOB: 56.2% (81% yield for an infectious cause vs 56% for a noninfectious cause) FOB+TBB yield: 70% Complication rate: 21%: minor bleeding (13%); pneumothorax (4%)
Azoulay E, et al³	RCT	Nonintubated cancer patients (n = 219)	Diagnostic yield of FOB-BAL 34% vs 71% with noninvasive tests
Velez L, et al¹⁹	Prospective study	Immunocompromised predominantly AIDS patients (n = 101)	Diagnostic yield of FOB-BAL: 51% (infections accounted for 65%)
Ekdahl K, et al²⁰	Prospective study	Nonselected patients (n = 53)	Diagnostic yield of FOB 53% in immunocompromised vs 19% in immunocompetent patients
Fagon JY, et al²²	Randomized uncontrolled trial	Patients suspected of VAP (n = 413) FOBBAL/PBS vs nonquantitative endotracheal aspirate cultures	Invasive group had reduced mortality at 14 days (16.2% vs 25.8%) More antibiotic-free days (11.5 ± 9.0 days compared with 7.5 ± 7.6 days)
Papazian L, et al²³	Prospective study	Medical-surgical patients with negative BAL (n = 100) Open lung biopsy performed after 5 days of no improvement of ARDS	Fibrosis 53% (fibrosis with infection 55%) Miscellaneous 14%: systemic lupus erythematosus, rheumatoid arthritis lung, drug toxicity, allograft rejection, lung cancer Complications: 2 pneumothoraces and 8 moderate airleaks
Shannon VR, et al²¹	Retrospective study	HSCT patients < 100 days (n = 501) Impact of early vs late FOB (< 4 days vs > 5 days)	Diagnostic yield of FOB-BAL 55%; highest yield (75%) within 24 hour 30-day mortality was 6% in early FOB group vs 14% in late FOB

HIV = human immunodeficiency virus; FOB = fiberoptic bronchoscopy; TBB = transbronchial biopsy; RCT = randomized controlled trial; AIDS = acquired immunodeficiency syndrome; BAL = bronchoalveolar lavage; VAP = ventilator-associated pneumonia; PBS = protected brush specimen; ARDS = acute respiratory distress syndrome; HSCT = hematopoietic stem cell transplant

was utilized compared with patients managed clinically, showed that the invasive approach was associated with reduction in mortality on day 14 (16% vs 25%), decreased organ dysfunction score on day 3 and 7, less use of antibiotics, mean number of antibiotic-free days (7 ± 7 vs 11 ± 9 days).²²

Reliance on semiquantitative cultures from endotracheal aspirates which may not distinguish a true pathogen from a colonizer, can lead to more or broader antibiotic use and potential delay in the diagnosis of extrapulmonary infection. Thus, semiquantitative cultures of tracheal aspirates cannot be used reliably as quantitative cultures to define the presence of pneumonia and the need for antibiotic

therapy.¹⁶ However, it is recommended that patients with community-acquired pneumonia should be investigated for specific pathogens only if it would alter the standard (empiric) management decisions when the presence of such pathogen is suspected based on the clinical and epidemiologic clues.¹⁶ For example, such alteration in therapy is likely to benefit patients with psittacosis, tularemia, endemic fungi, M. tuberculosis or antibiotic resistance issues.

FOB-BAL is also favored in the presence of non-infectious pulmonary infiltrates causing ARF since as described previously, noninfectious disorders explained most of the missed diagnoses.^{3,19} In addition, transbronchial or surgical open lung biopsy

(OLB) may be considered in select patients to obtain a definitive diagnosis and guide therapy when it is believed to make a substantial impact in the management and improvement in the prognosis. These include patients with suspected cryptogenic organizing pneumonia, fungal lung infections, and acute exacerbation of a chronic interstitial lung disease, vasculitis, or disseminated cancer. In a prospective study of 100 nonselected patients with ARF of unknown etiology after a negative BAL, OLB provided a contributive result in 78% of patients. A change in the management was associated with improved survival to 67% compared to 14% when OLB did not help in management. The most common diagnoses obtained by OLB were fibrosis associated with infections (55%), followed by pulmonary infections (42%) (CMV, herpes, *M. tuberculosis*, invasive aspergillosis) and miscellaneous diagnoses such as systemic lupus erythematosus, bronchoalveolar carcinoma, intraalveolar hemorrhage, drug toxicity, and carcinomatous lymphangitis.²³

FOB is commonly associated with alteration in gas exchange; however, hypoxemia is usually mild and transient.²⁴ The severity of hypoxemia during bronchoscopy may vary depending on the patient's comorbid conditions, indications of the procedure and the type of bronchoscopic interventions performed. The risk of hypoxemia may be further decreased when using noninvasive ventilation and/or target controlled sedation during bronchoscopy which have both been shown to not only limit discomfort but also reduce the subsequent respiratory worsening.²⁵ In various studies, the risk of FOB-BAL has been proven to be small with no effect on outcome.^{3,26} In few selected patients, the diagnostic yield improves if FOB-BAL is performed in the ICU within 24 hours of admission; thereafter, this benefit seems to fade with less favorable risk/benefit ratio.³

A multicenter prospective observational study evaluated the safety of FOB in critically ill non-intubated patients with hypoxemic ARF due to a variety of causes including immunodeficiency (37%), atelectasis (29%), healthcare-associated pneumonia (27%), acute diffuse pneumonia (27%), community-acquired pneumonia (12%), hemoptysis (3%), suspected malignancy (3%), and chronic

diffuse infiltrative pneumonia (1%). The patients had a $\text{PaO}_2/\text{FiO}_2$ ratio of less than 300 and were on noninvasive ventilation or receiving oxygen supplementation of more than 8 L/min. FOB provided the diagnosis in 59% of cases with subsequent change in the management in 51% of patients. Factors independently associated with the need of invasive ventilatory support were COPD and cancer but not the extent of radiologic opacities, $\text{PaO}_2/\text{FiO}_2$ ratio, BAL, or injected BAL volume. The overall incremental risk associated with bronchoscopy is small and has no effect on mortality. It is generally considered safe with arterial oxygen saturation more than 90% on FiO_2 of less than 0.5 and PaO_2 more than 60 mm Hg.

SUMMARY

Recent advances in the sensitivity and specificity of noninvasive diagnostic investigations may change the risk/benefit ratio in favor of conservative noninvasive testing in patients with ARF. However, a subset of patients may still benefit from the addition of FOB-BAL when performed safely in addition to noninvasive testing, particularly when protective procedural strategies such as noninvasive ventilation and/or targeted controlled sedation are used. It is hoped that further refinement of molecular techniques and their enhanced diagnostic yield will decrease the need for invasive procedures in the future. Current evidence suggests that noninvasive and invasive strategies both offer benefits and complement each other. The main consideration in deciding which approach to take is the influence any result would have on management. Noninvasive tests are generally useful in determining the accurate diagnosis in immunocompromised patients. On the other hand, FOB-BAL and other invasive techniques have an advantage especially in the setting of suspected *M. tuberculosis*, PCP, malignancy and interstitial lung diseases. Invasive testing should be reserved for immunocompetent patients only when conservative techniques are likely to miss the diagnosis. We conclude that an individualized approach based on available clinical information and epidemiologic data should facilitate the relevant use of noninvasive and/or invasive testing for diagnosing ARF.

“Controversies: Ventilator Management in ARDS: One Size Fits All?”

Muhammad Adrish, MD and Graciela J. Soto, MD, MS

KEY POINTS

- 1 The pathophysiologic changes in the acute respiratory distress syndrome (ARDS) produce low-compliant lungs containing areas of atelectasis and reduced lung volumes.
- 2 Positive pressure ventilation in this heterogenous syndrome can lead to overdistension of normally aerated lung regions and stress injury in atelectatic alveoli due to cyclic recruitment and derecruitment.
- 3 Use of low-tidal-volume ventilation as lung-protection strategy has been studied since 1960s. Despite suggested benefits, concerns regarding additional metabolic abnormalities and hypoxemia in critically ill patients have existed.
- 4 Results of the landmark ARDS in a large multicentre randomized trial found that the use of low tidal volume (6 mL/kg ideal body weight [IBW]) rather than “standard” tidal volume (12 mL/kg IBW) significantly reduced mortality. Although the trial was criticized for using excessively large tidal volumes in controls, the trial investigators subsequently published trial data detailing the clinical benefits of tidal volume and plateau pressure reduction across the range of disease severity and plateau pressures.
- 5 Recent data suggest that many mechanically ventilated patients with ARDS have stress index that indicates alveolar hyperventilation while receiving positive end-expiratory pressure (PEEP) according to the ARDS Network recommendation, advocating even lower tidal volumes.
- 6 Use of adjunct therapies such as extracorporeal membrane oxygenation may be useful in select patients where lowering tidal volume can lead to serious metabolic abnormalities.

INTRODUCTION

The pathophysiologic changes in the acute respiratory distress syndrome (ARDS) produce low-compliant lungs with atelectasis and reduced lung volumes. Such stiff lungs frequently lead to respiratory failure from severe hypoxemia requiring mechanical ventilation for life support. Computed

tomography shows a heterogeneous involvement of lung injury in ARDS and that approximately only a third of the lung is normally aerated (“baby lung”).¹ Positive pressure ventilation can worsen lung injury due to differential distribution of each ventilator-delivered breath. The normally aerated lung regions with the highest compliance receive the largest

part of the tidal volume (TV) and are exposed to overdistention from high alveolar wall tension and stress. Conversely, atelectatic nonaerated alveoli are exposed to further damage from shear stress due to cyclic recruitment and derecruitment. Therefore, ventilation strategies in ARDS need to simultaneously reverse life-threatening hypoxemia while protecting the lungs from further injury. Since the first description of ARDS by Ashbaugh in 1967, several decades of experimental and clinical research have shifted the primary goal of mechanical ventilation from a normalization of the arterial-blood gas to a more “lung-protective” ventilation strategy. What follows is a description of the history of mechanical ventilation in ARDS, data on published clinical trials, the debate on low-TV ventilation, barriers for implementation of this approach, and our conclusions and suggestions to the readers.

HISTORY OF VENTILATORY STRATEGIES IN ARDS

In the 1960s, the use of high TVs in all mechanically ventilated patients was considered routine care based on the study by Bendixen et al that showed improved oxygenation, less acidosis and atelectasis in anesthetized patients undergoing laparotomy with high TVs (15 mL/kg) compared to lower TVs (5-7 mL/kg).² At that time, experimental data by Greenfield et al were the first to show the adverse consequences of mechanical ventilation of normal lungs with high pressures and volumes (peak airway pressures of approximately 30 cm H₂O).³ In the following decades, ventilator-induced-lung injury from high TVs were further supported by experimental data from Webb, Tierney, and others showing that ventilation with peak airway pressures more than 30 cm H₂O and high TVs led to pulmonary edema, increased alveolar-capillary permeability, structural abnormalities, translocation of inflammatory mediators, multiple-organ-failure and death. These experimental data were supported by the clinical study by Ranieri et al, showing that ARDS patients who received a lung-protective ventilator strategy that limit airway pressures and TV to 5 to 8 mL/kg of ideal body weight (IBW) had a significant reduction of inflammatory markers in plasma and bronchoalveolar lavage.⁴ This preclinical and

clinical data raised concerns in the medical community that what was considered “best practice” at the time could exacerbate lung injury from excessive stress or strain to the lung tissues during mechanical ventilation and aggravate on-going inflammation and diffuse alveolar damage. In the 1990s, the pioneering studies by Hickling et al using low-volume pressure-limited ventilation were the first to demonstrate a reduction in mortality by decreasing TV to 5 to 7 mL/kg in order to lower the end-inspiratory pressure while allowing hypercapnia. In these studies, the mortality was lower than that predicted by the severity of illness (Acute Physiology and Chronic Health Evaluation, APACHE II) and the results suggested that the physiologic derangements from “permissive hypercapnia” could be minimized if the rise in CO₂ is more gradual, allowing the intracellular pH to normalize.⁵ The work of Hickling and colleagues led to further clinical trials to address the potential clinical benefits of limiting airway pressures by using a low TV in ARDS. In a prospective randomized controlled trial (RCT) by Amato et al, a “protective strategy” of mechanical ventilation (TV of 6 mL/kg actual body weight and PEEP of +2 cm above the lower inflection point [LIP]), was associated with 46% decrease in 28-days mortality, higher rate of weaning from mechanical ventilation, and lower rate of barotrauma.⁶ However, 3 additional RCTs showed no benefits from a low TV strategy.⁷⁻⁹ From 1996-1999, the ARDS Network evaluated the effects of a lower TV strategy in patients with ARDS in a large multicentre randomized trial (ARMA) sponsored by the National Institute of Health (NIH).¹⁰ In the ARMA study, a traditional ventilation with a TV of 12 mL/kg of predicted body weight (PBW) and plateau pressure (Ppl) less than or equal to 50 cm H₂O was compared to ventilation with a low TV (6 mL/kg of PBW) and Ppl less than or equal to 30 cm. The trial was stopped after the enrollment of 861 patients because of a significant 22% relative reduction in mortality in the experimental group treated with low TV (31.0% vs 39.8%, $P = 0.007$)—this mortality benefit persisted at 6 months from randomization. Furthermore, the experimental group also had significantly more ventilator-free days (VFDs) at 28 days (12 vs 10, $P = 0.007$), and organ-failure-free days compared to the low TV group.

LOW TIDAL VOLUME STRATEGY CONTROVERSY: DOES ONE SIZE FIT ALL?

Soon after publication of the ARMA trial, the study raised intense debate in the medical community and was criticized by its study design, use of surrogate markers of lung injury, and selection of the control group. Many experts in the field argued that a single ventilator strategy with low TVs may not be beneficial or applicable to all patients with ARDS due to the heterogeneity of the underlying lung injury that characterizes this population of critically ill patients.

One Size Fits All?: CON

The ARMA study was criticized for comparing 2 extremes of TV (6 mL/kg PBW vs 12 mL/kg PBW) rather than a safer range of TV (8-10 mL/kg PBW) which was the routine practice at the time of the trial. In the controversial meta-analysis by Eichacker et al the authors examined the results of 5 RCTs on low TV ventilation in ARDS and questioned the validity of the ARMA trial.¹¹ The authors argued that in the 2 RCTs that showed a survival benefit from a low TV, the traditional arm received excessively large TVs (≥ 10 mL/kg) that were not the standard of care (8-9 mL/kg). In contrast, the 3 RCTs that showed no survival benefit from a low TV strategy used TVs in the traditional arm that resulted in lower airway pressures (Ppl 28-32 cm H₂O). Therefore, the mortality benefit from a low TV strategy may reflect an excess mortality in the traditional arm exposed to unconventionally high pulmonary pressures (Ppl 34-37 cm H₂O) rather a benefit from low TVs. This analysis and the authors' conclusions have been vigorously challenged and rebutted by others. However, even though it did not prove the benefit of a low TV approach over traditional practice, this meta-analysis did indicate that using a high TV and high Ppl had deleterious effects.

Two subsequent meta-analyses by 2 independent groups of investigators combined the mortality data from the same 5 RCTs examined by Eichacker et al and performed statistical analysis to account for the overall clinical heterogeneity in these studies.^{12,23} The results of the treatment effect on mortality were similar. Petrucci and Lacovelli found that

even though the 28-days mortality was significantly reduced by lung-protective ventilation (RR (relative risk): 0.74, 95%CI: 0.61-0.88), the mortality was not significantly different between low and conventional TV if the control groups kept the Ppl less than or equal to 31 cm H₂O (RR: 1.13, 95%CI: 0.88-1.45).¹² Similarly, the meta-analysis by Moran et al found that the pooled estimate of treatment effect favored protective ventilation but was not statistically significant. However, the treatment effect on 28-days mortality was significant for ARDS patients receiving a TV less than 7.7 mL/kg PBW if the control group had a Ppl more than or equal to 30 cm H₂O but not if the controls had Ppl less than 30 cm H₂O.²³ These results remained unchanged in 2 subsequent meta-analyses by Petrucci et al which included all RCTs available to date.^{13,14} The authors suggested that their results may involve variations in transpulmonary pressure in the individual patient. A large TV might induce lung damage when the transpulmonary pressure is high. On the other hand, when transpulmonary pressures are within the safe range, a TV in the middle range (8-10 mL/kg) could be used avoiding deleterious effects. The results of this meta-analysis supports the belief of other leaders in the field that the TV in ARDS patients should be adjusted based on other markers of lung injury such as airway pressures or lung strain. Their rationale is that although some patients, such as those with poor pulmonary compliance and high airway pressures, would benefit from very low TV, others with less severe lung injury may require larger volumes to maintain ventilation and avoid alveolar collapse.

To prove this point, Deans et al provided data to support that the mortality in the ARMA trial depended on the lung compliance prior to randomization into a mechanical ventilation strategy.¹⁵ In patients with less compliant lungs (< 0.6 mL/cm H₂O/kg PBW), there was a direct linear relationship with TV and these patients received lower TVs. There was no association in patients with better lung compliance (≥ 0.6 mL/cm H₂O/kg PBW) and in those patients the TV remained constant. Furthermore, the effect on mortality by changing TV was significantly associated with the prerandomization lung compliance. In patients with more compliant lungs, a lower TV was associated with higher mortality. Conversely, in those patients

with less compliant lungs, a low TV was associated with lower mortality compared to a high TV. These associations persisted even after accounting for differences in age, APACHE II, and $\text{PaO}_2/\text{FiO}_2$ ratio. Overall, these findings strongly suggest that mechanical ventilation should be managed according to other parameters than TV and Ppl and that a single ventilator strategy with a TV of 6 cc/kg PBW may not be applicable to all patients with ARDS. To further support their findings, Deans et al also performed a retrospective analysis of 2587 patients screened by the ARDS Network who met enrollment criteria but were ineligible due to technical reasons (eg, difficulties with consent). This group of patients received routine care during the course of the ARMA trial and reflected the standard practice of the time. Remarkably, these ineligible patients for the ARMA trial had a comparable mortality rate to the low TV arm in that study (31.7% and 31%, respectively).

In a recent counterpoint analysis, Gattinoni challenged the use of low TV set at 6 mL/kg PWB because PBW is not an appropriate surrogate for the “resting lung volume” when defining lung strain as the ratio of TV to the resting lung volume.¹⁶ In patients with ARDS, PBW cannot be considered an acceptable surrogate for lung volume because the normal relationship between PBW, lung volume, and height is lost. Even though lung strain always increases with TV, the same applied TV/PBW may lead to completely different strain depending on the available lung volume still open to ventilation (“baby lung” volume) confirming that one size of TV may not fit all patients. In a subgroup of patients with very low “baby lung,” a TV 6 cc/kg PBW could be excessively high. In another subgroup of patients with a greater “baby lung,” a TV 6 cc/kg PBW could be unnecessarily low increasing the risk of atelectasis, respiratory acidosis, and need for supplementary sedation. This controversy stems from the difficulties of measuring transpulmonary pressure at the bedside—the real distending force of the lung and the cause of alveolar trauma. The ideal ventilation would measure the lung volume and transpulmonary pressure because IBW and Ppl are inadequate surrogates for lung stress and strain. However, it may not be feasible to have these measurements available on a routine basis in most ICUs and a lower TV/PBW might be a better choice than

a higher TV/PBW because the risks associated with an unnecessarily low TV are lower than those associated with an unnecessarily high TV.

One Size Fits All?: PRO

The methodologic and safety concerns raised by Eichacker and colleagues were addressed by the ARDS Network investigators and the Office of Human Research Protections (OHRP). The OHRP conducted a thorough investigation to assess whether the control arm was subjected to a range of TVs that conferred a disadvantage. In their published reports, the OHRP, declared that the risks to the subjects in the ARDS Network trial were minimal and reasonable in relation to the anticipated benefits given the high variability in the care of ARDS patients at the time and the lack of standard of care.^{17,18} In their response to Eichacker et al, the ARDS Network investigators challenged the methodology of their critic’s meta-analysis and reiterated that at the time of the study there was no standard of ventilator strategy.¹⁹ They indicated that at the time of the ARMA trial the Ppl was not used to adjust TVs in any systematic fashion and that there was disparity in physician-selected TVs and the threshold for a Ppl limit indicating equipoise in the medical community on the most appropriate approach to mechanical ventilation. A “standard control” reflective of prevailing ventilation strategy at that time did not exist and the physician’s interpretation of the preclinical data and the resulting clinical practices were highly variable. For instance, in the 5 RCTs evaluated by Eichacker et al, there were 4 different ways to calculate the TV based on PBW, IBW, dry, and measured actual body weight. The ARDS Network investigators indicated that the mean TV of patients in the traditional arm after randomization was 10 mL/kg PBW which was consistent with the prevailing clinical practice in the 1990s. They also challenged the meta-analysis conclusions of lack of efficacy due to the small sample size of the 3 nonbeneficial studies, small differences in TVs between study groups in the 2 beneficial studies, and the lack of a pooled estimate of mortality or clinical heterogeneity. In addition, the ARDS Network investigators subsequently published further data from the ARMA trial that detailed the clinical benefits of TV and Ppl reduction across the range of

disease severity and Ppl on day 1 of randomization.²⁰ They showed greater severity of disease in patients with lower respiratory system compliance and that the Ppl was an independent predictor of mortality—decreasing Ppl decreased mortality in ARDS patients, but the investigators caution that this data should not be interpreted to suggest that TV should be lowered below 6 mL/kg PBW.

A subsequent analysis of the ARMA trial examined the efficacy of a low TV ventilation strategy in patients with different clinical risk factors for ARDS.²¹ Even though the risk of death was significantly higher in certain subgroups of patients (sepsis, pneumonia, aspiration), a low TV strategy was equally effective across ARDS patients with different clinical risk factors, pulmonary versus nonpulmonary etiology, or infection-related versus noninfection-related conditions. The results from this study strongly support the beneficial effect of low TV ventilation in patients with diverse clinical risk factors for ARDS.

Further studies have showed a benefit of a low TV approach and a recent meta-analysis of 9 RCTs on lung-protective ventilation by Putensen et al has shed some light on the clinical benefits of this ventilatory strategy.²² Contrary to prior meta-analysis that did not focus on the comparison between lower and higher TV at similar PEEP,^{11,12,23} the authors analyzed data according to the effect of different lung-protective strategies: higher versus lower TV at similar PEEP, higher versus lower PEEP strategies during low TV ventilation, and lower TV and PEEP titrated greater than the LIP of the individual's pressure-volume curve versus higher TV and lower PEEP. The authors showed that compared to higher TV ventilation at similar PEEP, lower TV ventilation-reduced hospital mortality (OR (odds risk): 0.75%, 95%CI: 0.58-0.96), a higher PEEP did not reduce hospital mortality compared with lower PEEP using low TVs but that a higher PEEP reduced the need for rescue therapy to prevent life-threatening hypoxemia. These findings support the hypothesis that the higher heterogeneity found in previous meta-analysis can be partially attributed to the inclusion of RCTs that simultaneously investigated lower TV and higher PEEP strategies. Similar to the data from Moran and Petrucci, the authors also found that a lower TV approach did

not improve outcomes when higher TV ventilation results in Ppl less than 30 cm H₂O. However, none of the analyses demonstrated an advantage of high TV ventilation. The authors concluded that low TV ventilation seems to be beneficial in patients with ARDS for routine clinical practice if potential side effects, such as hypercapnia and respiratory acidosis, are not contraindicated. This recent data indicate that TV is a determinant of lung-injury risk and that a lung-protective ventilator approach in ARDS limits further ventilation-induced damage locally and systemically. In the ARMA trial, low TV ventilation was associated with significant reduction in the plasma level of IL-6 and IL-8 and a more rapid attenuation of the inflammatory response by day.²⁴ More recently, Determann et al showed a greater decrease in IL-6 levels in patients receiving low TVs as compared to a conventional approach (51 ng/mL to 11 ng/mL vs 50 ng/mL to 21 ng/mL; $P = 0.01$).²⁵ The CT studies by Terragani et al identified ARDS patients in whom tidal inflation occurred largely in normally aerated compartments (more protected) and those in whom tidal inflation occurred largely in the hyperinflated compartments (less protected). They found that pulmonary cytokines were significantly lower in the more protected patients and concluded that limiting TV to 6 mL/kg PBW and Ppl to 30 cm H₂O may not be sufficient in patients with larger nonaerated compartments.²⁶ Grasso et al demonstrated that many patients with ARDS have a stress index that indicates alveolar hyperventilation while receiving PEEP according to the ARDS Network recommendations.²⁷ These data point toward utilization of even lower TVs that may increase the likelihood of hypoxemia and other metabolic abnormalities.

Over the last few years, advances in extracorporeal technology have led to significant rise in the use of extracorporeal membrane oxygenation (ECMO) to minimize these metabolic abnormalities in ARDS.²⁸ With the adjunctive use of ECMO, even lower TVs can be achieved while removing CO₂ to correct the low-tidal-volume-induced respiratory acidosis. The recent Xtravent RCT in ARDS patients evaluated the effect of low TV (3 mL/kg PBW) using ECMO versus the ARDS Network strategy (TV of 6 mL/kg PBW) without the use of an extracorporeal device.²⁹ Although there were no significant differences in

VFDs or mortality between the study groups, a post-hoc analysis revealed significantly more VFDs at 60 days in patients with more severe hypoxemia ($\text{PaO}_2/\text{FIO}_2 \leq 150$) who were in the ECMO group (40.9 ± 12.8 vs 28.2 ± 16.4 , $P = 0.033$). Overall, the use of ECMO in ARDS still remains controversial with conflicting survival data and the ongoing EOLIA RCT (“ECMO to rescue lung injury in severe ARDS”) will attempt to clarify the role of ECMO in these patients.

CHALLENGES OF A LUNG-PROTECTIVE VENTILATION IN CLINICAL PRACTICE

Although the clinical benefit of lung-protective ventilation has been known for years, many ARDS patients receive large TVs in routine practice. Over a decade ago, the ARMA trial demonstrated a 22% relative reduction in mortality and well-tolerated hypercapnia with a lung-protective approach. Despite the significant benefit and favorable cost-effectiveness profile,³⁰ implementation of this approach into clinical practice has been slow and only half of eligible patients receive low TV ventilation.³¹ Centers participating in mechanical ventilation networks or that use educational tools to improve care have higher compliance; however, this does not reflect real-life practice. Several studies, including a survey in all the ARDS network sites, identified several barriers to implementing lung-protective ventilation such as physician’s willingness to relinquish control of ventilator, provider discomfort with low TV, perceptions of patient contraindications to receive low TV, patient discomfort, hypercapnia, acidosis, hypoxemia, and the use of sedatives and paralytics.³² Implementation of a low TV strategy has been recently challenged by the shifting trend in ICU practice of early mobilization to prevent the long-term neuromuscular and cognitive sequelae of critical illness by limiting the use of sedatives and paralytics. In addition to these factors, many patients with ARDS are either unrecognized or not diagnosed by clinicians in a timely manner, especially if the ARDS is mild, and do not receive lung-protective protective ventilation. Even when ARDS is properly recognized, provider reliance on the actual body weight instead of PBW in the calculation of the set TV is a frequent

error, particularly when the calculation yields an apparently too small TV, leading to overtreatment with higher TVs. The patient’s actual weight on admission is influenced by obesity, prehospital morbidity, and fluid resuscitation. In many instances, the height of the patient is unknown, particularly outside of the surgical ICUs, and women in particular are mostly affected. Han et al recently showed that patient height is a significant factor in predicting provider adherence with lung-protective ventilation guidelines and women are less likely than men to receive low TV during the first 48 hours of critical illness.³³ Because obesity is more common among adult women than men in the United States, the use of actual body weight would result in larger TVs for women.

Currently, the lung-protective strategy recommends a TV of 6 to 8 mL/kg of PBW in ARDS. Recent data from the United States and Europe indicate that the average TV in ARDS patients receiving lung-protective ventilation is close to 8 cc/kg PBW (the accepted upper limit of a low TV strategy in the ARMA trial).³⁴⁻³⁶ Epidemiologic data from the Irish Critical Care Trials group reported a mean TV of 8.4 mL/kg IBW.³⁷ The ALIEN Network reported a mean TV of 7.2 mL/kg PBW and a mean Ppl of 26 cm H₂O in the Spanish ICUs.³⁸ In a secondary analysis of 829 patients on mechanical ventilation at 22 centers in the United States, Chang et al found that patients initially intubated with ARDS had a median TV of 7.96 mL/kg PBW which was significantly lower than the median TV in patients without ARDS (8.45 mL/kg PBW) ($P = 0.004$). Although the difference between the 2 groups was statistically significant, the absolute difference in TVs was quite small (< 0.5 mL/kg IBW).³⁹ This study suggests that in recent years mechanical ventilation practices have moved toward the use of lower TVs even in patients without ARDS and this trend may obscure any differences in ventilator-related outcomes.

CONCLUSIONS

After decades of research, there is still much uncertainty regarding the best ventilator care for patients with ARDS. The ongoing debate on the beneficial effects of the lung-protective strategy using a low TV approach has hindered the implementation of this

ventilation strategy in clinical practice. Although recent United States and European data show a shift in mechanical ventilation practices in recent years, there are still multiple barriers to achieve what is considered the best evidence-based medicine.

The evidence to date strongly suggests that ventilation with high TV and high P_{pl} is associated with increased risk of death and a definite trend has been seen toward using lower TV in ARDS and non-ARDS patients. There is a clear benefit of low TV ventilation on mortality; however, there are no RCTs comparing ventilation with a TV of 6 to 8 mL/kg PBW to a TV of 8 to 10 mL/kg PBW in ARDS patients. ARDS is a heterogeneous disease process and physicians may encounter situations where ventilation with TV even lower than 6 mL/kg PBW might be desired to minimize lung strain, maintain acceptable airway pressures, and hence may risk significant metabolic and hemodynamic instability. Adjunctive techniques aimed at removing excess CO₂ may counteract the metabolic derangements encountered in clinical practice.

Individualization of care is where the true artist of medicine excels and there is no substitute for the clinician's judgment at the bedside monitoring the response to the necessary adjustments in the ventilator. A gentle and safe ventilator strategy requires careful titration of the TV and airway pressures by the clinician in order to minimize lung injury and maintain adequate oxygenation using all available tools and evidence-based medicine at the bedside.

Controversies: Corticosteroids for ARDS: Friend or Foe?

68

Paul E. Marik, MD, FCCM, FCCP

INTRODUCTION

The acute respiratory distress syndrome (ARDS) is a common and vexing problem faced by critical care providers worldwide. Despite extensive investigation over the last three decades, the impact of ARDS in terms of morbidity, mortality, and health care costs remains very high. In the United States alone, ARDS affects as many as 200,000 people per year with a mortality rate from 30% to 50% and costs in excess of \$60,000 per hospitalization.^{1,2} The management of patients with ARDS is essentially supportive using a lung protective ventilatory strategy and treatment of the precipitating cause.³ The use of corticosteroids in patients with ARDS is controversial with widely dissenting opinions on this topic.⁴ At least 6 meta-analyses have been performed with conflicting conclusions.⁵⁻¹⁰ However, a summation of this data would suggest that glucocorticoids (GCs) improve oxygenation, increase the number of ventilator-free days, decrease intensive care unit (ICU) and hospital length of stay with a possible mortality benefit with no clear evidence of an increase in complications. Despite the potential benefit of GCs in patients with ARDS, survey data suggest that most clinicians do not prescribe these agents to their patients with ARDS.¹¹ The purpose of this review is to outline the rationale for GC treatment in ARDS, discuss the factors affecting response to treatment, review the results of clinical trials and the myths concerning GC-related side effects and outline a protocol for GC treatment based on the best available data.

BRIEF REVIEW OF PATHOGENESIS

ARDS develops rapidly, in most patients within 12 to 48 hours of developing an illness associated with severe systemic inflammation. Injury to the

alveolar-capillary membrane (ACM) causes exudative neutrophilic inflammatory edema, resulting in severe gas exchange impairment and lung compliance abnormalities. The lung-injury score (LIS) quantifies the impaired respiratory physiology in ARDS by using a 4-point score based on the level of positive end-expiratory pressure (PEEP), ratio of partial arterial oxygen tension (PaO_2) to fraction of inspired oxygen (FiO_2) ($\text{PaO}_2:\text{FiO}_2$), the quasistatic lung compliance, and the degree of infiltration on chest radiograph.¹² Using these criteria, the evolution of ARDS can be divided into resolving and unresolving ARDS based on achieving a 1-point reduction in LIS by day 7.¹³

Experimental and clinical evidence has demonstrated a strong cause and effect relationship between persistence in systemic inflammation and progression (unresolving) of ARDS. At the cellular level, patients with unresolving ARDS have inadequate GC-GR receptor (GR)-mediated downregulation of inflammatory transcription factor nuclear factor- κB (NF- κB) despite elevated levels of circulating cortisol, a condition recently defined as critical-illness-related corticosteroid insufficiency (CIRCI).^{14,15} Patients with unresolving ARDS have persistent elevation in both systemic and bronchoalveolar lavage (BAL) levels of inflammatory mediators, markers of fibrogenesis, and ACM permeability. At the tissue level, uninhibited increased NF- κB activation leads to ongoing tissue injury, intravascular and extravascular coagulation, and proliferation of mesenchymal cells, resulting in maladaptive lung repair and ultimately end-organ dysfunction and failure.¹⁴ The ability of activated GC-GR to downregulate systemic inflammation and restore tissue homeostasis can be significantly enhanced with exogenous GC treatment.¹⁶ In a randomized trial,¹⁷ longitudinal measurements of biomarkers provided compelling evidence that prolonged methylprednisolone treatment modifies CIRCI and

positively affects all aspects of ARDS.¹⁸ Treatment with prolonged methylprednisolone was associated with increased GC-GR α activity and reduced NF- κ B DNA binding and transcription of inflammatory mediators.¹⁶ In ARDS, methylprednisolone treatment led to rapid and sustained reduction in plasma and BAL levels of proinflammatory mediators,^{16,19} chemokines and adhesion molecules, and markers of fibrogenesis²⁰ and ACM permeability¹⁹ while increasing the anti-inflammatory cytokine interleukin-10 (IL-10) and anti-inflammatory to proinflammatory cytokine ratios.

FACTORS AFFECTING
RESPONSE TO PROLONGED
GLUCOCORTICOID
TREATMENT

Duration of treatment is an important determinant of both efficacy and toxicity. Optimization of GC treatment is affected by 3 factors: (1) actual biological duration of the disease process (systemic inflammation and CIRCI), (2) recovery time of the hypothalamic-pituitary-adrenal (HPA) axis, and (3) cumulative risk associated with prolonged treatment (risk) and the essential role of secondary prevention (risk reduction).

1. Longitudinal measurements of plasma and BAL inflammatory cytokine levels in ARDS showed that inflammation extends well beyond resolution of respiratory failure.^{14,21,22} One uncontrolled study found that, despite prolonged methylprednisolone administration, local and systemic inflammation persisted for 14 days (limit of study).¹⁹ Similar findings were reported in an randomized controlled trial (RCT) for inflammatory mediators on day 10 of treatment.¹⁶
2. Prolonged GC treatment is associated with downregulation of the GR levels and suppression of the HPA axis (reviewed later), affecting systemic inflammation after discontinuing treatment. Experimental and clinical literature underscores the importance of continuing GC treatment beyond clinical resolution of acute respiratory failure (extubation).⁹ In the recent ARDS Network

trial, methylprednisolone was removed within 3 to 4 days of extubation and likely contributed, as acknowledged by the authors, to the deterioration in PaO₂:FiO₂ ratio and higher rate of reintubation and associated mortality.^{9,23} In 2 other ARDS trials,^{17,24} GC treatment was continued for up to 18 days to maintain reduction in inflammation.^{17,24} Prolonged GC treatment was not associated with relapse of ARDS.

3. **Table 68–1** shows potential complications masked by or associated with prolonged GC treatment and secondary prevention measures.
Infection surveillance—Failed or delayed recognition of nosocomial infections in the presence of a blunted febrile response represents a serious threat to the recovery

TABLE 68–1 Potential complications associated with prolonged glucocorticoid treatment and secondary prevention measures.

Potential Complications	Secondary Preventive Measures
Glucocorticoids blunt the febrile response leading to failed or delayed recognition of nosocomial infections	Surveillance BAL sampling at 5-7 days intervals in intubated patients. Systematic diagnostic protocol if patient develops signs of infection
Glucocorticoids given in combination with neuromuscular blocking agents increase the risk of prolonged neuromuscular weakness	Avoid concomitant use of neuromuscular blocking agents
Glucocorticoids given as intermittent bolus produce glycemic variability	Following an initial bolus, administer glucocorticoids as a constant infusion
Rapid tapering is associated with rebound inflammation and clinical deterioration	Slow taper over 9-12 days. During and after taper monitor CRP and clinical variables, if patient deteriorates escalate to prior dosage or restart treatment
Suppression of endogenous cortisol synthesis	Avoid concomitant use of etomidate which causes further suppression of cortisol synthesis

of patients receiving prolonged GC treatment. In 2 randomized trials^{17,24} that incorporated infection surveillance, nosocomial infections were frequently (56%) identified in the absence of fever. The infection surveillance protocol incorporated bronchoscopy with bilateral BAL at 5- to 7-days intervals in intubated patients (without contraindication) and a systematic diagnostic protocol when patients developed clinical and laboratory signs suggestive of infection in the absence of fever.²⁵

Increased risk for neuromuscular weakness with neuromuscular blocking agents—The combination of GCs and neuromuscular blocking agents versus GCs alone increases the risk for prolonged neuromuscular weakness.²⁶ Consequently the combined use of neuromuscular blocking agents and GCs were considered contraindicated. However, Papazian and colleagues randomized patients with severe ARDS to receive cisatracurium besylate or placebo for 48 hours.²⁷ In this study, about 40% of patients were concomitantly receiving GCs. The incidence of neuromuscular weakness was similar in both groups. This study suggests that it may be safe to use GCs together with a short course of a neuromuscular blocking agent; however, the prolonged use of a neuromuscular blocking agent should be avoided.

GC treatment can impair glycemic control—It is well established that exogenous GCs administered as a bolus produce hyperglycemic variability, an independent predictor of ICU and hospital mortality.²⁸ Two studies have shown that GC infusion is superior to intermittent boluses in preventing glycemic variability by decreasing changes in insulin infusion rate.^{29,30}

Avoidance of rebound inflammation—There is ample evidence^{20,31-37} that early removal of GC treatment may lead to rebound inflammation and an exaggerated cytokine

response to endotoxin.³⁸ Experimental work has shown that short-term exposure of alveolar macrophages³⁹ or animals to dexamethasone is followed by enhanced inflammatory cytokine response to endotoxin.⁴⁰ Similarly, normal human subjects pretreated with hydrocortisone had significantly higher tumor necrosis factor alpha (TNF- α) and IL-6 response after endotoxin challenge compared to controls.⁴¹ Two potential mechanisms may explain rebound inflammation: homologous downregulation and GC-induced adrenal insufficiency. GC treatment downregulates the GR levels in most cell types, thereby decreasing the efficacy of the treatment. The mechanisms of homologous downregulation have been reviewed elsewhere.⁴² Downregulation takes place at both the transcriptional and translational level, and hormone treatment decreases receptor half-life by approximately 50%.⁴² In experimental animals, overexpression of GRs improves resistance to endotoxin-mediated septic shock while GR blockade increases mortality.⁴³ No study (to the best of our knowledge) has investigated recovery of GR levels and function following prolonged GC treatment in patients with sepsis or ARDS.

REVIEW OF CONTROLLED CLINICAL STUDIES

Eight controlled studies (5 RCTs and three cohorts) have evaluated the effectiveness of prolonged GC treatment initiated before day 14 of early ALI/ARDS (N = 334)^{24,44-46} and late ARDS (N = 235).^{17,23,47-49} These trials consistently reported that treatment-induced reduction in systemic inflammation^{17,23,24,45-47,49} was associated with significant improvement in PaO₂: FiO₂,^{17,23,24,45-47,49} and significant reductions in multiple-organ dysfunction score,^{17,23,24,45,47,49} duration of mechanical ventilation,^{17,23,24,44-46} and ICU length of stay (all with P values < 0.05).^{17,23,24,44,45} Four of the 5 randomized trials provided Kaplan Meier curves for

continuation of mechanical ventilation; each showed a 2-fold or greater rate of extubation in the first 5 to 7 days of treatment.^{17,23,24,45} In the ARDS Network trial, the treated group—before discontinuation of treatment—had a 9.5-days reduction in duration of mechanical ventilation (14.1 ± 1.7 vs 23.6 ± 2.9 ; $P = 0.006$) and more patients discharged home after initial weaning (62% vs 49%; $P = 0.006$).²³ As shown in [Figure 68–1](#), GC treatment initiated before day 14 of ARDS was associated with a marked reduction in the risk of death (Relative Risk (RR) = 0.68, 95%CI: 0.56-0.81; $P < 0.001$; I^2 56%).⁹ There was, however, significant heterogeneity between studies. As a result of the marked differences in study design and patient characteristics, the limited size of the studies (fewer than 200 patients), the cumulative mortality summary of these studies should be interpreted with some caution. For this reason, a recent consensus statement recommended early initiation of prolonged GC treatment for patients with severe ARDS ($\text{PaO}_2\text{:FiO}_2 < 200$ on PEEP 10 cm H₂O) and before day 14 for patients with unresolving ARDS.¹⁵ The ARDS Network trial reported that treated patients had increased mortality when randomized after day 14 of ARDS (8% vs 35%; $P = 0.01$).²³ This subgroup ($N = 48$), however, had large differences in baseline characteristics, and the mortality difference lost significance ($P = 0.57$) when the analysis was adjusted for these imbalances.⁵⁰

MYTHS ABOUT COMPLICATIONS OF PROLONGED GLUCOCORTICOID TREATMENT

The most commonly cited complications that might temper enthusiasm for GC treatment include increased risks of infection and neuromuscular weakness. Substantial evidence has accumulated showing that systemic inflammation is also implicated in the pathogenesis of these complications,⁵¹⁻⁵³ suggesting that treatment-induced downregulation of systemic inflammation could theoretically prevent, or partly offset, their development and/or progression.

GC treatment does not increase infection risk—

Contrary to older studies investigating a time-limited (24-48 hours) massive daily dose of GCs (methylprednisolone, up to 120 mg/kg/day),^{54,55} recent trials have not reported an increased rate of nosocomial infections. In fact, new cumulative evidence indicates that downregulation of life-threatening systemic inflammation with prolonged low-to-moderate dose GC treatment improves innate immunity^{37,56} and provides an environment less favorable to the intracellular and extracellular growth of

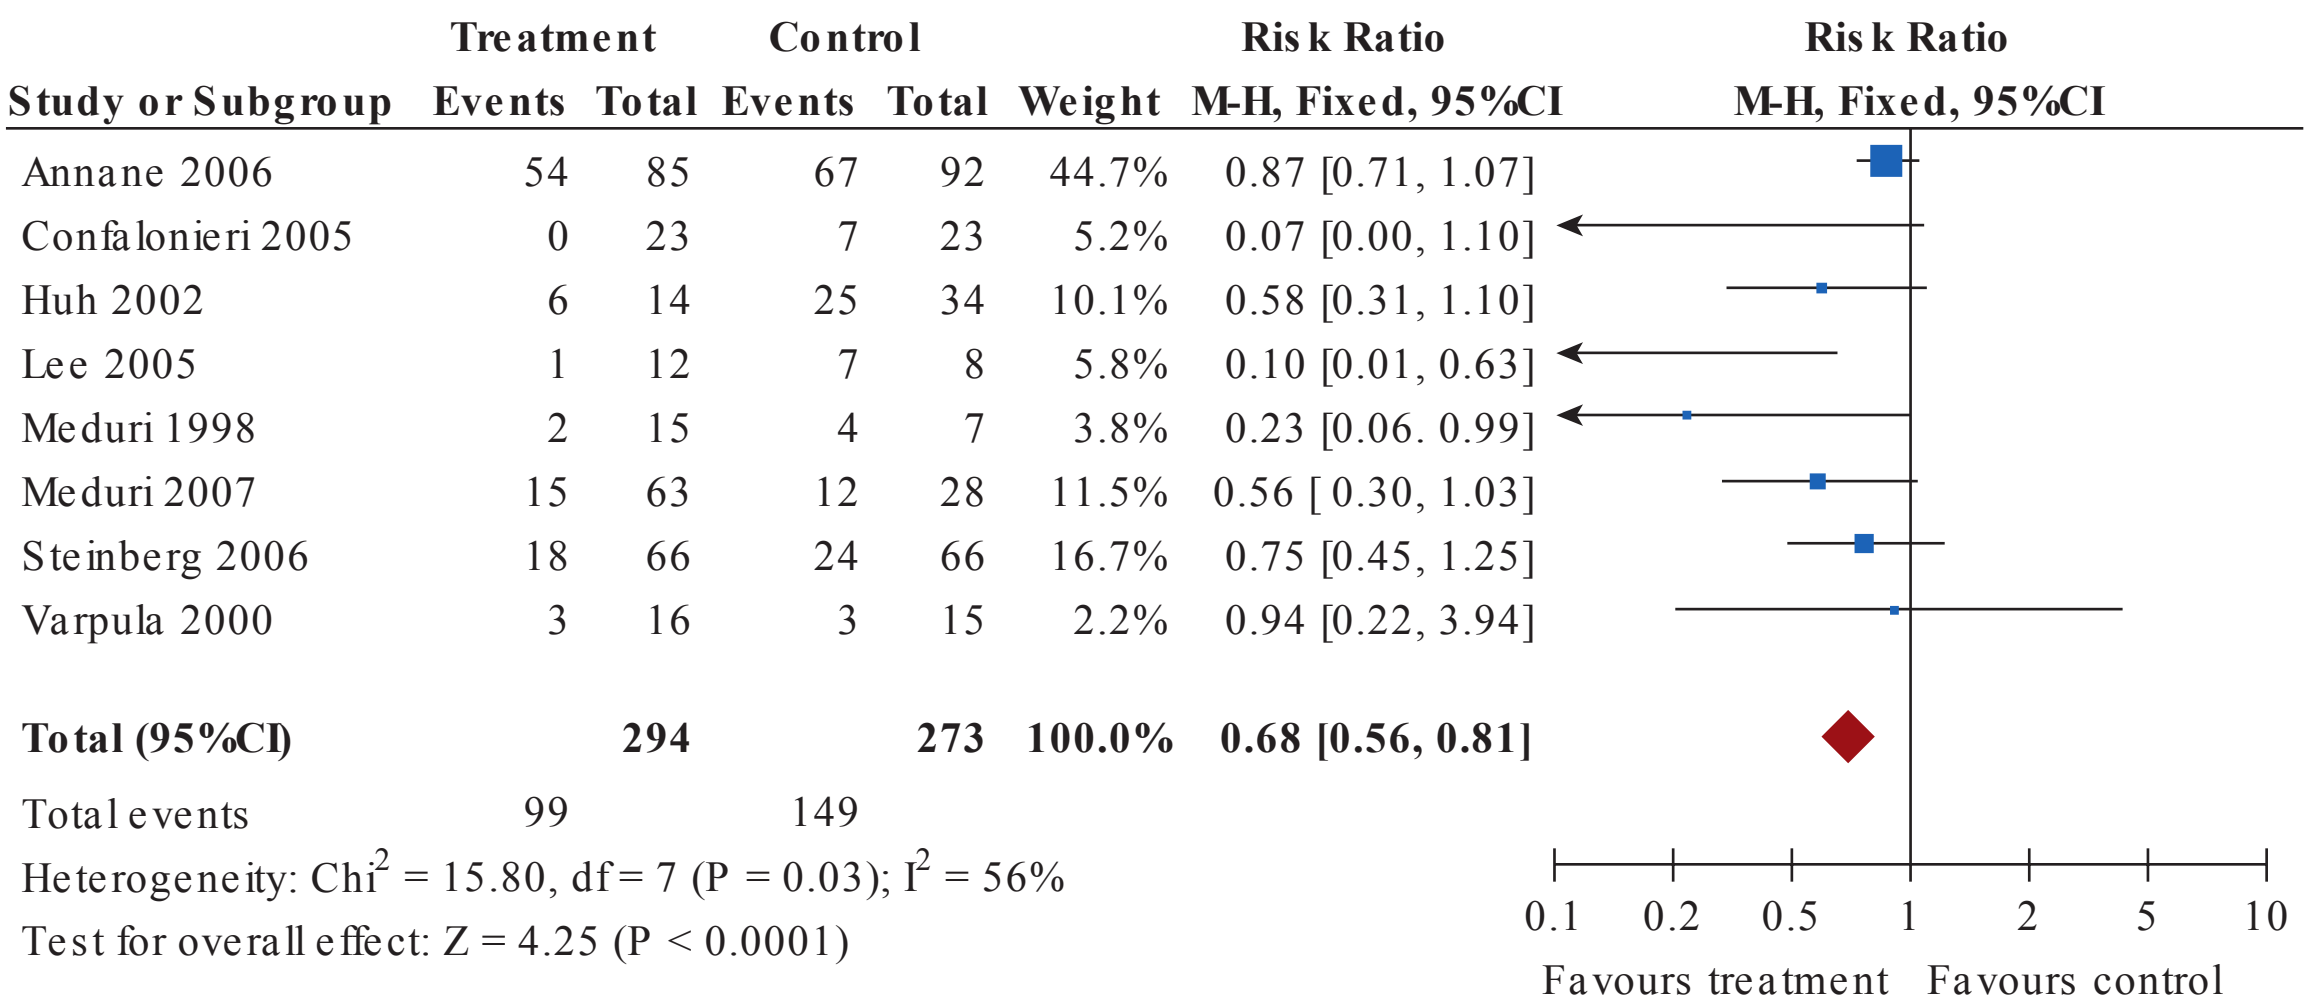

FIGURE 68–1 Effects of prolonged glucocorticoid treatment on acute respiratory distress syndrome survival.

bacteria.⁵⁷ GCs, however, do blunt the signs and symptoms of infection as detailed above (Table 68–1).

GC treatment does not increase the risk of neuromuscular weakness—The incidence of neuromuscular weakness is similar between groups treated with or without prolonged GCs (17% vs 18%).⁷ Two recent studies found no association between prolonged GC treatment and electrophysiologically or clinically proven neuromuscular dysfunction.^{58,59} Given that neuromuscular dysfunction is an independent predictor of prolonged weaning⁶⁰ and ARDS randomized trials have consistently reported a significant reduction in duration of mechanical ventilation,^{17,23,24,45,46} clinically relevant neuromuscular dysfunction caused by GC or GC-induced hyperglycemia seems highly unlikely. It should be noted that the combination of GCs and neuromuscular blocking agents versus steroids alone significantly increases the risk for prolonged neuromuscular weakness (Table 68–1).²⁶

RECOMMENDATIONS FOR TREATMENT

We have reviewed data showing that the benefit-risk of GC treatment in ARDS is largely determined by the drug dosage, timing and duration of administration, weaning protocol, and implementation of secondary preventive measures. The results of one randomized trial in patients with early severe ARDS²⁴ indicates that 1 mg/kg/day of methylprednisolone given as an infusion and tapered over 4 weeks is associated with a favorable risk-benefit profile when secondary preventive measures are implemented. Treatment response should be monitored with daily measurement of LIS and multiple-organ dysfunction syndrome (MODS) scores and C-reactive protein level.^{24,45} Secondary prevention is important to minimize complications. GC treatment should be administered as a continuous infusion (while the patient is in ICU) to minimize glycemic variations.^{29,30} GC treatment blunts the febrile response; therefore, infection surveillance is essential to identify early and treat nosocomial

infections (as outlined above). Finally, a slow GC dosage reduction (9–12 days) after a complete course allows recovery of GR numbers and the HPA axis, thereby reducing the risk of rebound inflammation. Laboratory evidence of physiologic deterioration (ie, worsening PaO₂:FiO₂) associated with rebound inflammation (increased serum C-reactive protein) after the completion of GC treatment may require reinstitution of treatment.

GLUCOCORTICOIDS TO PREVENT ALI/ARDS

As GCs have demonstrated a benefit in patients with established ARDS it has been postulated that these agents may be useful in preventing ARDS. Four studies have tested this hypothesis; however, this strategy was associated with a trend to an increase in both the odds of developing ARDS and the risk of mortality in those who developed ARDS.⁵ The reason for the seemingly differential effect of preventative and therapeutic steroid therapy in ARDS is unclear. In a propensity-based analysis of a large hospital database, the concurrent use of corticosteroids at the time of hospitalization did not reduce the risk of developing ARDS nor did it affect the requirement for mechanical ventilation or influence mortality.⁶¹

SUMMARY AND CONCLUSIONS

In this review, we presented a rationale for the use of GC treatment in ARDS. Based on molecular mechanisms and physiologic data, a strong association between dysregulated inflammation and progression of ARDS has been established. Further, these data support a strong association between treatment with exogenous GCs leading to regulation of the inflammatory response, improvement in organ physiology (LIS, MODS), and resolution of ARDS. The available clinical trials of prolonged GC treatment show favorable effects on clinical outcomes including ventilator-free days, ICU-free days, and mortality. Although the balance of the available data from controlled trials provides strong evidence for improvement in patient-centered outcomes (sizeable reduction in duration of mechanical ventilation and

ICU length of stay) and weak evidence for a survival benefit, the findings recently reported with low-dose methylprednisolone (1 mg/kg/day) in early severe ARDS²⁴ should be replicated in a larger trial of patients with ALI/ARDS.

Thrombolytic Therapy for Submassive Pulmonary Embolism

Samarth Beri, MD and Stephen M. Pastores, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 Acute pulmonary embolism (PE) is the most frequent and potentially fatal venous thromboembolic event.
- 2 Clinically, acute PE can be classified as either massive or submassive. Thrombolytic therapy is the recommended treatment for patients with acute massive PE who are hemodynamically unstable and do not have a high bleeding risk.
- 3 In patients with submassive PE, the use of thrombolytic therapy remains controversial.
- 4 Risk stratification with echocardiography may assist when deciding to use thrombolytic therapy for hemodynamically stable patients with submassive PE and evidence of right ventricular (RV) dysfunction.
- 5 Echocardiographic findings in patients with acute PE include RV hypokinesis and dilatation, interventricular septal fattening and paradoxical motion toward the left ventricle, tricuspid regurgitation, pulmonary hypertension and loss of inspiratory collapse of the inferior vena cava.
- 6 The hemodynamic status of the patient with acute PE is the most significant predictor of mortality in the short term.
- 7 Among patients with submassive PE being treated with unfractionated heparin, the administration of tenecteplase reduced the composite endpoint of all-cause mortality or hemodynamic decompensation at 7 days when compared to placebo but was associated with an increased rate of bleeding.

INTRODUCTION

Acute pulmonary embolism (PE) remains the most frequent and potentially fatal venous thromboembolic event. It is estimated that 100,000 to 180,000 deaths occur annually in the United States from acute PE. The outcome of acute PE depends on both the severity of pulmonary arterial obstruction and the presence and severity of preexisting cardiopulmonary disease in the patient. Acute PE can be classified as massive or submassive. Massive PE accounts

for 5% of patients with acute PE and is associated with hypotension (defined as systolic blood pressure [SBP] less than 90 mm Hg or a decrease in SBP of 40 mm Hg or more from baseline) and frequently results in acute right ventricular (RV) failure. Submassive PE accounts for approximately 20% to 25% of patients with acute PE and is associated with normotension and evidence of RV dysfunction including RV enlargement documented by transthoracic echocardiography or computed tomographic (CT)

pulmonary angiography and elevated biomarkers of myocardial injury (troponins I or T- and B-type natriuretic peptide [BNP]).¹⁻³

The recent guidelines from the American College of Chest Physicians and American Heart Association recommend treatment with thrombolytic agents for patients with acute massive PE who present with persistent hypotension and do not have a high bleeding risk.^{4,5} Several studies have demonstrated that thrombolytic therapy offers angiographic and hemodynamic benefits compared with standard heparin anticoagulation for patients with acute PE.^{4,5} The most studied thrombolytic agents for the treatment of PE are recombinant-tissue-type plasminogen activator (TPA, alteplase), streptokinase, and recombinant human urokinase. Other agents include tenecteplase, and reteplase. Absolute contraindications include any prior intracranial hemorrhage, known structural intracranial cerebrovascular disease (eg, arteriovenous malformation), known malignant intracranial neoplasm, ischemic stroke within 3 months, suspected aortic dissection, active bleeding or bleeding diathesis, recent surgery encroaching on the spinal canal or brain, and recent significant closed-head or facial trauma with radiographic evidence of bony fracture or brain injury.⁴

The use of thrombolytic therapy in patients with submassive PE remains controversial. This chapter will discuss the role of thrombolytic therapy in submassive PE focusing on risk stratification and the complex decision to administer systemic thrombolysis in patients with acute submassive PE.

RISK STRATIFICATION IN ACUTE PE

In recent years, there has been an increased appreciation of the need for risk stratification of patients with acute submassive PE who are hemodynamically stable but with evidence of RV dysfunction.⁶ In these patients, RV dysfunction is defined as the presence of at least one of the following: RV dilatation (apical 4-chamber RV diameter/left ventricular [LV] diameter more than 0.9 on echocardiography or chest CT, or RV systolic dysfunction on echocardiography); elevation of BNP more than 90 pg/mL or N-terminal pro-BNP more than 500 pg/mL; or

electrocardiographic changes including new complete or incomplete right bundle branch block, anteroseptal ST-segment elevation or depression, or anteroseptal T-wave inversion. Myocardial necrosis is defined as either elevation of troponin I (> 0.4 ng/mL) or troponin T (> 0.1 ng/mL).^{4,5} Several studies have shown a 2- to 2.5-fold increased risk of mortality in patients with normal BP and RV dysfunction compared with those without RV dysfunction.^{4,5}

Imaging of the RV with echocardiography detects the changes occurring in the morphology and function of the RV as a result of acute pressure overload in PE.⁶ Echocardiography also allows for estimation of pulmonary artery pressure. Echocardiographic findings in patients with acute PE include RV hypokinesis and dilatation, interventricular septal flattening and paradoxical motion toward the left ventricle, tricuspid regurgitation, pulmonary hypertension, and loss of inspiratory collapse of the inferior vena cava.¹ Several studies including registries have demonstrated an association between echocardiographic parameters of RV dysfunction and a poor in-hospital outcome.⁶⁻⁸ Nevertheless, the prognostic value of echocardiography in hemodynamically stable patients appears moderate at best, primarily due to the poor standardization of echocardiographic criteria.^{7,8} In a prospective randomized trial, Konstantinides et al reported that normotensive patients with submassive PE defined by echocardiography appeared to have a low early mortality risk, regardless of whether they received thrombolysis plus heparin or heparin alone.⁹

Four-chamber views of the heart on multidetector-row chest CT may, besides visualizing the thrombi in the pulmonary vasculature, also detect RV enlargement and (indirectly) dysfunction.⁷ In an international prospective cohort study, Becattini et al confirmed the prognostic value of an enlarged right ventricle on CT in patients with acute PE.¹⁰ However, RV dilatation on CT has been shown to have resulted in only a small ability to classify risk in these patients.¹¹

Elevated levels of cardiac biomarkers (troponins I or T and BNP), in combination with the presence of RV dilatation or hypokinesis on echocardiography significantly helps with risk stratification for acute PE.¹²⁻¹⁶ Elevated troponins are often found in hemodynamically stable patients with echocardiographic signs of RV overload suggesting myocardial injury.² Pruszczyk

and colleagues found that an elevated troponin T level more than 0.01 ng/mL was the only parameter to predict adverse events in normotensive patients with acute PE.¹³ In a multicenter, multinational study, the high-sensitivity troponin was examined in 526 normotensive patients with PE and demonstrated a high negative predictive value (98%).¹⁴ Similarly, a meta-analysis of 1132 patients showed that 51% of patients with an acute PE had elevated BNP or NT-pro-BNP and were associated with increased early death and complications during hospitalization.¹⁵ However, the positive predictive value of BNP or NT-pro-BNP for higher risk has been rather low.

Heart-type fatty acid-binding protein and growth differentiation factor-15 are 2 promising new cardiac biomarkers that have been shown to provide relevant prognostic information in patients with non-high-risk PE.⁶ Both of these biomarkers increase sharply after pressure overload or myocardial ischemia and are undergoing further study.

The most extensively validated clinical score for risk stratification of patients presenting with PE is the Pulmonary Embolism Severity Score (PESI).^{17,18} The PESI allows the clinician to rule out an adverse outcome by having a high negative predictive value at the lowest level of PESI classes. The score is however complex to calculate. A more practical approach is the use of the simplified PESI (sPESI) score with 6 parameters: age more than 80 years, history of cancer, history of either heart failure or chronic lung disease, systolic BP less than 100 mm Hg, heart rate more than 110 beats/min, and an arterial oxyhemoglobin saturation less than 90%.¹⁹

DECISION-MAKING IN ACUTE SUBMASSIVE PE

The hemodynamic status of the patient with PE is the most significant predictor of mortality in the short term. Early mortality rates for PE range from 3% in clinically stable patients to 58% in patients with cardiogenic shock.²⁰ If the patient survives the initial presentation of PE, the most common cause of death during the first month is PE-associated RV dysfunction.²¹ Cardiac failure from PE is due to a combination of the increased wall stress and cardiac ischemia that compromise RV function and impair

LV output.²² The development of recurrent PE or progression of RV dysfunction in patients with submassive PE may lead to hemodynamic collapse, even though these patients may have initially presented with hemodynamic stability. Thus the practice of evaluating risk in patients with PE based solely upon the presence of hypotension may neglect key prognostic features and may delay further prognostic testing and initiation of more appropriate therapy.²² Risk stratification is therefore, paramount to differentiate between subsets of patients.

The outcomes of patients with PE who have received thrombolytic therapy have been reviewed from 4 large registries: Management Strategy And Prognosis of Pulmonary Embolism Registry (MAPPET), International Cooperative Pulmonary Embolism Registry, Registro Informatizado de la Enfermedad TromboEmbolica, and Emergency Medicine Pulmonary Embolism in the Real-World Registry (EMPEROR).^{4,5,20,23} These registries have reported a trend toward a decrease in all-cause mortality from PE, especially massive PE in those patients who received thrombolytic therapy. The 30-days mortality from PE in normotensive patients in the EMPEROR was 0.9% (95%CI: 0%-1.6%).²³ The recently completed Prognostic Value of Multidetector CT Scan in Hemodynamically Stable Patients With Acute Symptomatic Pulmonary Embolism study of normotensive patients with acute PE showed a 30-days PE-related mortality of 1.3% (95%CI: 0.5%-2.1%).²⁴ Overall, these studies have showed that short-term mortality directly attributable to submassive PE in patients treated with heparin anticoagulation is less than 3%. The investigators have concluded that even if adjunctive thrombolytic therapy has an extremely high efficacy (eg, 30% relative reduction in mortality), the effect size on mortality due to submassive PE is probably less than 1%. They propose that secondary outcome measures such as persistent RV dysfunction and chronic thromboembolic pulmonary hypertension (CTEPH), and impaired quality of life be used as important surrogate goals of treatment.^{4,22} CTEPH is a rare but serious complication, affecting patients who survive acute PE. It can cause severe RV dysfunction and is often lethal. The etiology of CTEPH is unclear but proposed mechanisms include intricate and complex interactions involving thrombotic

and thrombolytic processes and cellular remodeling confounded by various predisposing risk factors.^{4,25}

A prospective evaluation of RV function and functional status 6 months after acute submassive PE showed that in patients who received heparin only, 27% demonstrated an increase in RV systolic pressures (RVSP) at 6-months follow-up, and 46% had either dyspnea at rest or exercise intolerance.²⁶ Interestingly, not a single patient treated with TPA showed an increase in RVSP suggesting that thrombolytic therapy may have benefit in reducing the incidence of CTEPH. More recently, the results of the Moderate Pulmonary Embolism Treated with Thrombolysis trial showed that the incidence of pulmonary hypertension was lower in patients who received TPA and concomitant anticoagulation with reduced-dose enoxaparin or unfractionated heparin than in the standard anticoagulation group (16% vs 57%, $P < 0.001$). There were no in-hospital bleeding events reported in either group.²⁷

STUDIES OF THROMBOLYTIC THERAPY FOR SUBMASSIVE PE

Three randomized controlled trials (RCTs) were specifically aimed to address the patients with submassive PE benefit from thrombolytic therapy: MAPPET-3, Tenecteplase Italian Pulmonary Embolism Study (TIPES), and the Pulmonary Embolism Thrombolysis (PEITHO) trials.^{9,28,29} Of note, tenecteplase is not approved by the Food and Drug Administration in the United States for the treatment of PE.

In the MAPPET-3 trial, 256 hemodynamically stable patients with acute submassive PE were randomized to receive intravenous (IV) recombinant TPA 100 mg over 2 hours followed by unfractionated heparin infusion or placebo TPA plus heparin anticoagulation.⁹ The primary endpoint was in-hospital death or clinical deterioration requiring escalation of therapy defined as catecholamine infusion, rescue fibrinolysis, mechanical ventilation, cardiopulmonary resuscitation, or emergency surgical embolectomy. The investigators found that compared with heparin anticoagulation alone, thrombolytic therapy resulted in a significant reduction in the primary endpoint (10.2% vs 24.6%, $P = 0.004$). They ascribed the difference in the primary endpoint to a higher

frequency of escalation of therapy in patients randomized to heparin anticoagulation alone compared to those treated with TPA. Both groups had low rates of major bleeding, although the heparin treatment group, surprisingly, had a trend toward more major bleeding episodes compared to the TPA-treatment group (3.6% vs 0.8%, $P = 0.29$).⁹

The TIPES trial randomized 58 patients to receive weight-adjusted single-bolus IV tenecteplase or placebo.²⁸ The primary efficacy endpoint was reduction of RV dysfunction on echocardiography at 24 hours. The investigators found that in the tenecteplase group, there was a 0.31 ± 0.08 reduction of the right-to-left ventricle end-diastolic dimension ratio at 24 hours versus a reduction of 0.10 ± 0.07 in the placebo group ($P = 0.04$). At 30 days, 1 patient randomized to tenecteplase suffered a clinical event (recurrent PE), versus 3 patients randomized to placebo (1 recurrent PE, 1 clinical deterioration, and 1 non-PE-related death). Two nonfatal major bleedings occurred with tenecteplase (1 intracranial), and 1 occurred with placebo.

The PEITHO trial was a prospective, multicenter, double-blind, placebo-controlled randomized trial of thrombolysis with a single-bolus injection of tenecteplase plus heparin versus placebo plus heparin in normotensive patients with submassive PE.^{29,30} Eligible patients were those with acute symptomatic PE confirmed by CT pulmonary angiography and RV dysfunction on echocardiography or CT plus evidence of myocardial injury with a positive troponin I or T value. The primary outcome was the composite of death from any cause or hemodynamic collapse within 7 days of randomization. A total of 1005 patients were included in the intention-to-treat analysis. The investigators found that a single-bolus injection of tenecteplase resulted in a significantly lower risk of early death or hemodynamic decompensation (2.6%) versus 5.6% in the placebo plus heparin group. However, tenecteplase was also associated with a 2% rate of hemorrhagic stroke and a 6.3% rate of major extracranial hemorrhage versus 0.2% and 1.2% in the placebo plus heparin group.

More recently, Kucher et al reported the results of the Ultrasound Accelerated Thrombolysis of Pulmonary Embolism trial.³¹ This trial randomized 59 patients with acute main or lower lobe PE and echocardiographic evidence of RV dysfunction to receive

unfractionated heparin and an ultrasound-assisted catheter-directed thrombolysis (USAT) regimen of 10 to 20 mg recombinant TPA over 15 hours or unfractionated heparin alone. The primary outcome was the difference in the RV/LV ratio from baseline to 24 hours. The authors found that a standardized USAT regimen was superior to anticoagulation with heparin alone in reversing RV dilatation at 24 hours, without an increase in bleeding complications. However, the study had several limitations including the lack of a thrombolysis control group without ultrasound, possible selection bias, lack of monitoring of quality of anticoagulation therapy with dose adjustments of heparin (based on activated partial thromboplastin time levels) and of vitamin K antagonists (based on international normalized ratio values), poor quality of the echocardiographic images in some patients and the lack of assessment of residual embolic burden by repeated contrast-enhanced CT.³⁰

SUMMARY

To date, there has been no adequately powered RCT that has demonstrated that the survival of patients with submassive PE is improved with the administration of thrombolytic therapy. Furthermore, there is currently no validated prediction rule that can identify the subgroup of patients with submassive PE who are at high risk for PE-related complications and who may benefit from thrombolysis. We believe that select patients with acute submassive PE who have severe RV dysfunction on echocardiography and myocardial injury (elevated troponin or BNP levels) and who are at low risk of bleeding complications may be considered for thrombolytic therapy. Ultimately, as other experts have suggested, clinicians should weigh the risks and benefits, consider the patients' preferences, clot burden, acute physiology, comorbidities, and bleeding risk on a case-by-case basis when deciding to use thrombolytic therapy for patients with submassive PE.³¹

Controversies: Enteral Nutrition—Pyloric Versus Postpyloric

Amar Anantdeep Singh Sarao and Roopa Kohli-Seth

INTRODUCTION

Critically ill patients are often in hypermetabolic states with increased nutritional needs. At the same time, however, such patients are often unable to take adequate oral intake, necessitating the use of supplementary nutrition. Maintaining adequate nutrition in the critically ill patient has shown to decrease infectious complications.¹ Early enteral nutrition in the critically ill mechanically ventilated patient has shown to decrease ICU and hospital mortality rates with the greatest benefit derived in the sickest of patients.² Malnutrition on the other hand is known to adversely impact the length of ICU and hospital stay.³ It is because of the benefits seen with providing optimal nutrition in the ICU that nutritional support therapy has now become an indispensable component in the management of the critically ill patient. Although nutrition can be provided via the enteral or parenteral route, the enteral route is preferred over the latter due to its lower cost, ease of institution and decreased infectious complications.⁴ Not using the gastrointestinal tract predisposes to gut mucosal atrophy, resulting in translocation of the bacteria across the gut wall leading to bacteremia.

Shock, sepsis, traumatic brain injury as well as pharmacologic agents commonly used in the ICU setting (opioid analgesics, vasoactive, and paralytic agents), all predispose critically ill patients to develop impaired gastric emptying and decreased enteral motility that is seen in up to 60% of this patient population.⁷ As a consequence of impaired gastrointestinal motility, high gastric residual volumes (GRVs) are frequently encountered. Finding high GRVs is often used clinically, as an indication of intolerance to enteral feeds. Feeds are thus held or stopped altogether upon encountering high GRVs. It is thought

that feeding past the pylorus may result in a lower incidence of high GRVs leading to fewer interruptions in enteral feeding and ultimately in increased nutritional delivery to the patient. However, whether routine monitoring of GRVs is warranted in the critically ill is yet another area of controversy.

ENTERAL NUTRITION: SITES OF DELIVERY

Enteral nutrition in the critically ill is usually delivered via an enteric tube which is inserted either through one of the nares or through the oral cavity. The distal tip of this tube may terminate in the stomach (nasogastric or orogastric tube) or in the duodenum (nasoduodenal tube) or alternatively in the jejunum (nasojejunal tube). These feeding tubes can be placed by surgical techniques as well, namely, gastrostomy (percutaneous endoscopic gastrostomy (PEG) if placed via an endoscopic technique) and jejunostomy (percutaneous endoscopic jejunostomy (PEJ) when placed via an endoscopic technique).

Feeding into the stomach is often termed pyloric or prepyloric feeding, whereas feeding into the duodenum or the jejunum is appropriately called postpyloric feeding because the distal end of the feeding tube rests past the pylorus. Although there are a relatively few clinical conditions ([Table 70–1](#)) in which feeding via the postpyloric route may be indicated, in a vast majority of the critically ill patients, the issue of pyloric versus postpyloric feeding has been an area of debate. Controversies surround issues of delivery of nutritional goals, time, and resources expended in placement of feeding tubes, as well as rates of infectious and noninfectious complications seen with the 2 modes of enteral feeding.

TABLE 70–1 Conditions in which postpyloric feeding may be clinically indicated.

- Proximal gastrointestinal fistulous disease such as a trachea-esophageal fistula
- Severe diabetic gastroparesis not responsive to medical therapy⁵
- Jejunal feeding in severe acute pancreatitis
- Hyperemesis gravidarum unresponsive to medical therapy⁶
- Gastric or duodenal outlet obstruction in neoplastic disease
- Certain postoperative states such as after Whipple's procedure

PLACEMENT OF ENTERIC TUBES

Before enteric feeds can be initiated, enteral access must first be obtained. Although the placement of nasogastric or orogastric tubes may be somewhat cumbersome for the patients, they are placed with a relative ease by the clinicians. Often air insufflation, although considered unreliable by many, and pH testing of the gastric contents are undertaken to confirm the placement of the nasogastric tube in the stomach. A chest X-ray (CXR) is also performed in order to confirm that the tip of the feeding tube is in its intended location and not in the lung.

Multiple techniques exist for the placement of postpyloric feeding tubes, and no one technique has been adopted as the standard. Methods employed in the placement of postpyloric feeding tubes range from blind placement at the bedside, placement under fluoroscopy guidance in the radiology suite, to placement by endoscopy under direct visualization. Techniques utilizing prokinetic agents, magnets, weighted-tip tubes, have been well described in literature for small bowel feeding tube placement at the bedside. Recently, CORPAK MedSystems, Inc. have introduced the CORTRAK 2 Enteral Access System to place postpyloric feeding tubes at the bedside. This method uses an electromagnetic sensing device placed on a patient's chest to track the path that the tip of the feeding tube takes and displays it on a visual monitor. Once the tube is placed in its intended location, the electromagnetic transmitting stylet, preinstalled in the feeding tube, is removed.

POINTS OF CONTROVERSY TIME AND RESOURCES UTILIZED IN PLACING POSTPYLORIC TUBES

Placement of postpyloric enteral tubes may take a considerable amount of time especially when these tubes are placed via endoscopy or fluoroscopic guidance as opposed to bedside techniques. Delays in placing small bowel or duodenal tubes primarily happen when the radiologist or the endoscopist is not available after-hours or during weekends or holidays. Scheduling difficulties with radiology or endoscopy suites also, at times, may contribute to delays in the placement of small bowel tubes. Delays of up to 24 hours to initiate feeds are not uncommon when postpyloric tubes are placed via the endoscopic method.⁸ Such delays in the initiation of feeds ultimately affect the amount of nutrition a critically ill patient receives during her or his stay in the ICU. Adequately trained ICU staff skilled in placing postpyloric tubes at the bedside, however, ameliorates the need to take the patient to radiology or endoscopy suites for placement of tubes. Median times as low as 6.6 hours from admission to the ICU or initiation of mechanical ventilation to begin feeding while achieving 80% success rate in placement of postpyloric tubes by bedside nurses has been reported.⁸ Placement of postpyloric tubes at the bedside also forgoes the risks associated with transporting a critically ill patient, along with the paraphernalia of tubes and machines, in and out of the ICU. Cost reductions of greater than 60% have been noted when postpyloric tubes are placed at the bedside by dietitians as opposed to placement by the radiologist under fluoroscopic guidance.⁹ It is advisable, thus, that an attempt to place a postpyloric feeding tube should ideally be made at the bedside by an adequately trained professional, preferably a nurse or a dietitian. If it proves difficult to obtain enteral access at the bedside, only then should alternate means to obtain enteral access be pursued.

ACHIEVING NUTRITIONAL GOALS IN THE CRITICALLY ILL PATIENTS

A number of studies have looked in to whether differences exist in achieving nutritional goals based on whether a patient is fed into the stomach or past the pylorus.

A fair number of studies have found that patients fed past the pylorus received greater amount of nutrition overall^{10–13} compared to those fed in to the stomach. Another set of studies, however, found no difference between the 2 groups.^{14,15} Evidence also exists which shows that those fed past the pylorus received less overall nutrition than those fed in to the stomach.⁸ One study found no difference over all, but upon a subgroup analysis found that in centers which have previous experience with postpyloric feeding, patients fed via the postpyloric route met nutritional goals more frequently than those fed in to the stomach.¹⁴ In a retrospective review of 150 episodes of postpyloric feeding in 146 patients, including 20 patients fed at home for various durations of time, nutritional

requirements were met in 90% of the patients.¹⁶ The results of these studies are summarized in [Table 70–2](#).

Meta-analyses that have evaluated this issue have yielded mixed results as well, with some that have reported no difference in achievement of nutritional goals^{17,18} while others that have reported a signal toward increased nutritional intake with postpyloric feeding.¹⁹

PNEUMONIA IN PYLORIC VERSUS POSTPYLORIC FEEDS

Given that critically ill patients have a high incidence of delayed gastric emptying, up to 60% in some studies,⁷ high GRVs are frequently

TABLE 70–2 Nutritional outcomes in pyloric versus postpyloric feeding in critically ill patients.

Study	Patient Type	Number of Patients	Results
Montecalvo et al	Mixed, medical, and surgical	38	PP group received higher nutritional intake, P value < 0.05
Kortbeek et al	Trauma (75% had head injury)	80	PP group reached target feed rate faster than P group. 34 vs 43.8 hours, P value < 0.02
Kearns et al	Medical	44	%REE higher in PP group. 69% vs 47%, P value < 0.05
Davies et al	Medical	73	PP group had significantly decreased GRV
Montejo et al	Mixed	101	NSG in caloric intake. Subgroup analysis limited to experienced centers: significantly higher nutritional intake in PP group
Jones et al	Mixed, not all patients critically ill, outpatients included in study also	150 episode of PP feeding in 146 patients	Nutritional goals met in 90% of cases
White et al	Medical	104	Pyloric group reached nutritional goals earlier, average daily energy deficit significantly higher in PP group
Hsu et al	Medical	121	Average daily nutritional intake significantly higher in PP group
Acosta-Escribano et al	Severe traumatic brain injury	104	Mean efficacious volume of diet delivered significantly higher in PP group. P value: 0.01
Davies et al	Mixed, on mechanical ventilation	181	NSG in nutrition delivered

P, pyloric; PP, postpyloric; NSG, no significant difference; %REE, (mean calories delivered/resting energy expenditure) × 100; NJ, naso-jejunal; GRV, gastric residual volume. Note that all studies listed in the table are randomized controlled trials except the study from Jones et al, which is a retrospective analysis.

encountered when these patients are fed in to the stomach. High GRVs are thought to predispose a critically ill patient to a higher chance of developing gastroesophageal reflux, leading to an increased incidence of macroaspiration and microaspiration of gastric contents ultimately resulting in greater incidence of pneumonia. The idea of feeding past the pylorus to decrease reflux, aspiration, and ultimately prevent pneumonia is not an unfounded one. It has been shown in clinical studies that feeding a patient past the pylorus significantly reduces gastroesophageal reflux and results in a trend toward decreased pulmonary aspiration.²⁰ Whether this decreased incidence of reflux and aspiration of gastric contents leads to clinically important outcomes such as decreased incidence of nosocomial and ventilator associated pneumonias, has been extensively debated in multiple studies.

CURRENT EVIDENCE VALUATING RISK OF PNEUMONIA IN PYLORIC VERSUS POSTPYLORIC FEEDING

A number of studies have found no significant difference in the incidence of pneumonia in

patients fed via the pyloric versus the postpyloric route.^{8,11,14,15,21} One of the earlier studies did however show a decreased incidence of pneumonia with postpyloric feeding compared to gastric feeding.¹⁰ Two additional studies have also shown a significant decrease in pneumonia with the use of postpyloric feeding as compared to prepyloric feeding.^{12,13}

Mostly, studies evaluating controversies surrounding pyloric versus postpyloric feeding have been relatively small. Given the plausibility of how postpyloric feeding can theoretically decrease the incidence of pneumonia and a number of studies showing both benefit and no benefit at all, a number of meta-analyses been carried out to investigate this issue further. Two of the earlier meta-analyses,^{17,18} which utilized 9 and 11 studies, respectively; found no difference in rates of pneumonia between the pyloric and postpyloric feeding groups. More recent meta-analyses,^{19,22} however, both of which are from 2013, with each including 15 studies, did show significant reduction in incidence of pneumonia with postpyloric feeds. [Table 70–3](#) summarizes the results of the studies exploring pneumonia in pyloric versus postpyloric feeding.

TABLE 70–3 Impact of pyloric versus postpyloric feeding on incidence of pneumonia in critically ill patients.

Study	Year of Publication	Patient Type	Number of Patients	Result
Montecalvo et al	1992	Mixed medical and surgical	38	2 episodes of pneumonia in gastric vs none in jejunal
Kortbeek et al	1999	Trauma (75% had head injury)	80	NSG
Kearns et al	2000	Medical	44	NSG
Montejo et al	2002	Mixed	101	NSG
White et al	2009	Mixed	104	NSG
Hsu et al	2009	Medical	121	8.6 vs 3.1 per 1000 ventilator days for P vs PP, P value: 0.01
Acosta-Escribano et al	2010	Severe traumatic brain injury	104	32% vs 57% for PP vs P, P value: 0.01
Davies et al	2012	Mixed, on ventilator	181	NSG

All studies are randomized controlled trials. P, pyloric; PP, postpyloric; NSG, no significant difference.

COMPLICATIONS OF PYLORIC VERSUS POSTPYLORIC FEEDING TUBES

A few studies have reported lower incidence of increased GRVs in the postpyloric group.^{13,14,26} Higher incidence of diarrhea, however, has been reported in the postpyloric group.¹⁰ This is at times attributed to the inability of the small bowel to handle high osmotic loads in polymeric feeds. Thus partially hydrolyzed or semielemental feeds may prove to be useful in these instances. Complications related to tube maintenance have been noted to be higher in the postpyloric group.^{14,16} Due to their smaller caliber, postpyloric tubes clog more frequently than gastric tubes. Tube blockage with postpyloric feeding tubes can be seen in up to 17% of the cases.¹⁶ Fifty-milliliter water flushes every 4 to 6 hours can help avoid clogging of the tubes. A meta-analysis¹⁸ found that proportion of patients needing an alternate form of feeding because of tube placement or tube blockage was significantly higher in the postpyloric group.

EFFECT ON MORTALITY, ICU AND HOSPITAL LENGTHS OF STAY

Most of the studies done to date have found no statistically significant difference in rates of mortality, ICU, or hospital lengths of stay.^{8,11,12,14,21} In addition, none of the meta-analyses conducted to date has shown a difference in mortality between the 2 groups.

CURRENT GUIDELINES

The 2009 American Society for Parenteral and Enteral Nutrition (ASPEN) guidelines²³ for nutrition support therapy in the critically ill do not make any specific recommendation for gastric or small bowel feeding and note that either of the two is an acceptable strategy. They do, however, recommend small bowel feeding for those at high risk of aspiration or intolerant of gastric feeding (grade C). These guidelines further recommend that withholding enteral feeds for multiple

episodes of high gastric residuals is sufficient for one to consider initiating small bowel feeding (grade E).

The 2013 Canadian critical care nutrition guidelines²⁴ suggest that feeding critically ill patients through the small bowel may be associated with a lower incidence of pneumonia. These guidelines recommend that in ICUs where placement of postpyloric tubes is feasible, critically ill patients should be routinely fed through the postpyloric route. In ICUs where logistical difficulties exist in obtaining postpyloric access, postpyloric feeding should be considered only in patients who are at high risk for intolerance to enteric nutrition such as those on continuous infusion of sedatives and opioids, vasoactive agents and paralytics. If small bowel access is not feasible due to lack of fluoroscopy or endoscopy or due to lack of expertise in blind techniques, postpyloric feedings should be considered only in those patients who are intolerant of gastric feeds and those who repeatedly demonstrate high GRVs.

FUTURE WORK NEEDED

With the current evidence that is available, it is clear that the controversy about pyloric versus postpyloric is far from over. Larger studies in the future may show clearer differences in clinical outcomes between pyloric and postpyloric feeding. There is evidence to suggest that differences in clinical outcomes from pyloric versus postpyloric feeding may not be achieved in less critically ill patients and that the benefit of postpyloric feeding may be primarily seen in those with ASPEN II scores greater than 20.²⁵

Controversies: Continuous Versus Intermittent Renal Replacement in the Critically Ill Patient

Min Jung Kim, MD and John M. Oropello, MD, FACP, FCCP, FCCM

INTRODUCTION

Acute kidney injury (AKI) is frequently a part of multiorgan dysfunction syndrome in critically ill patients in the intensive care unit (ICU), and a significant portion, about 2% in some reports,¹ will require renal replacement therapy (RRT). There is controversy about the optimal treatment of AKI regarding modality, dose, and appropriate timing of RRT.

RRT for AKI can be classified as intermittent or continuous, based on the duration of treatment. The duration of intermittent therapy is less than 24 hours, whereas the duration of continuous therapy is at least 24 hours. Intermittent RRT (IRRT) includes intermittent hemodialysis (IHD) and sustained low-efficiency dialysis (SLED). SLED refers to hemodialysis performed with a conventional dialysis machine over a longer time period (usually ≥ 5 hours) than traditional IHD. Continuous therapies include peritoneal dialysis and continuous RRT (CRRT). The 4 main types of CRRT by mechanism of solute removal are slow continuous ultrafiltration (fluid removal only); continuous venovenous hemofiltration (CVVH) (convection); CVV hemodialysis (CVVHD) (diffusion); and CVV hemodiafiltration (CVVHDF) (concurrent diffusion with convection). In developed countries, peritoneal dialysis is rarely used for AKI in the ICU setting because it provides inefficient solute clearance, increases the risk of peritonitis, and compromises respiratory function. In developing countries, peritoneal dialysis is still used for AKI due to low maintenance and cost.

MODALITIES OF RRT: IRRT VERSUS CRRT

Whether IRRT or CRRT influences clinical outcomes remains the subject of debate. Even though the worldwide standard RRT in the ICU is IHD, survey evidence has consistently shown considerable variation in RRT practice patterns. In recent years, the use of SLED has risen and is mainly driven by its convenience and lower cost compared to CRRT.

Several nonrandomized studies have suggested that CRRT may contribute to improved survival and a higher rate of renal recovery; however, other similar studies have failed to show any additional benefit with CRRT. The first randomized controlled trial (RCT) was done in 2001 by Mehta et al.² IHD was averaged 5 days/week for 3 to 4 hours per session. Univariate intention-to-treat analysis revealed a higher mortality among patients receiving CRRT. However, multivariate analysis revealed no impact of RRT modality on all-cause mortality or recovery of renal function. Because Mehta et al, there have been 8 RCTs, comparing CRRT and IRRT (Table 71–1) (IHD,^{3–8} SLED^{9,10}). There is significant variation among these RCTs in terms of study population (exclusion of chronic kidney disease, illness severity, and etiology of AKI), methods of RRT (criteria for RRT, device/technique, doses, and membrane material). Serious concerns have been identified in some trials due to unbalanced baseline characteristics, inappropriate sample size, and significant crossover between dialytic modalities.¹¹ Most studies^{3–5,7,8} used

TABLE 71–1 **Characteristics of CRRT and IRRT within randomized controlled trials.**

RRT Characteristics									
Trial	RRT Decision	IRRT Dose	IRRT Pump Speed	CRRT Dose	Mortality	Renal Recovery	Hypotension	Pressor Requirements	Fluid Balance/ Solute Clearance
Mehta et al ²	BUN > 40 mg/dL, serum Cr > 2.0 mg/d	IHD: 4 h/session; 5 days/week	200-300 mL/min	CAVHDF or CVVHDF: urea clearance 22 mL/min	ND ^a	ND	NA	NA	CRRT ^b /CRRT
John et al ⁵	serum Cr > 3 mg/dL, UO < 10 mL/h	IHD: 4 h/session	250 mL/min	CVVHF: 2 L/h	ND	NA	IHD > CVVH	ND	NA/CRRT
Gasparovic et al ⁴	3X □ Cr, hyperkalemia > 5.5 mmol/L, base deficit > 6	IHD: 3-4 h/session: daily	200-250 mL/min	CVVHF: 18 and 35 mL/kg/h	ND	NA	ND	NA	NA
Augustine et al ³	Clinical decision	IHD: K ⁺ /V 3.6/week; 3 sessions/week	300 mL/min	CVVHD: K ⁺ /V 3.6/week	ND	ND	IHD > CVVH	IHD	CRRT/NA
Uehlingger et al ⁷	serum Cr > 4 mg/dL, UO < 20 mL/h	IHD: urea clearance 200 mL/min: 3-4 h/session	150-350 mL/min	CVVHDF: 2 L/h or urea clearance 20 mL/min	ND	ND	ND	ND	ND/ND

	CRRT	IHD
Recovery of renal function	+	
Hemodynamic stability	+	
Control of azotemia and volume overload	+	
Clotting of dialysis filter and bleeding complications		+
Practicality and cost		+

CRRT, continuous renal replacement therapy; IHD, intermittent hemodialysis; +, advantage.

IHD 3 times per week; however, recently, Lins et al⁶ performed a multicenter prospective RCT comparing IHD (7 days/week, 4-6 hours per session) with CVVH, with a higher sample size, and better control of the severity of illness of the study population. Lins et al reported that after AKI, the modality of RRT had no impact on ICU outcome. However, the dose of IHD (42 hours/week) was far greater than the typical 9 to 12 hours of IHD being delivered in the ICU setting. To date, none of the RCTs and meta-analyses¹¹⁻¹⁴ has demonstrated any significant difference in mortality between modalities. However, there are other important factors for selecting the RRT modality (Table 71–2).

RECOVERY OF RENAL FUNCTION: CRRT VERSUS IHD

In an animal model of AKI, there was loss of autoregulation of renal blood flow with poor renal perfusion when systolic blood pressure decreased to less than 90 mm Hg.¹⁵ Therefore, improved hemodynamic stability during RRT may be associated with fewer episodes of reduced renal blood flow, less renal ischemia, and more rapid renal recovery. Augustine and colleagues³ found that renal recovery was influenced by blood pressure changes during RRT; however, the dialysis modality itself did not impact renal recovery. To date, most randomized controlled studies^{2,3,6-8} have failed to demonstrate the superiority of CRRT with regard to recovery of renal function. Not surprisingly, results from meta-analyses have been inconsistent.

Three meta-analyses^{11,13,14} including RCTs reported no statistical difference in renal recovery with regard to RRT modalities. Most recently, Schneider and colleagues¹⁶ performed a meta-analysis specifically to compare the rate of dialysis dependence among severe AKI survivors according to the choice of initial RRT modality. They found that patients who received IRRT as an initial RRT modality for AKI had 1.7 times increased risk of remaining dialysis dependent as compared with those who initially received CRRT, but this finding did not reach statistical significance. Allocation bias was present in observational trials, with IRRT appearing to be allocated to patients with lesser illness severity, putting them at even less risk for dialysis dependence, potentially favoring CRRT to an even greater degree. In 2014, Wald and colleagues¹⁷ published a large retrospective cohort study, comparing CRRT with IHD in terms of chronic dialysis, defined as the need for dialysis for a consecutive period of 90 days. The risk of chronic dialysis was significantly lower among patients who initially received CRRT versus IHD. This finding was more prominent among those with preexisting chronic kidney disease and heart failure.

In summary, IRRT appears to be associated with a higher rate of chronic dialysis dependence than CRRT. Randomized prospective trials are needed to confirm these findings.

HEMODYNAMIC STABILITY: CRRT VERSUS IHD

Despite the inconsistent results from RCTs and meta-analyses, there might be a hemodynamic benefit for CRRT despite the lack of survival benefit for CRRT. Proponents of CRRT advocate that continuous techniques with a lower ultrafiltration rate provide better hemodynamic stability than with IHD. Augustine and colleagues³ reported more changes in mean arterial pressure during IHD (3 days/week, treatment times based on a goal of greater than 5 hours on average) as compared to CVVHD. More patients on IHD therapy required an increase in vasopressor dose during the initial therapy. However, Uehlinger and colleagues⁷ reported no significant difference between CVVHDF and IHD, in terms of vasopressor requirements, hypotensive episodes, or hemodynamic instability.

However, they used therapeutic maneuvers to enhance hemodynamic stability during IHD (such as lower blood flow rate and lower net ultrafiltration during the initial IHD) with a mean of 5 IHD sessions per week.

In the Cochrane meta-analysis,¹⁴ mean arterial pressure at the end of the study period was significantly higher with CRRT than with IRRT, whereas the number of hypotensive episodes and norepinephrine doses were not different. A meta-analysis by Bagshaw and colleagues¹¹ reported that CRRT was associated with fewer episodes of hemodynamic instability; however, another systematic review¹³ reported nominal differences.

Some argue that improved hemodynamics may be simply related to hypothermic vasoconstriction during CRRT. A similar effect can be obtained in IRRT by cooling the dialysate. Other measures to improve hemodynamics include less aggressive ultrafiltration, more frequent IHD (eg, daily), dialysate sodium and calcium concentrations to 145 and 1.5 mmol/L, respectively, using low blood filter flow (< 150 mL/min), low dialysate flow, and cool dialysate with high sodium concentration.^{8,18} Notably, trials reporting no significant difference in hypotensive episodes between CRRT and IHD have used extraordinary measures to reduce hypotensive IHD, which do not reflect standard clinical practice.^{7,8} Considering the cost-effectiveness and practicality of IHD as one of its main advantages, applying all these maneuvers to the current IHD technique diminishes the purported advantages in cost and labor intensity.

Patients with cerebral edema or intracranial hypertension have impaired autoregulation of cerebral blood flow. A decrease in systemic blood pressure during RRT can cause decreased cerebral blood flow and cerebral ischemia, possibly exacerbating brain edema. CRRT has been proven superior in maintaining cerebral blood flow in patients with acute liver failure and cerebral edema compared with IHD.¹⁸

In summary, CRRT is associated with greater hemodynamic stability during RRT, as compared with standard IHD. As expected, increasing the frequency and duration of IHD decreases the differences between IHD and CRRT; however, it does not represent the typical IHD sessions conducted in the ICU. CRRT may be the most beneficial in patients with preexisting hemodynamic instability, brain injury, and fulminant liver failure.

CONTROL OF AZOTEMIA AND VOLUME OVERLOAD: CRRT VERSUS IHD

One of the advantages of CRRT is better control of azotemia and volume overload due to slow, constant blood flow, and ultrafiltration, as compared to IHD. In addition, CRRT may allow administration of medications and nutrition with less concern for volume overload. Mehta et al² showed that cumulative solute removal with CRRT is greater than that with IHD. Augustine et al³ found a marked difference in total fluid balance over 3 days (−4005 mL for the CVVHD group and +1539 mL for the IHD group). However, Uehlinger et al⁵ showed that the average daily solute clearance was comparable between the CVVHDF and IHD groups and the amount fluid removed daily by RRT and average fluid balance did not differ between 2 groups. Also, there was no difference in the use of parenteral or enteral nutrition. These inconsistent results may be due to different CRRT techniques used in each study. A retrospective controlled study by Morimatsu et al¹⁹ compared CVVHDF with CVVH in terms of azotemic control. CVVH (ultrafiltration rate: 2 L/h, urea clearance: 28 mL/min) achieved superior control of azotemia when compared to CVVHDF (ultrafiltration rate: 700 mL/h, urea clearance: 27 mL/min). In our institution, CVVH has been used over CVVHDF, due to the past experience that CVVHDF reduced the ultrafiltration rate; CVVH achieved better azotemic control.

In view of all of the uncertainties mentioned earlier and because of the physiologic plausibility, fluid-overloaded patients are among those with the potential to benefit from CRRT.

CONTROL OF ACID-BASE AND ELECTROLYTES: CRRT VERSUS IHD

Constant solute removal with replacement of electrolytes and base (bicarbonate or acetate) in CRRT is more beneficial in stabilizing and maintaining blood pH, which may improve hemodynamic stability and the response to vasopressors. CRRT is also helpful in maintaining electrolyte homeostasis and in providing a more gradual correction of chronic

hyponatremia to avoid osmotic demyelination syndrome. CRRT is preferred in patients with cerebral edema and intracranial hypertension¹⁸ to avoid rapid decreases in serum osmolality leading to increased brain edema as well as the hemodynamic benefits on cerebral blood flow.

In contrast to CRRT, IHD can remove small molecules effectively, so it may be more useful in acute life-threatening conditions such as severe hyperkalemia, rhabdomyolysis, tumor lysis syndrome, and certain cases of intoxication.¹⁸

BLEEDING COMPLICATIONS AND DIALYSIS FILTER CLOTTING: CRRT VERSUS IRRT

Filter clotting is a common problem during RRT, causing poor filter performance. Anticoagulation may be necessary for both IRRT and CRRT to prevent clotting of the dialysis filter. CRRT has a higher risk of filter clotting due to higher rates of ultrafiltration, lower blood flows, and longer duration of RRT. Heparin is the preferred anticoagulant at many institutions but the optimal intensity of heparinization is unknown. Hemodialysis can be performed without anticoagulation, and regular saline flushes can be used in the dialysis circuit instead. Also with CRRT, placement of the replacement fluid before the circuit (predilution hemofiltration) will dilute the blood and decrease filter clotting. Although predilution replacement fluid also dilutes the solute concentration of blood entering the filter, diminishing overall clearance rates, predilution actually increases urea clearance by washing out urea from the red cells. Regional citrate infusion can also be used in CRRT. Citrate chelates calcium in the serum and inhibits activation of the coagulation cascade. Use of citrate anticoagulation, however, increases the complexity of RRT by requiring customized dialysate solutions or replacement fluid and frequent monitoring of laboratory results to minimize metabolic complications. In cases of heparin-induced thrombocytopenia, the direct thrombin-inhibitor argatroban can be used.

In a Cochrane meta-analysis,¹⁴ patients on CRRT had a significantly higher risk of recurrent dialysis filter clotting when compared to those on IRRT, as expected. There was no significant difference in the

risk of bleeding between CRRT and IRRT. Another meta-analysis¹¹ also reported no difference in severe bleeding complications by modality; however, the largest RCT⁸ of the meta-analysis excluded patients who had coagulation disorders or uncontrolled hemorrhage. In coagulopathy associated with severe bleeding, continuous replacement of blood products, and FFP coupled with maintenance of fluid balance with CRRT may help to correct coagulopathy and minimize fluid overload and pulmonary edema. In summary, CRRT can often be successfully performed without any anticoagulation; however, in case of frequent filter clotting despite anticoagulation or in the presence of contraindications for systemic anticoagulation, IRRT is preferable.

REMOVAL OF CYTOKINES: CRRT VERSUS IRRT

Experimental and clinical data show that many middle molecules, such as tumor necrosis factor that may be involved in the inflammatory response, can be removed by CRRT modalities.²⁰ As per the analysis of Ronco et al,²⁰ septic patients may benefit from a higher dose of treatment (high-volume hemofiltration [HVHF]) allowing blood purification from the inflammatory cytokines during systemic inflammatory and septic states. Oudemans-van Straaten et al²¹ conducted a prospective cohort analysis in 306 critically ill patients who received intermittent HVHF at a mean ultrafiltration rate of 4 L/h. Mortality in HVHF patients was lower than that predicted by illness severity scores. In a subgroup analysis, an improvement in cardiac index, blood pressure, and stroke volume was observed after the first HVHF run in patients with low cardiac output. Cole and colleagues²² measured hemodynamics, serum cytokines, and the complement concentration in 11 patients with septic shock and multiorgan dysfunction syndrome. Patients were randomly assigned to HVHF (8 hours; ultrafiltration rate 6 L/h) or to standard CVVH. HVHF was associated with a greater reduction in norepinephrine requirements than CVVH. HVHF was associated with a greater reduction in the area under the curve for C3a and C5a, but the measured soluble mediators in the ultrafiltrate was negligible, indicating a greater role in filter

adsorption of studied mediators. Some drawbacks of HVHF include the large volumes of replacement fluid, the high cost and practicality, should be considered along with the potential benefits.

To date, the significance of inflammatory cytokine removal by standard CRRT is unclear. Some argue that insignificant numbers of these mediators are removed by CRRT in comparison with endogenous clearance, and that CRRT can also remove anti-inflammatory cytokines. In addition, exposure to an extracorporeal circuit can activate proinflammatory cytokines, so a shorter duration of RRT (IHD, SLED) might be more beneficial than CRRT in terms of net clearance of proinflammatory cytokines. Of note, removal of cytokines and other large molecules can be obtained just as well, if not better, with IHD or SLED, under the condition that open membranes with large pore size (so-called high-flux membranes) are applied, even though it removes cytokines intermittently but not continuously.

With regard to cytokine removal, more studies are needed to answer several questions: which technique (IRRT with high-flux dialyzers, standard CRRT, HVHF, and adsorption) gives the best results at the lowest technical cost, and how much cytokine removal has a significant effect (if, any) on mortality and morbidity in critically ill patients.

DOSES OF RRT: INTENSIVE THERAPY VERSUS LESS INTENSIVE THERAPY

The ideal dose of dialytic therapy in critically ill patients has not yet been conclusively determined. Schiff et al²³ compared daily IHD (6 days/week) with alternate-day IHD (3 days/week) in 160 patients with acute renal failure. The study reported lower mortality (28% vs 46%) and shorter duration of AKI (9 vs 16 days) in the daily IHD group. However, the actual delivered dialysis dose per session was substantially lower than that in usual care practices, and the weekly delivered doses were even lower in the alternate-day IHD group. Ronco et al²⁴ performed a large single-center prospective RCT to evaluate the impact of different ultrafiltration doses in CRRT on survival and found that doses of 45 and 35 mL/kg/h in CVVH reduced 15-day mortality compared with 20 mL/kg/h in CVVH. A large

multicenter RCT²⁵ (Acute Renal Failure Trial Network Study) was performed in 2008 to compare intensive RRT (IHD and SLED 6 times per week and CVVHDF at 35 mL/kg/h) with less intensive RRT (IHD and SLED 3 times per week and CVVHDF at 20 mL/kg/h). Sixty-day mortality was 53.6% with intensive therapy and 51.5% with less-intensive therapy (odds ratio, 1.09; $P = 0.47$). There was no significant difference between the 2 groups in the duration of RRT or the rate of recovery of kidney function. A potential reason for this failure could be that the higher intensity of solute removal also has a downside such as greater removal of drugs resulting in inadequate drug concentrations (eg, of antimicrobials) or more electrolyte disturbances.^{8,26} Also, in the Acute Renal Failure Trial Network Study,²⁵ patients in the less-intensive therapy group were better dialyzed than patients receiving usual care in typical clinical practice, the dose delivered during CVVH was 89% of that prescribed for intensive treatment group, 95% for the less intensive treatment group. In usual care practices, CRRT is frequently interrupted owing to clotting of the filter, surgery, diagnostic investigations, or other procedures. In summary, the ideal dose of RRT in critically ill patients remains undetermined to date. It seems that increasing beyond an adequate level of intensity provides no additional benefit in critically ill patients.

PRACTICALITY AND COST: CRRT VERSUS IRRT

The frequency and duration of IRRT can be adjusted according to the patients' condition, allowing more flexibility. IRRT can be performed with the same machines used for chronic IHD, and the same machines can be used for an extended mode (eg, SLED) when needed. This contrasts with CRRT machines, which do not allow an increase of the intensity of the treatment to allow shorter treatments.

Currently, in all of the studies comparing cost, IRRT was less costly than CRRT.²⁷⁻²⁹ Even, when the cost of ICU nurses for CRRT was not included into its whole cost, CRRT was more expensive than IHD (at least \$3500 per week for CRRT vs \$1342 per week for IHD).²⁴

Especially, dialysate and replacement fluid costs and extracorporeal circuit costs were in favor of IRRT worldwide.

SUSTAINED LOW-EFFICIENCY DIALYSIS

SLED or extended daily dialysis is a hybrid technique that combines several advantages of both IHD and CRRT. This slower dialytic modality runs for prolonged periods using conventional hemodialysis machines with modification of blood and dialysate flows. Typically, SLED uses lower blood-pump speeds of 200 mL/min and lower dialysate flow rates of 300 mL/min for 6 to 12 hours daily. It allows for improved hemodynamic stability through gradual solute and volume removal as in CRRT, in addition to high solute clearance as in IHD. Still, it is less labor intensive and costly than CRRT. Frequency and duration of therapy can be adjusted based on the needs of the patient as in IHD, and it offers a dialysis-free period, giving opportunities to mobilize patients during their time off dialysis, as in IHD. Kielstein et al³⁰ compared CVVH with 12-hour daily SLED. Average mean arterial pressure was not significantly different in both therapies. Urea reduction rate was similar with SLED compared with CVVH therapy. Correction of acidosis was accomplished faster with SLED than CVVH, and the amount of heparin used was significantly lower with SLED. A large RCT by Schwenger et al³¹ compared CVVH with 12-hour daily SLED. Ninety-day mortality and hemodynamic stability did not differ between groups, whereas duration of mechanical ventilation and time to renal recovery were significantly shorter in the SLED group. Solute clearance was more effective in the SLED group. Patients treated with SLED needed fewer transfusions had substantial reduction in nursing time and costs. However, in usual clinical practice (ie, outside of research protocol), due to time and personnel constraints, SLED can be, and often is, run faster for shorter time periods causing hemodynamic instability similar to IHD.

CONCLUSIONS

To date, neither the modality of RRT the dose, or the timing^{32,33} of RRT has been demonstrated to have an impact on patient survival. The benefits of CRRT over IHD in the critically ill patient include hemodynamic stability, potential for decreased need for chronic HD, and improved electrolyte and acid-base

homeostasis. IHD is beneficial in the hemodynamically stable patient or and when filter clotting prevents CVVH. CVVHD does not have a clear benefit over CVVH due to reduced filtration. The choice of dialytic modality should be based on the clinical status of the patient, the resources available in the institution, and in the manner that RRT is performed.

Clinical Controversies: Ventilator-Associated Pneumonia: Does It Exist?

Kaye Hale, MD

CLINICAL CONTROVERSIES: VAP: DOES VAP EXIST?

In the United States, ventilator-associated pneumonia (VAP) is the most commonly diagnosed hospital-acquired infection in intensive care units (ICUs), affecting upward of 20% of ventilated patients with varyingly estimated attributable mortality ranging from 10% to 55%.¹ Acquisition of VAP is responsible for prolonged ICU and hospital length of stay (LOS), increased hospital costs, and increased utilization of antibiotics. In a post hoc retrospective-matched cohort analysis of microbiologically confirmed cases of VAP in the North American Silver-Coated Endotracheal Tube study, the authors calculate median total charges for patients with VAP were almost \$200,000 compared to under \$100,000 for patients without VAP. This was accounted for by the patients requiring intubation up to 5 days longer and as a consequence, significantly prolonging their ICU and hospital stays by 11 and 13 days, respectively.² A subsequent large, retrospective study comparing 2144 patients who had VAP as determined by International Classification of Diseases, Ninth Revision code to a matched cohort of patients without VAP showed similar findings. The patients with VAP had longer mean durations of mechanical ventilation (21.8 vs 10.3 days), prolonged ICU and hospital LOS (20.5 vs 11.6 and 32.6 vs 19.5, respectively), and an increase in hospital costs of almost \$40,000.³ The high attributable mortality and costs associated with VAP have garnered much attention from national patient safety organizations as well as state and federal health agencies, mandating compliance with preventive measures and reporting metrics.

However, to begin any discussion about VAP, one must first consider by which criteria VAP

is defined. Until recently, there was significant discrepancy between medical professional society's definition of VAP and the Centers for Disease Control (CDC)/National Healthcare Safety Network's reportable surveillance definition ([Table 72–1](#)). Crucial differences in timing of the onset of pneumonia in a mechanically ventilated patient and whether microbiologic criteria were necessary for diagnosis left these competing criteria at odds. As clinical and reporting definitions of VAP diverged, our ability to reliably estimate rates, costs, and impact of VAP diminished. This is demonstrated in a study by Klompas, where 3 infection control personnel (following the CDC surveillance definition) and 1 physician (used clinical judgment), independently reviewed 50 cases and were only able to agree on a diagnosis of VAP in 3 patients while the range of cases identified varied from 7 to 20 depending on the reviewer.⁴ In response to widespread confusion and concern over the discrepancy leading to misleading VAP rates and unclear VAP-associated mortality, the CDC altered its definition to include solely objective data for diagnosis and limited the diagnosis to onset after a minimum of 48 hours of ventilation with stable ventilator settings. This led to an entirely new classification of reportable ventilator-associated events (VAEs): ventilator-associated condition (VAC), infection-related ventilator-associated complication (iVAC), and finally possible VAP and probable VAP.⁵ Some would argue, however, that these new diagnoses, VAE, VAC, iVAC, and their criteria have yet to be fully vetted for sensitivity, specificity, preventability, and significant impact on patient outcomes. Therein lies the controversy surrounding VAP, our community of health care providers lacks a unified view of what the real clinical problem is and whether that fairly compares to what

TABLE 72–1 Summary of key differences in diagnostic criteria for VAP according to professional society guidelines (ATD/IDSA) and CDC surveillance definition.

ATS/IDSA 2005 ⁷		CDC VAP 2008 ⁸
Radiographic signs	X-ray presence of a new or progressive infiltrate	Two or more serial X-rays with at least one of the following: <ul style="list-style-type: none">• New or progressive and persistent infiltrate• Consolidation• Cavitation
Clinical signs	At least two of the following: <ul style="list-style-type: none">• Fever (> 38°C)• WBC (< 4000 or > 12,000 cells/μL)• Purulent secretions	At least one of the following: <ul style="list-style-type: none">• Fever or• WBC or• Altered mental status (for adults > 70-year old) AND at least two of the following: <ul style="list-style-type: none">• New onset purulent or changes in sputum• New onset or worsening tachypnea• Rales/bronchial breath sounds• Worsening gas exchange with increased vent requirements
Microbiologic criteria	Optional qualitative or quantitative culture of respiratory secretions (PSB: 10 ³ cfu/mL or BAL: 10 ⁴ -10 ⁵ cfu/mL)	At least one of the following: <ul style="list-style-type: none">• Positive blood culture not related to another infection• Positive pleural fluid culture• Positive quantitative culture (BAL or PSB)• BAL fluid with > 5% cells with intracellular bacteria on microscopy• Positive histopathology

BAL, bronchoalveolar lavage; PSB, protected specimen brush.

regulatory bodies feel should be preventable and thus a marker of ICU quality.

VAP ACCORDING TO WHOM?

As previously stated, the lack of uniformly accepted diagnostic criteria for VAP has led to variability in publically reported rates, difficulty in determining accurate causes, epidemiology, prevention measures, and effective treatment. The Infectious Disease Society of America (IDSA) and American Thoracic Society (ATS) define VAP as pneumonia that develops more than 48 to 72 hours after initiation of ventilation via an endotracheal tube (EET) or tracheostomy tube.^{6,7} Pneumonia is suggested by a new or progressive infiltrate on chest X-ray associated with signs or symptoms of infection (fever, leukocytosis, and purulent sputum) and worsening oxygenation. Chest X-ray findings are integral to the clinical diagnosis, wrought as they are with subjectivity, and difficulties in interpretation in the ICU setting due to the presence of overlying lines and tubes, as well as frequently abnormal baseline

radiographs in patients admitted for respiratory failure due to pneumonia and acute respiratory distress syndrome. This constellation of clinical criteria possesses high sensitivity but low specificity. The addition of a lower respiratory tract specimen is recommended as it can improve diagnostic accuracy and guide antimicrobial use. This microbiologic approach, however, is also contentious with regards to how the specimen should be collected (protected specimen brush, bronchoscopically, tracheal aspirate, or mini-bronchoalveolar lavage) and how it should be analyzed (quantitatively or qualitatively). Regardless of the microbiology, the principle of VAP diagnosis according to these professional guidelines focuses on clinical criteria and initiation of empiric antimicrobial therapy pending clinical improvement. The original CDC surveillance definition for VAP also began with chest radiograph interpretation, this time specifying serial X-rays, distinguishing findings on whether the patient had an abnormal X-ray at baseline. After meeting radiographic criteria, innumerable combinations from an extensive menu of signs and

symptoms of infection (including subjective assessments of character and quantity of sputum, findings on auscultation, and respiratory symptoms such as dyspnea and cough), worsening gas exchange, and laboratory data could arrive one at a diagnosis of VAP on clinical grounds alone or by virtue of positive culture results.⁸ The wide array of diagnostic possibilities may have been intended to provide the infection preventionist (someone trained in the field of infection control) with a menu of all the possible observed phenomena that could occur as a result of VAP; however, in practice, this was burdensome, impractical, and easily manipulated.

WHAT CAUSES VAP?

Since at least 1987, it has been recognized that the presence of an ETT predisposes patients to the development of pneumonia.⁹ In the constant battle between host defense mechanisms and microbial virulence factors, the presence of the ETT and ventilatory circuit present a worthy adversary. Bypassing anatomic barriers such as the glottis with an ETT, impairing cough reflexes with sedatives and hampering mucociliary function by desiccation of secretions from continuous air flow, undermines the body's ability to prevent aspiration of organisms into the normally sterile lower respiratory tract and lung parenchyma. Risk of infection is compounded by eventual biofilm formation on the ETT and colonization of the upper airway with gram-negative organisms and frequently resistant hospital-acquired flora. Additionally, independent risk factors for VAP have been identified and include nonmodifiable host factors (age > 60 years, underlying pulmonary disease and severity of illness) as well as modifiable risk factors inherent to bedside management of the patient (histamine-2 receptor antagonist use, sedation, duration of mechanical ventilation, maintenance of the ventilatory circuit, head of bed (HOB) position, and presence of a nasogastric tube).¹⁰

WHAT ARE VAES?

As earlier mentioned, in efforts to simplify VAP surveillance and reporting, the CDC revamped its surveillance definition to include a compilation of

VAC	iVAC	VAP
At least 2 days of sustained rise in PEEP ≥ 3 cm or $\text{FiO}_2 \geq 20\%$ following a 2 day period of stable ventilator settings	Meets VAC plus temp < 36 or $> 38^\circ\text{C}$ or WBC ≤ 4 or $\geq 12 \times 10^3$ cells/mL and at least one new antibiotic initiated and continued for ≥ 4 days	Meets iVAC plus sputum/BAL with ≥ 25 PMN and ≤ 10 epithelial cells per hpf and/or positive respiratory culture

FIGURE 72–1 Ventilator-associated events: ventilator-associated condition (VAC); infection-related ventilator-associated complication (iVAC); ventilator-associated pneumonia (VAP).

VAEs in January 2013.⁵ This shift in surveillance stemmed from the dispute and complexity of defining VAP, nonpneumonic complications associated with the ventilator (eg, ventilator-associated tracheobronchitis) and a desire to develop objective-surveillance criteria for uniformity and ease in reporting. VAEs as listed earlier include VAC (minimum sustained increases in positive end expiratory pressure (PEEP) or FiO_2 after a 2-days period of ventilator stability), iVAC (VAC plus signs of infection and initiation of a new antimicrobial agent that is continued for at least 4 days), possible VAP (iVAC plus symptoms of lower respiratory tract infection or positive cultures from respiratory specimen), and probable VAP (iVAC plus symptoms of lower respiratory tract infection and positive culture results from respiratory specimen).⁵ This new surveillance approach depicts VAEs as a spectrum of disease (Figure 72–1). However, Muscedere et al showed that agreement between VAC, iVAC, and VAP was low with positive predictive values of VAC and iVAC for VAP of only 28% and 40%, respectively.¹¹

IS VAE A BETTER QUALITY INDICATOR THAN VAP?

A large retrospective multicenter study examining VACs, as evidenced by threshold increases in ventilatory support (> 2 days of sustained increase in PEEP of 2.5 cm H_2O or $\text{FiO}_2 > 15$ points) after a 48-hour period of stability, found a statistically significant association between VAC and duration

of mechanical ventilation (median 13 vs 6 days, $P < 0.001$), ICU LOS (median 16.3 vs 8.0 days, $P < 0.001$), and hospital LOS (median 21 vs 16.0 days, $P < 0.001$) as well as hospital mortality (38% + VAC, 23% – VAC, $P = 0.001$) when compared to matched patients without VAC.¹² The authors appropriately cite the concern that it may be difficult to distinguish a VAC from a patient who requires increasing ventilatory support for respiratory failure from a disease that progresses despite intubation. This concern is mirrored by Muscedere's study which showed higher Sequential Organ Failure Assessment (SOFA) scores in patients who subsequently developed VAC and iVAC compared to those who did not.¹¹ A subsequent small retrospective study by Lewis et al evaluating risk factors for VAEs, identified use of mandatory ventilator modes, positive net daily fluid balance, and benzodiazepine use prior to intubation as independent risk factors for VAC (mode of ventilation and fluid balance) and iVAC (benzodiazepine use).¹³ Not surprisingly, there was no impact of the individual ventilator bundle components on VAC or iVAC cases when compared to controls. So, while VAEs are more readily identifiable by objective criteria that can be easily extracted from the medical record, until more, large, prospective studies can be performed the clinical entity of VAEs as preventable, VACs remains debatable.

CAN VAP BE PREVENTED?

There are innumerable reports in the medical literature touting the achievement of “zero VAP” rates with implementation of the “VAP bundle.” Except, these publications vary in how they define VAP and no such VAP bundle actually exists. The ventilator bundle was introduced by the Institutes for Healthcare Improvement in 2005 as a means to improve clinical outcomes in mechanically ventilated patients.¹⁴ The elements of the ventilator bundle are well known and now routinely referred to as the VAP bundle despite measures such as deep venous thrombosis and stress ulcer prophylaxes that have no direct benefit to preventing VAP and in the latter case, may even increase risk of pneumonia and other complications such as *Clostridium difficile* infection in critically ill patients.¹⁵ Other bundle

elements, including daily sedation “vacation” to limit duration of mechanical ventilation and HOB elevation target well-established independent risk factors for VAP as mentioned earlier but can be difficult to achieve in real practice. Nonetheless, health care quality agencies and state governments require compliance with these ventilator or VAP bundle elements to achieve zero VAP rates. Although all ICUs would aim to provide the best evidence-based care to achieve optimal outcomes for their patients, zero VAP is an unrealistic benchmark. There are non-modifiable patient and disease-related risk factors that are outside of a care provider's control. By proposing this benchmark, patient safety forums are misleading the public into believing that a patient's course on a ventilator should be brief and uncomplicated, and if not achieved, may speciously reflect poor care and lack of bundle compliance. Furthermore, hospitals may be persuaded to use the subjectivity of some of the surveillance definitions to their advantage in order to report potentially lower VAP rates.

WHAT DOES THE FUTURE HOLD FOR VAP?

As with other hospital-acquired infections, the surveillance definition is not meant to be used clinically and differs out of the necessity to apply the surveillance definition across all hospitals, regardless of resources available, and ideally allows for minimal subjective interpretation to minimize case finding bias and allow for fair comparisons among hospitals. The CDC's replacement of VAP with publicly reportable VAEs such as VAC and iVAC will undoubtedly shift focus away from the controversial and subjective VAP and toward establishing VAC and iVAC as the real threat to mechanically ventilated patients. And as with any novel initiative to improve patient safety and outcomes, new and potentially costly ideas for prevention will be brought to light and added to our ventilator bundle. As critical-care practitioners continue to strive to provide the best available evidence-based care for their patients, whether current clinical practice and professional guidelines will reflect this shift remains to be seen.

Controversies: ScvO₂ Versus Lactate Clearance to Guide Resuscitation in Septic Shock?

Jan Bakker, MD, PhD, FCCP

INTRODUCTION

Septic shock has been defined as a state in which hypotension persists despite adequate fluid resuscitation or the presence of a lactate level more than 4 mmol/L (so-called sepsis-induced tissue hypoperfusion) in patients with confirmed or suspected infection.¹ In these conditions, the Surviving Sepsis Campaign Guidelines suggest to restore mean arterial pressure (MAP) more than 65 mm Hg and normalize lactate levels and central or mixed venous hemoglobin saturation (ScvO₂/SvO₂).¹ Basically this reflects restoring perfusion pressure, improving tissue perfusion and restoring the balance between oxygen delivery and oxygen demand.

A recent study showed a 46% mortality rate in septic patients with increased lactate levels and hypotension.² In addition, a study using ScvO₂ as an endpoint of resuscitation³ and a study using both ScvO₂ and lactate clearance as endpoints of resuscitation⁴ showed significant improvements in mortality. However, a study (mostly septic-shock patients) comparing the use of either ScvO₂ or lactate clearance in early resuscitation with common goals for central venous pressure and MAP did not show differences in mortality.⁵ In addition, a recent study in septic-shock patients comparing early goal-directed therapy based on ScvO₂ measurements, protocol-based standard therapy based on systolic blood pressure, and heart-rate measurement without mandatory central venous catheter placement and usual-care based on the bedside physician similarly did not show differences in mortality.⁶

Therefore, controversy exists on how to use ScvO₂ or lactate levels in the resuscitation of septic-shock patients. In this chapter, both the background

physiology of both parameters and their clinical use in the treatment of septic-shock patients is reviewed.

PHYSIOLOGY OF VENOUS OXYGENATION

Many aspects of venous oximetry have recently been reviewed.^{7,8} There is an abundance of oxygen available in the circulation. The red blood cells leave the left ventricle with almost 100% saturated hemoglobin to return, after exchanging oxygen in the microcirculation, to the right ventricle with around 75% saturated hemoglobin. When oxygen delivery to the tissues is decreased, stepwise oxygen consumption is maintained by using this surplus of oxygen resulting in a gradual decrease of venous oxygenation.⁹ When the decrease in oxygen delivery reaches a critical level, lactate levels generally start to increase.^{10,11} In these models, venous oxygenation is proportional to cardiac output (CO) as arterial oxygen saturation and hemoglobin levels are usually stable. Venous oxygenation in these conditions thus reflects the balance between whole body oxygen demand and CO. It is important to realize that SvO₂ does not reflect regional venous oxygenation levels.¹² When cardiac function is normal, decreases in oxygen content are met by increases in CO thus minimally affecting venous oxygenation.¹³ However, when cardiac function is limited or the decrease in oxygen content is excessive, the surplus of oxygen in the system is mainly used to compensate for changes in oxygen demand so that venous oxygenation decreases.¹⁴ Although in clinical conditions, venous oxygenation is dependent on many factors ([Figure 73–1](#)), the response of CO to changes in oxygen content and oxygen demand is probably the main factor.

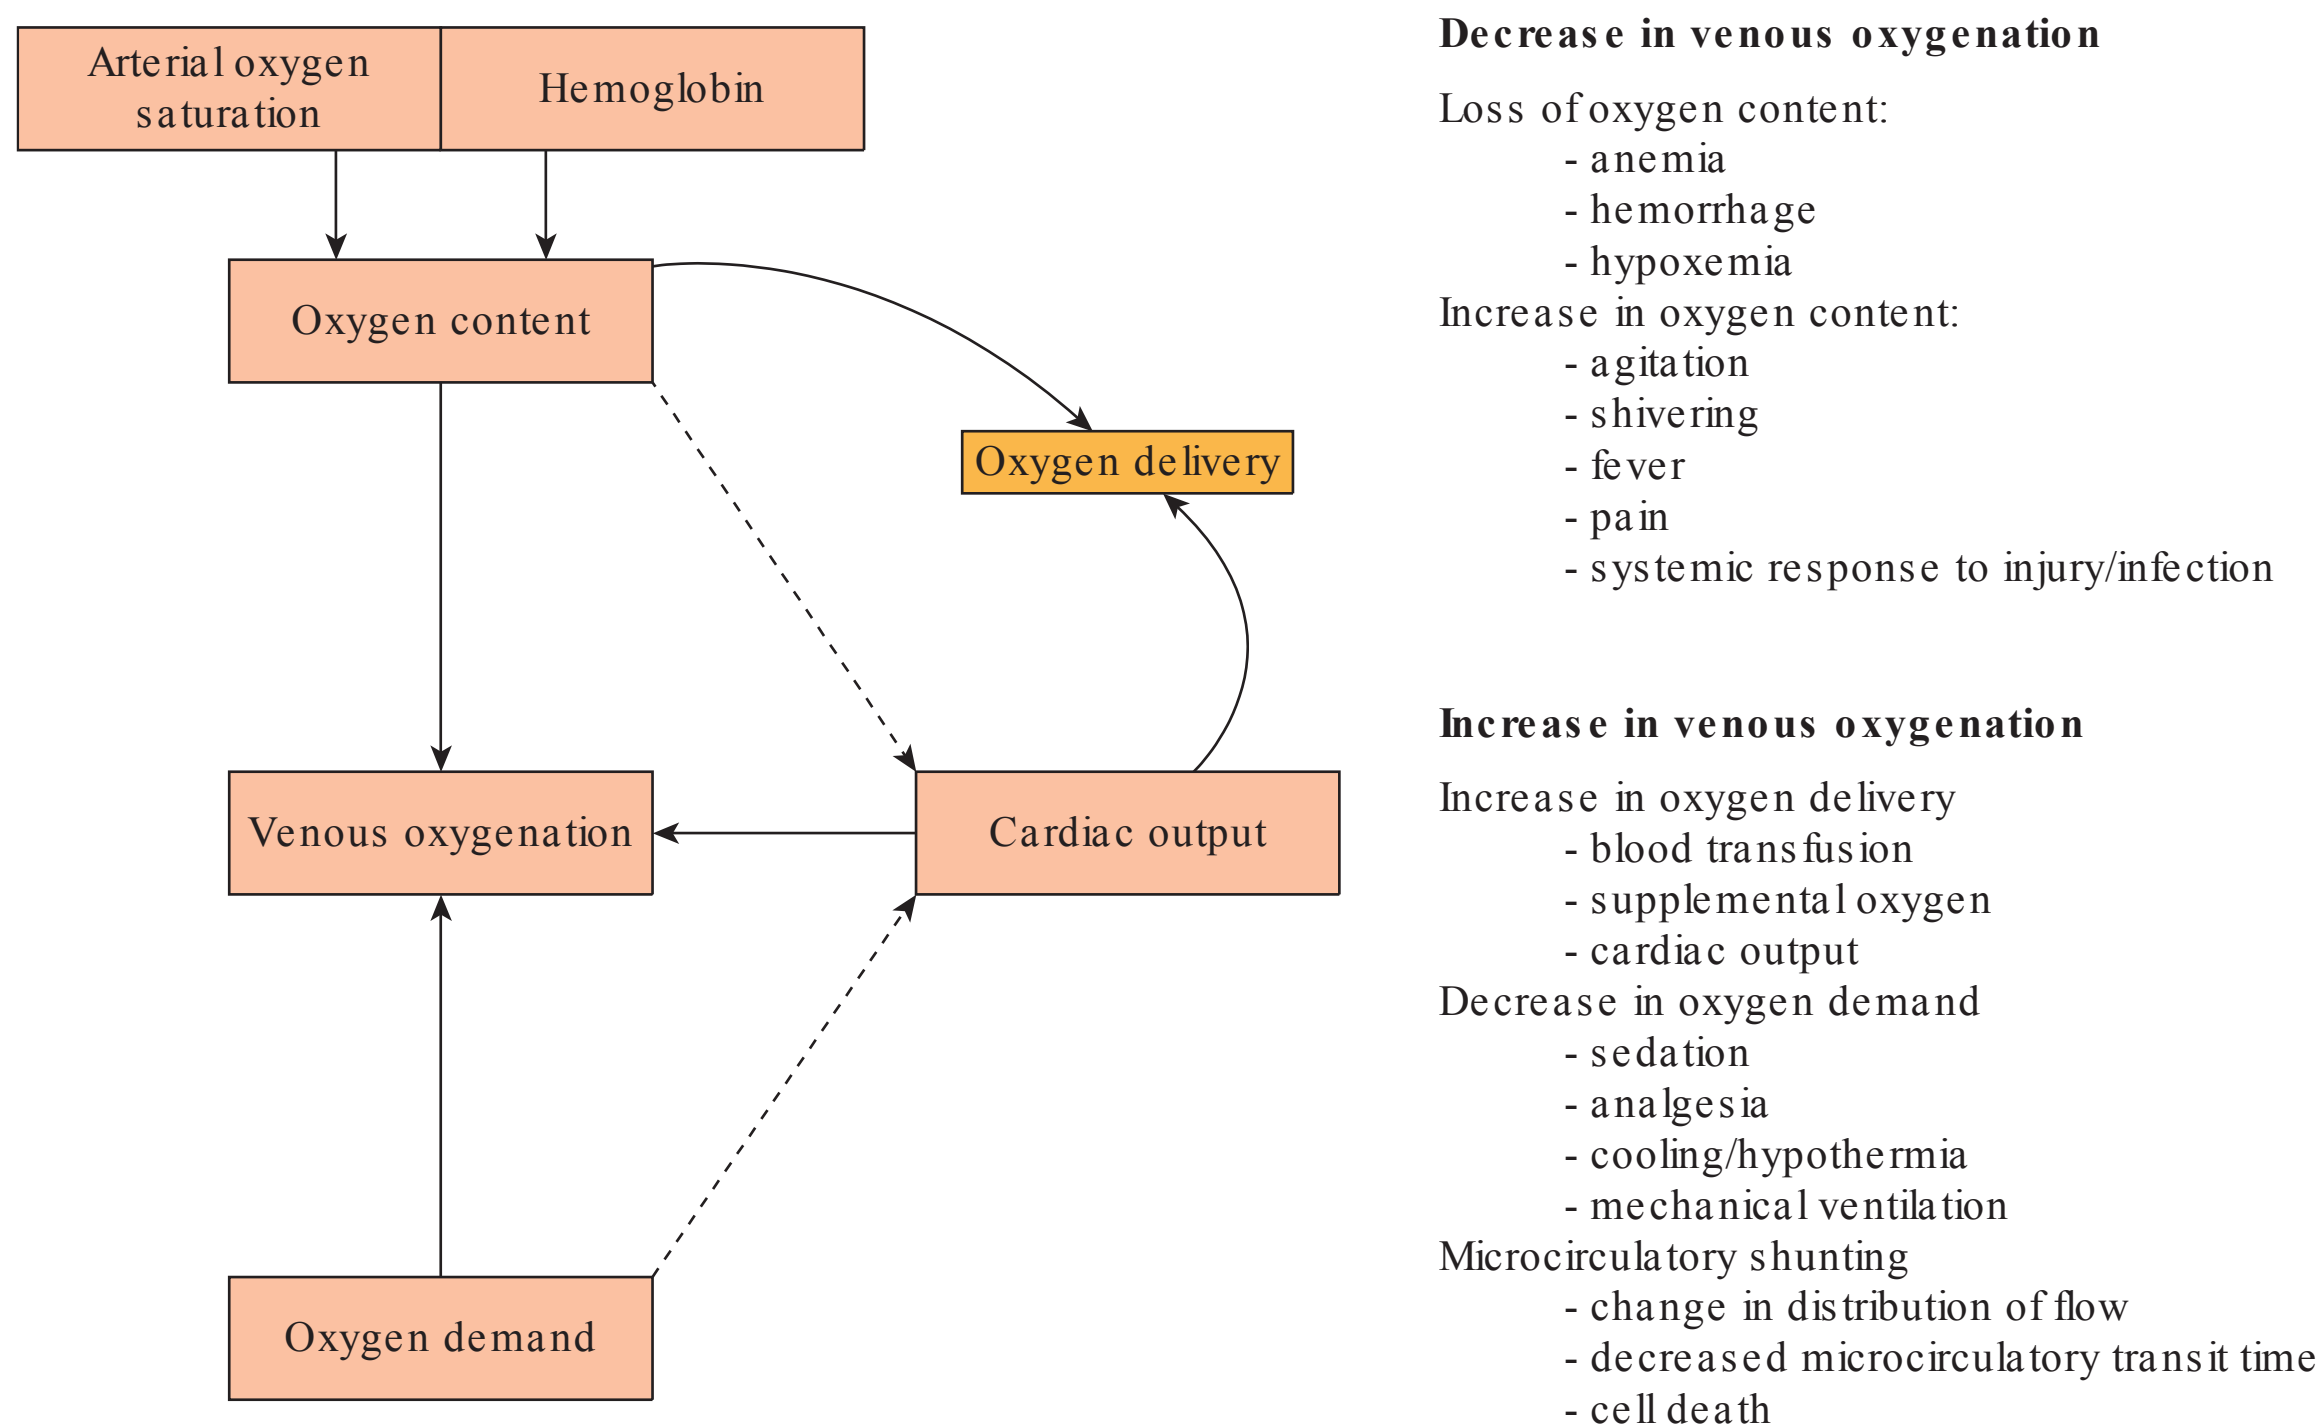

FIGURE 73–1 Factors influencing venous oxygenation. CO plays a central role as this is the only variable that can rapidly adjust for changes in oxygen demand and the different components of oxygen content.

In hyperdynamic septic shock, patients seldom exhibit low levels of venous oxygenation,¹⁵ whereas it is more frequently found in the early unresuscitated patients with severe sepsis.³

SCVO₂ AS A SURROGATE FOR SvO₂

The true venous oxygenation reflecting total body oxygen exchange is the pulmonary artery hemoglobin saturation. However, as pulmonary artery catheters are hardly used anymore and central venous catheters are recommended in the complex septic-shock patients, ScvO₂ is frequently used as a surrogate for the SvO₂.

In controlled experimental conditions, where usually oxygen demand is stable, ScvO₂ and SvO₂ highly correlate in various pathologic conditions.¹⁶ However in clinical conditions, significant differences between ScvO₂ and SvO₂ may exist.¹⁷ This

could be related to the interindividual variation in the balance between oxygen demand and oxygen consumption as in low CO states, the ScvO₂ adequately reflects SvO₂.¹⁸ When conditions are stable and oxygen demand is acutely changed, ScvO₂ reflects the decrease in oxygen demand just like SvO₂.^{19,20}

Other sites for venous sampling (eg, femoral vein) or peripheral tissue oxygen saturation (eg, by near infrared spectroscopy) should not be used to replace ScvO₂.^{21,22}

Given the relationship of ScvO₂ with CO, a normal to high ScvO₂ might suggest adequate perfusion. However, normal or high venous oxygenation levels may not reflect adequate tissue oxygenation as microcirculatory shunting may result in increased venous oxygenation levels.²³ In addition, patients with high venous oxygenation levels, independently associated with increased mortality,²⁴ may have low CO responsive to fluid resuscitation that might contribute to this high mortality.²⁵ The venous-arterial

carbon dioxide difference (Pv-aCO₂) is dependent on CO in septic-shock patients.²⁶ In the presence of a normal or even increased ScvO₂, an increased Pv-aCO₂ may reflect low CO²⁷ that has been associated with a worse outcome.²⁸

PHYSIOLOGY OF LACTATE

Lactate, as a normal end product of glucose metabolism, is produced from pyruvate. When pyruvate concentration exceeds the capacity of the slow metabolic Krebs cycle pathway, the fast metabolic pathway to lactate production is preferred resulting in the net production of 2 mol ATP per mol glucose metabolized. Although this amount of ATP is small compared to the additional 34 mol ATP produced in the Krebs cycle, the lactate pathway is fast and can thus produce large amounts of energy.²⁹ The increased levels of lactate in these conditions thus do not reflect the pathologic condition where pyruvate accumulates due to hypoxia. Lactate at the level of the organism also acts as an intermediate fuel that can be exchanged between various tissues.³⁰ In clinical practice, it is frequently difficult to separate these 2 states that clearly have significantly different impact on survival.

Lactate and Tissue Hypoxia

Decreasing oxygen delivery to the cells will ultimately result in decreasing oxygen consumption and increasing lactate levels.^{31,32} It is important to realize that lactate levels do not necessarily represent the adequacy of oxygenation in different regional circulations as these have different levels of critical oxygen delivery.^{33,34}

When oxygen delivery decreases below a critical level, oxygen consumption starts to decrease and lactate levels increase. This supply-dependent oxygen consumption in relation to increased lactate levels is a key characteristic of shock. Whereas this relationship is easily shown in experimental conditions, clinical circumstances, and ethical considerations limit the possibility to study this in humans. However, a few studies have identified the presence of supply-dependent oxygen consumption in relation to increased lactate levels also in patients with septic shock.³⁵⁻³⁷

FIGURE 73–2 Effects of progressing tamponade resulting in a decrease in CO and thus oxygen delivery. Beyond a critical point of oxygen delivery, oxygen consumption rapidly falls and lactate levels (measured at 3 time points) start to increase (data in *italic*). Following the restoration of CO and thus oxygen delivery, oxygen consumption increases and lactate levels return to baseline (data in **bold**). (Data from Zhang H, Spapen H, Benlabed M, et al: Systemic oxygen extraction can be improved during repeated episodes of cardiac tamponade, *J Crit Care* 1993 Jun;8(2):93-99.)

In a model of tamponade, Zhang et al³² recently showed that decreasing oxygen delivery beyond the critical value resulted in a rapid increase in lactate levels. Subsequent resolution of the tamponade resulted in supply-independent oxygen consumption and normalization of lactate levels ([Figure 73–2](#)). In the same model, van Genderen et al³⁸ showed that increasing tamponade was associated with decreased microvascular perfusion and increased lactate levels. In this model, resolving tamponade was associated with a normalization of microvascular perfusion and rapidly decreasing lactate levels. In patients with septic shock, Friedman et al showed similar findings.³⁵ Supply-dependent oxygen consumption was a characteristic of patients early in septic shock with hyperlactatemia, whereas supply-independent oxygen consumption was found following resuscitation and normalization of lactate levels. In addition, improving microvascular perfusion in septic-shock patients with increased lactate levels has been associated with decreasing lactate levels.³⁹

Lactate and Aerobic Metabolism

These important observations as mentioned earlier underscore the importance of evaluating increased

lactate levels to diagnose and treat supply-dependent oxygen consumption in critically ill patients. However, as lactate is a normal end product of glucose metabolism, increased aerobic glucose metabolism has been shown to increase lactate levels in the presence of adequate tissue oxygenation. Increases in pyruvate either by increasing glycolysis by means of hyperventilation or by infusing pyruvate result in increased lactate levels.^{40,41} Similarly, the administration of epinephrine and corticosteroids, known to increase glycolysis, results in dose-dependent increase in lactate.^{42,43} Very high lactate levels found in patients suspected of malignant lymphoma may have aerobic lactate production due to what is called the Warburg effect.⁴⁴ Treatment of the lymphoma is associated with a decrease in lactate levels, whereas subsequent tumor load leads to rapid increases in lactate levels.²⁹ In patients with septic shock, the increased activity of the cellular sodium/potassium pump has been associated with increased lactate levels not related to tissue hypoxia.⁴⁵ In addition, sepsis is also characterized by increased glycolysis due to cytokine-mediated glucose uptake.⁴⁶ Finally, mitochondrial dysfunction, not related to tissue hypoxia, can increase pyruvate levels and thus lactate levels.^{47,48} In clinical practice, infusion of Ringer's lactate does not interfere with lactate measurements,⁴⁹ whereas high-volume hemofiltration using lactate-buffered solutions do result in transiently increased lactate levels.^{50,51} Many other causes of increased lactate levels, not related to the presence of tissue hypoxia, have been identified.⁵²⁻⁵⁶ In the presence of ethylene glycol intoxication, a high lactate level measured with a point-of-care device may be confounded by the adverse reaction to the lactate electrode in the machine.⁵⁷ A subsequent normal lactate in the central laboratory can even be used as a diagnostic tool in these circumstances.⁵⁸

Clearance of Lactate

The body is able to clear large lactate loads rapidly as demonstrated by the decrease in lactate levels following exercise, cessation of seizures, or return of circulation in cardiac arrest. However, in specific circumstances, the clearance of lactate may be limited that could result in prolonged increased lactate levels following resuscitation or in limited increased lactate levels in the case of normal production.

Impaired liver function is known to decrease the clearance of lactate by the liver.^{36,59} Also in patients following cardiac surgery, clearance is impaired following a bolus infusion of lactate.⁶⁰ The dysfunction of pyruvate dehydrogenase in septic conditions, which can be alleviated by the administration of dichloroacetate, also limits lactate metabolism and results in increased lactate levels, where adequate oxygenation may be present.^{61,62}

HOW AND WHERE TO MEASURE LACTATE LEVELS

Various devices are available to rapidly measure lactate levels. A point-of-care blood gas analyzer has the advantage of delivering both the measurement of ScvO₂ and the lactate level. This can be used in clinical practice as the sampling site for lactate measurement (arterial, venous, capillary, etc) does not have a significant impact on the results.⁶³⁻⁶⁵ In addition, hand-held devices to measure lactate have acceptable limits of agreement and clinical value when not used interchangeably with laboratory devices.^{66,67}

THE CONTEXT OF LACTATE AND VENOUS OXYGENATION

Physiologically, it is clear that low ScvO₂ levels represent a state where the oxygen delivery is not matched to oxygen demand. When this is coincided with an increased lactate level, supply-dependent oxygen consumption might be present. As lactate is not specific for tissue hypoxia and ScvO₂ is only specific when very low, the clinical identification of tissue hypoxia represents a challenge. Therefore, clinical context and other signs of abnormal perfusion or limited oxygen transport should be included. Especially in sepsis, no critical values for venous oxygenation exist.²⁴ This is probably related to the interindividual range of oxygen demand⁶⁸ and the microcirculatory shunting that is frequently present.²³ However, other signs also relate to abnormal perfusion and abnormal organ function.⁶⁹⁻⁷³ In the presence of hypotension, patients with normal lactate levels have less organ failure and better preserved microcirculatory perfusion than hypotensive patients with increased lactate

levels.⁷⁴ Some of these are even strongly related to a worse outcome.⁷⁵ Next to other signs of tissue hypoperfusion the context/history of the patient is important. We usually accept low ScvO₂ levels in patients with chronic cardiac dysfunction when no signs of impaired organ perfusion exist. In addition, a diabetic patient on metformin presenting with high lactate levels without a clear history that might result in hypovolemia or myocardial dysfunction is likely to have metformin-associated hyperlactatemia even in the presence of acidosis.⁷⁶ This is clearly different from a patient admitted with severe trauma and increased lactate levels.^{77,78}

As ScvO₂ responds immediately to changes in blood flow⁷⁹ and lactate clearance takes at least 15 to 20 minutes,^{40,80} there is no clear relationship between the change in lactate levels and venous oxygenation levels.⁸¹

HOW THAN TO USE SCVO₂ AND LACTATE LEVELS IN CLINICAL PRACTICE?

Given the increased risk of the presence of tissue hypoperfusion and concomitant hypoxia, the Surviving Sepsis Campaign Guidelines and the Task Force of the European Society of Intensive Care on circulatory shock and hemodynamic monitoring recommend targeting a ScvO₂ of 70% and normalization of lactate levels in the resuscitation of septic-shock patients.^{82,83}

Given the physiologic coupling of abnormal ScvO₂ and increased lactate levels, the Task Force maintained this advice despite the study which showed that either targeting lactate or ScvO₂ had no difference in outcome⁵ and the study that showed that excluding ScvO₂ and lactate measurements from a protocol-based therapy did not affect outcome.⁶

The only study available today showing a significant impact on mortality when combining both ScvO₂ and normalization of lactate in the resuscitation of patients with circulatory failure (40% of whom had severe sepsis/septic shock) had a limited time frame of interventions.⁸⁴ The aggressive therapy lasted for not more than 8 hours. Given the current possibilities to rapidly improve tissue perfusion and oxygenation by different interventions,^{39,85,86} the

changes of persisting tissue hypoxia that responds to optimizing perfusion are small. Recently, Hernandez et al suggested the presence of flow-dependent phase in lactate clearance in survivors of septic shock.⁸⁷ This is so-called “inflection point” in the lactate versus time graph could identify a point where increased lactate levels are unlikely to be caused by persistent tissue hypoxia. In the study by Jansen et al, where the target was to decrease lactate by 20% every 2 hours (mainly by optimization of the balance between tissue oxygenation and tissue oxygen demand), this goal was met only in the first 2 hours of the study.⁸⁴

CONCLUSIONS

There is a physiologic coupling between decreases in venous oxygenation and increasing lactate levels. However, this relationship is dependent on many factors that are frequently present and can rapidly change in septic-shock patients. Thus, both venous oxygenation and increased lactate levels can have limited specificity and sensitivity to detect tissue hypoperfusion and hypoxia. Other parameters of tissue hypoperfusion are available and should be used to create context to venous oxygenation and increased lactate levels. Although ScvO₂ can be used as a surrogate of the true venous compartment, caution should be used in specific circumstances. The venoarterial PCO₂ difference, easily available in these circumstances, can help to disguise a low flow state in the presence of normal to high ScvO₂ levels. As the persistence of low ScvO₂ values following initial resuscitation is very low¹⁵ and the baseline values for ScvO₂ in recent randomized controlled trials were normal,^{5,6} lactate monitoring in circumstances where resources and placement of a central venous catheter is limited, represents an easy, cheap, and fast way to assess risk of morbidity and mortality of septic-shock patients.^{67,88} The use of both parameters, however, requires adequate understanding of their physiology.

Controversies: Is Glucose Control Relevant?

Adel Bassily-Marcus, MD and Inga Khachaturova, MD

HYPERGLYCEMIA IN CRITICAL ILLNESS: STRESS HYPERGLYCEMIA

Virtually all adult medical ICU patients experience at least 1 blood glucose value above the normal fasting level (110 mg/dL).¹ The stress of critical illness promotes a state of insulin resistance which is characterized by increased hepatic gluconeogenesis and glycogenolysis, impaired peripheral glucose uptake, and higher circulating concentrations of insulin. There is upregulation of hepatic glucose production triggered by elevated levels of cytokines and counterregulatory hormones such as glucagon, cortisol, growth hormone, and catecholamines. These metabolic disturbances together with common ICU treatments such as corticosteroids, sympathomimetic agents, and glucose-containing infusions explain the frequently observed phenomenon of hyperglycemia irrespective of the disease, diabetes mellitus.

Many practitioners have viewed moderately severe hyperglycemia among critically ill patients to be either an epiphenomenon or an adaptive response, not warranting significant concern or intervention.

Large observational studies in different types of ICU populations reveal a J-shaped relationship between blood glucose levels and mortality of critical illness, with the mortality nadir somewhere between 80 and 140 mg/dL depending on the type of illness and the presence of a history of diabetes mellitus. Observations such as these raised concerns that acute hyperglycemia itself was contributing to poor outcomes, potentially by leaving affected patients susceptible to some of the complications that have long been observed among chronic diabetics, including high infection rates, poor wound healing, and polyneuropathy.

CONTROLLING HYPERGLYCEMIA

The groundbreaking Leuven I study² in 2001, conducted in critically ill surgical patients, found a remarkable overall 3.4% ICU mortality reduction, a 9.6% mortality benefit in patients with ICU LOS more than 5 days, and a 34% hospital mortality reduction in the strict normoglycemia group (target glucose 80-110 mg/dL) compared to standard therapy. These beneficial outcomes resulting from the use of intensive insulin therapy targeting normoglycemic levels sparked a strong interest in glycemic management in the ICU. Intensive insulin therapy quickly became the standard of care in both medical and surgical ICUs. However, a follow-up study, done by the same group in 2006,³ demonstrated that in contrast to the earlier study, intensive insulin therapy did not reduce overall mortality and was associated with an even higher rate of serious hypoglycemia (18.7%). In the first study, it was speculated that the benefits seen were primarily due to a surgical patient population and the primary use of parenteral nutrition.

THE HARMFUL EFFECT OF TIGHT GLUCOSE CONTROL

Following 4 consecutive negative trials, the most comprehensive landmark NICE-SUGAR trial⁴ results were reported. They found that the intensive insulin therapy groups achieving normoglycemia had an absolute 2.6% increase in mortality ($P = 0.02$) and an increased incidence of hypoglycemia (6.8% vs 0.5%). Furthermore, subsequent meta-analyses demonstrated that intensive insulin therapy provided no survival benefit and was associated with increased morbidity secondary to severe hypoglycemic episodes. These findings are also consistent with

observational data reported from ICUs incorporating intensive insulin protocols as part of their hyperglycemic management. The overall consensus from the available evidence suggests that intensive insulin therapy (target glucose 80-110 mg/dL) as compared to standard insulin therapy (target glucose 140-180) does not provide an overall survival benefit, may increase mortality and is associated with a higher incidence of hypoglycemia.

THE IMPACT OF HYPOGLYCEMIA

Hypoglycemia has been shown in the critically ill patient to be independently associated with a 3-fold increase in mortality. In a trial of intensive insulin therapy, severe hypoglycemia occurred in up to 28% of patients.⁵ It is further speculated that the incidence of hypoglycemia is likely to be higher outside of clinical trials if intensive insulin protocols are used. The main consequences of acute and persistent hypoglycemia are neurologic deficits, which at times can be quite difficult to detect but remain a true concern. Hypoglycemia has been shown to cause acute electroencephalographic alterations. In a 4-year follow-up of patients treated with intensive insulin therapy (target blood glucose 80-110 mg/dL), this population was found to have impairments in quality of life and social functioning as compared to patients who received conventional insulin therapy.⁶

The relationship between hypoglycemia and outcome may be explained by an association with severity of illness and an increased risk of death, or a true deleterious biologic effect in critically ill patients. Hypoglycemia might exert biologic toxicity by increasing the systemic inflammatory response, inducing neuroglycopenia, inhibiting the corticosteroid response to stress, impairing sympathetic nervous system responsiveness, causing cerebral vasodilatation or by unidentified mechanisms. Furthermore, many experimental studies have demonstrated that both insulin and hypoglycemia can induce hypotension, vasodilatation, nitric oxide release, sympathetic system response exhaustion, and decreased ability to respond to repeated stress.

THE RELEVANCE OF HYPERGLYCEMIA

The repeated observation that hyperglycemia is associated with poorer outcomes among critically ill patients, together with the theoretical harm of acutely elevated blood glucose, represents the basis for focusing on glycemic control in the intensive care setting. However, the possibility remains that elevated blood glucose levels are actually beneficial to the critically ill individual, and that stress hyperglycemia is an appropriate and adaptive response to life-threatening illness, as no randomized trial investigating glycemic control has studied the effect of truly permissive hyperglycemia.⁷

Potential benefits of hyperglycemia include promotion of glucose delivery in the face of ischemic insults (enhanced glucose diffusion gradient), with insulin resistance favoring redistribution of available glucose stores toward cells of the immune and nervous systems, and away from peripheral tissues. Recent observational studies have provided some support for this view, reasserting the possibility that hyperglycemia is simply a marker of illness severity when controlled for hyperlactatemia.⁸ Our ability to identify patients most likely to suffer harm from hyperglycemia remains incomplete.

Several studies have concluded that the association between hyperglycemia and in-hospital mortality is attenuated among those with preexisting diabetes mellitus, with some even failing to demonstrate any association at all.

GLUCOSE VARIABILITY

Glucose variability (the difference between daily minimum and maximum glucose levels) may be a reflection of dysglycemia induced by severity of illness, inadequate control of glycemia by the treating clinicians resulting in excessive fluctuations of BG levels, or both. Additionally, patients with increased glucose variability are more likely to have experienced hypoglycemia, complicating the assessment of glucose variability versus hypoglycemia and mortality. Over the last several years a plethora of data, from observational studies evaluating a wide variety of acutely and critically ill populations, has

confirmed the correlation between glucose variability and increased odds of death. These findings raise the question that attempting to control hyperglycemia may be a major contributing factor in glucose variability and subsequent detrimental outcomes. There has been hope that continuous glucose monitoring will decrease variability and improve outcome, although the one study conducted thus far has failed to show such a relationship.⁹

CONCLUSION

In summary, it was naïve to conclude after a single center study² that a single intervention (tight glucose control) would lead to an impressive mortality benefit in our complex critically ill patients with organ failures. A single study should never be followed by widespread promotion and adoption of a basic intervention. For an intervention to be adopted, it should be reproducible in a realistic environment, with a clear benefit that outweighs the risks.

The current recommendations for critically ill patients overall, and for patients with severe sepsis, are that insulin therapy should be started when blood glucose exceeds 180 mg/dL with the goal of maintaining blood glucose between 144 and 180 mg/dL with insulin when necessary. However, even this less stringent advice needs to be validated in future studies.

Simulation and Education in the ICU

Maneesha Bangar, MD; Carla Venegas-Borsellino, MD and Lewis A. Eisen, MD

KEY POINTS

- 1 Simulation training is proven to be beneficial for teaching technical tasks as well as nontechnical skills necessary for the critical care practitioner.
- 2 Simulation is a broad method of training, which can include standardized patients, partial task trainers, hybrid simulators, advanced task trainers, high-fidelity simulators, screen-based computer simulators, or virtual reality simulators.
- 3 Simulation training allows the opportunity to learn from errors without jeopardizing patient safety.
- 4 Debriefing is a key component in any simulation to allow for deliberate practice and improvement.
- 5 Crisis resource management is a key component of simulation training and should be stressed in all team training scenarios.

INTRODUCTION

Critical care medicine (CCM) specialists face emergencies every day and are required to make decisions in a short span of time. These decisions have a great impact on patient outcomes and physicians may require years of experience in order to be competent in handling such situations. This process poses a real challenge for CCM physicians undergoing training.

As Confucius said: “I hear and I forget, I see and I remember, I do and I understand.” Similarly, Edger’s cone of experience emphasizes the importance of learning by doing. But, does that mean that physicians in their initial learning curve will continue to learn by doing procedures and executing

management plans on patients? If we were patients, would we want a physician’s first ever procedure to be on us? Would it not be better to practice on a model before we practice on a real patient? That is where simulation comes into play.

Simulation is defined as something that is made to look, feel, or behave like something else. Simulation training gives physicians exposure to different case scenarios in a shorter period of time, and imparts knowledge, experience, and skills to deal with them confidently. Learning could be passive such as listening to lectures or active whereby the learner participates verbally by giving comments or physically by participating in the simulation.

Knowles¹ described the adult learner as a self-directed learner who attaches more meaning to learning through experience than through passive learning, is more interested in learning things applicable to real life, is problem-oriented and performance-centric, and always seeks feedback in order to become more efficient. His principles of the ideal way to teach an adult learner have been included in simulation training.

HISTORY OF SIMULATION

Models simulating the brain, heart, airway, and other body organs have been used to teach human anatomy for many years. Medical science has come a long way from using those models to using today's high-fidelity simulation models that can talk, breathe, and have palpable pulses. Simulation-based training has been used in other high-hazard professions, such as aviation, the nuclear industry, and the military, to maximize training safety and minimize risk. Health care has lagged behind in simulation applications for a number of reasons, including cost and resistance to change.²

Review of literature shows that flight simulators have been utilized in training since the 1920s. Around the 1960s, the practice of using standardized patients for the training of medical students was started. ResusciAnnie and Harvey for cardiology examinations were developed at the same time that cardiopulmonary resuscitation (CPR) was introduced. The concept of virtual reality was introduced by the entertainment industry in the 1960s via Morton Heilig's Sensorama. Virtual reality entered the medical field through simulated endoscopies in the 1990s. With advancement in computer technology in the 1990s, software-based simulators were developed, leading to the extensive use of simulators in anesthesia.³

Before 1990, anesthesiologists were not provided formal training in crisis management, although they were suddenly called upon to manage life-threatening crises. Due to this gap in training, Dr. Howard and Dr. Gaba in the 1990s developed a course in anesthesia crisis resource management (ACRM) analogous to courses in crew (cockpit) resource management (CRM) conducted in commercial and military aviation. Two model demonstration

courses in ACRM were conducted using realistic anesthesia simulation systems to test the feasibility and acceptance of this kind of training.⁴ Subsequently, simulation was started to be used by many different subspecialties, including critical care, pediatrics, emergency medicine, and obstetrics/gynecology.⁵ Around the year 2000, Laerdal introduced a computer-controlled patient simulator mannequin—SimMan, with very realistic features and feedback responses, and subsequently developed more advanced high-quality human simulators. Haptic devices were also used to simulate laparoscopic procedures.

ADVANTAGES OF SIMULATION TRAINING

The main advantages of simulation training are as follows:

- Provides an opportunity to get hands-on experience of real-life scenarios on mannequins before dealing with patients.
- Enables learning of common procedural skills.
- Enables practicing rarely used procedures.
- Enables learning of leadership skills.
- Helps with crew crisis/resource management.
- Enhances communication skills.
- Provides feedback for enhancing the learning process.

Steadman et al⁶ conducted a study for training, based on either SIM (learning by simulation) or PBL (practice-based learning), to 31 fourth-year medical students in acute care management; the SIM group performed better than the PBL group (mean PBL 0.53 vs SIM 0.72, $P < 0.0001$). They concluded that SIM was superior to PBL for the acquisition of critical assessment and management skills.

Studies from aviation literature have shown that simulation reduces the number of training hours required to reach a proficiency level compared with other methods of training. Generalizing their results to health care, we can postulate that SIM will be of great help to produce efficient, skillful health care providers in a shorter period of time.⁷

TRANSFER OF TRAINING FROM SIMULATION TO REAL LIFE

This concept is adapted from the aviation literature and involves implementing the gathered knowledge/skills in real-life scenarios (Figure 75–1). Baldwin and Ford⁸ define the transfer of training as the application of knowledge and skills gained from training to real-life situations outside training and the maintenance of that transfer over a certain period of time. Later, Ford also mentioned that the factors affecting the transfer of training include trainee characteristics (ability, personality, motivation), training design (learning, sequencing, job relevance of training content), and the work environment (transfer climate, social support from supervisors and peers). Learning does not necessarily equate ability to perform tasks “on the job.” If that learning occurs in a simulated environment and does not result in transferable skills, then the training will be of no use.⁹ Assessment of this transfer would be by evaluating the trainees’ performance in real-life scenarios.

CLASSIFICATION OF SIMULATORS

1. Standardized patient simulator: It simulates a person acting as a patient reproducing the history, symptoms, and mien in response to the learner’s questions and physical
2. Part task trainers are life-like models of body parts used to enhance procedural skills such as airway management, line placements (Figure 75–2A), chest tube insertions, cricothyroidotomies, and intubations (Figure 75–2B).¹¹
3. Hybrid simulators consist of life-like body parts attached to a standardized patient.
4. Advanced task trainer: It consists of a body part model linked to a computer; it is used for procedures such as bronchoscopies (Figure 75–3) wherein the practitioner inserts the instrument into the body part and the computer screen displays the internal anatomy as maneuvers are performed. The system is programmed to respond to stimuli (ie, irritation by coughing if adequate analgesia is not given).

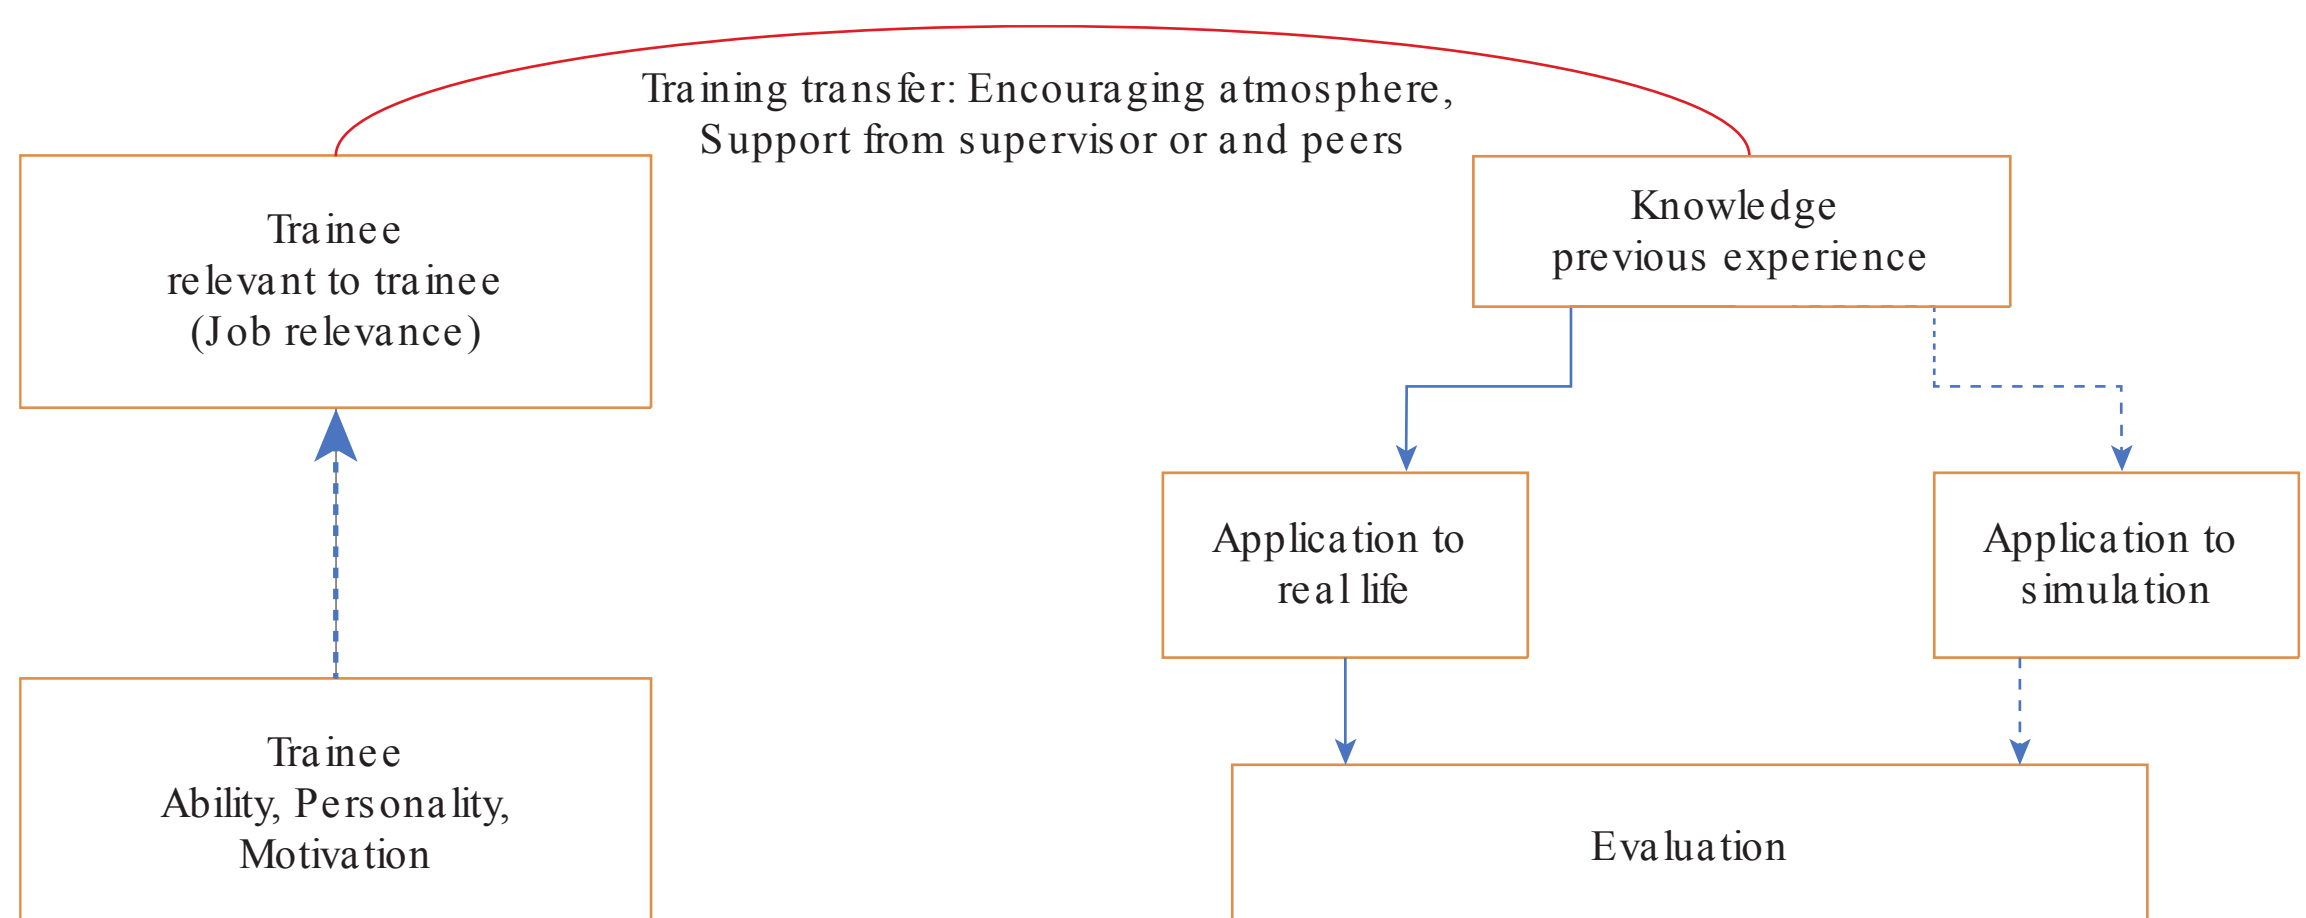

FIGURE 75–1 Transfer of training and its evaluation.

FIGURE 75–2 (A) Part task trainer for ultrasound guided central line placement. (B) Part task trainer for endotracheal intubation.

5. High-fidelity simulator (**Figure 75–4**): A mannequin simulator that very closely mimics real-life responses. It manifests all the physiologic characteristics—breathing, talking, having palpable pulses, and responding to the learner’s intervention. Simulation training is carried out on such simulators with real equipment.
6. Screen-based computer simulator: A computer screen projecting a patient’s history, vitals, details of various medications, for example. It responds realistically to the learner’s interventions.

FIGURE 75–3 Advanced task trainer for bronchoscopy.

7. Virtual reality simulators: Generally used in surgical fields for a 3-dimensional view of masses/polyps, etc, for laparoscopy, for colonoscopy, etc.

Simulation is not intended to replace the need for learning in a clinical environment, but through improved preparation, it enhances the clinical experience and improves patient care; thus, it is important to integrate it with clinical practice.¹²

The success of a simulator program is not determined primarily by the type of simulator used but more by the enthusiasm, skill, and creativity of instructors, as well as the time and effort devoted to preparing and performing credible simulation scenarios.¹³

FIGURE 75–4 High-fidelity simulator.

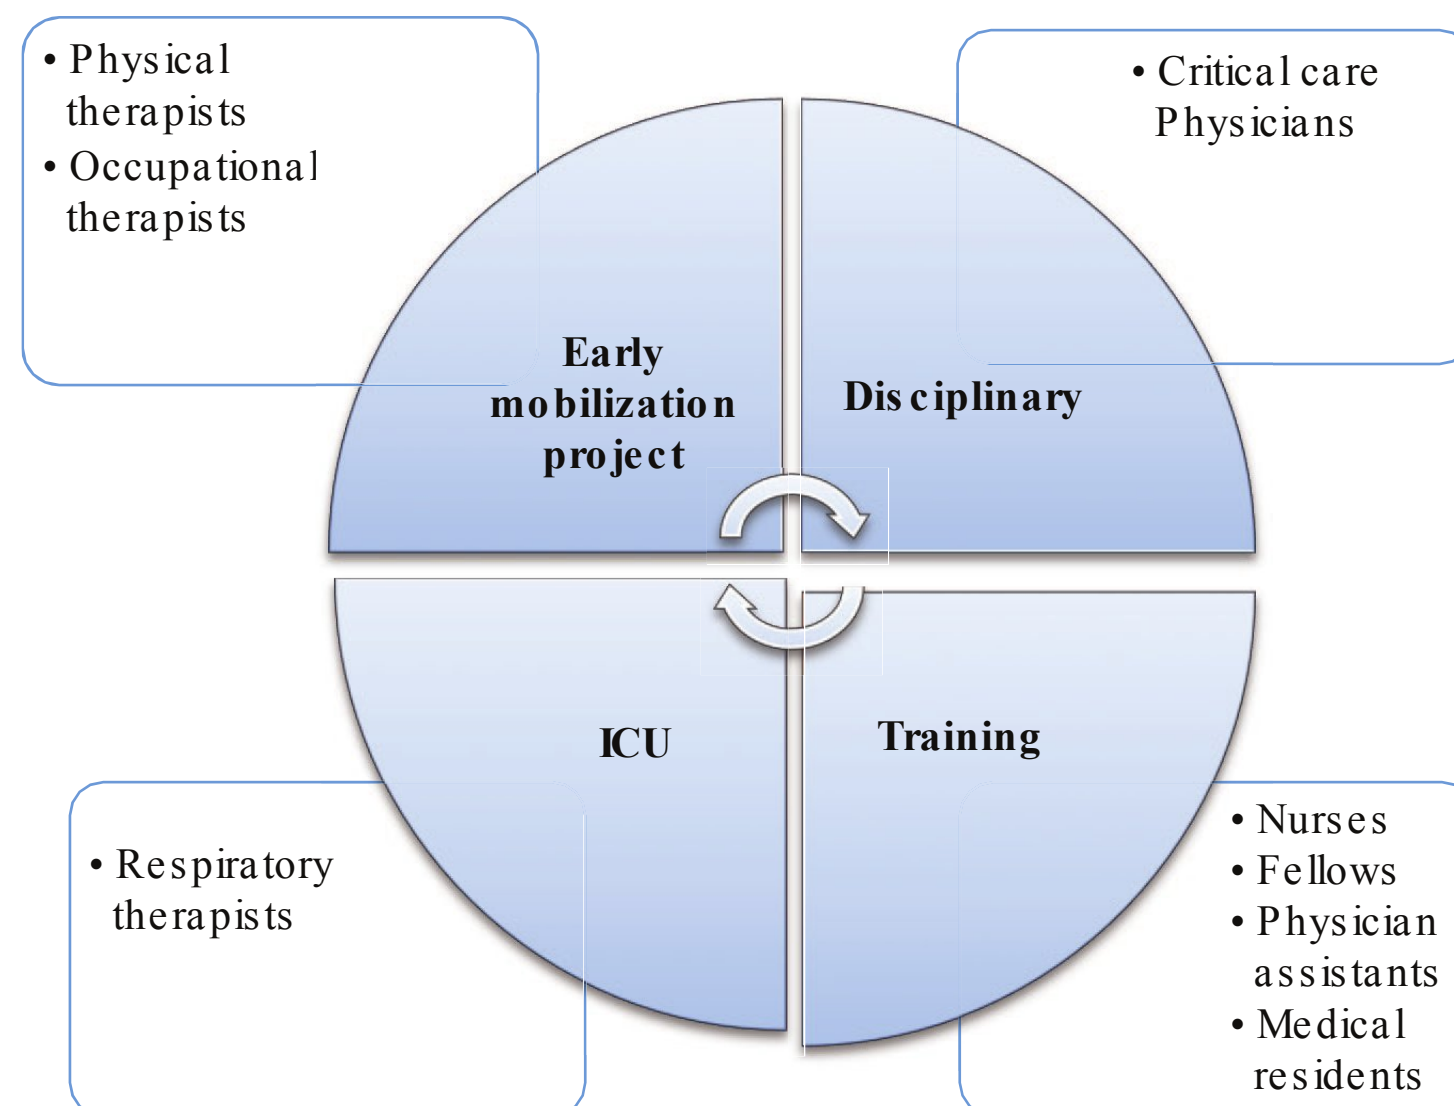

FIGURE 75–5 Interdisciplinary training in ICU.

INTERDISCIPLINARY TRAINING IN ICU

The intensivist has to work as part of a team that includes the nursing staff, respiratory therapist, physical/occupational therapy staff, and other consultants. All medical practitioners can derive benefits from simulation training, not only acquiring knowledge and clinical skills,¹⁴ but also improving team performance and developing leadership skills¹⁵ (Figure 75–5).

SIMULATION TRAINING FOR FELLOWS AND RESIDENTS

Simulation helps physicians improve their performance in highly stressful and life-threatening situations. The diagnosis and management of various shock scenarios, acute coronary syndromes, tachy/bradyarrhythmias, status epileptics, respiratory distress, anaphylaxis, metabolic disturbances, trauma, and post-surgical/cardiothoracic cases can be taught through simulation.

In the study by Sandahl et al,¹⁶ the participants reported that simulation training had increased their awareness of the importance of effective

communication for patient safety. However, they caution that the observed improvements will not last, unless organizational features such as staffing rotation and scheduling of rounds and meetings can be changed to enable use of the learned behaviors frequently in the work environment.

Tukey and Wiener¹⁷ in their study surveyed pulmonary and critical care program directors and found that many fellows currently occupied do not get the opportunity to gain proficiency in pulmonary artery catheterization (PAC), and proposed that fellowship training programs should consider alternate means of training fellows in PAC data interpretation, such as simulation.

SIMULATION FOR ULTRASOUND GUIDED LINE PLACEMENTS

With advanced technologies such as ultrasound being used for most ICU procedures, simulation plays an important role in giving trainees skills and confidence to perform procedures. Barsuk et al¹⁸ showed that simulation-based mastery learning increased residents' skills in simulated CVC

insertion, decreased the number of needle passes when performing actual procedures, and increased residents' self-confidence.

SIMULATION FOR AIRWAY

The types of airway handling techniques that can be taught in simulation range from the simple (bag and mask ventilation) to the complex (direct laryngoscopy intubations, glidoscope-guided intubations, tube exchangers, bougie use, cricothyrotomies, and percutaneous tracheostomy tube insertions). In a study with medical residents of basic airway management, Kory et al¹⁹ showed that scenario-based training with a computerized patient simulator was more effective in training medical residents than the traditional experiential method.

SIMULATION FOR BRONCHOSCOPIES

For pulmonary and critical care fellows, simulation allows practicing how to introduce and maneuver the bronchoscope in the simulated airway, thus allowing development of skills before the actual procedure is done on a real patient. The advanced task trainer for bronchoscopy produces natural patient reflexes such as coughing, and responds to sedation and analgesia like a real patient. It helps the new learner to get familiar with the basic techniques of holding and maneuvering the bronchoscope from the upper to the lower airways. If done first on an actual patient, a novice bronchoscopist could expose the patient to untoward events such as hypoxia or hypotension. These simulators may also allow training for bronchoscopic biopsy, brushing, and ultrasound.

Kennedy et al²⁰ performed a meta-analysis on studies evaluating simulation-based flexible or rigid bronchoscopy training compared to no intervention. In comparison with no intervention, simulation training was associated with large benefits in terms of skills and behaviors (pooled effect size, 1.21 [95%CI, 0.82-1.60]; $n = 8$ studies). They concluded that simulation-based bronchoscopy training is more effective than no intervention and also found that comparative effectiveness studies were few.

SIMULATION AS A TOOL FOR QUALITY IMPROVEMENT

Burden et al²¹ collected data for catheter-related bloodstream infection incidence (CRBSI), the number of ICU catheter days, mortality, laboratory pathogen results, and costs pre- and postintervention, which was simulation-based central venous catheter insertion training. They found that the CRBSI incidence and costs were significantly reduced for 2 years postintervention.

MECHANICAL VENTILATION

Mechanical ventilation can be taught by using either screen-based computer simulators or high-fidelity simulators. The screen projects the ventilator screen with waveforms and ventilator settings and pressures. It gives arterial blood gas values and creates scenarios with different airway and ventilation issues. It responds to learner intervention by appropriate changes in arterial blood gases.

SIMULATION IN PALLIATIVE CARE

It is obvious that the patient and their family members in the ICU require emotional support and other comfort measures. An intensivist must conduct family meetings to keep them updated about the patient. They may have to deal with varying responses from the family members. Given the patient's severity of illness, they may also have to discuss end-of-life issues. As mentioned before in this manuscript, simulation is now being used in this field.¹¹ A standardized patient can act as the patient. Family members' responses can also be simulated. This tool can also be used to evaluate residents'/fellows' baseline communication skills as well as to teach these skills effectively.

A study done by Efstathiou and Walker²² indicated self-perceived improvements in knowledge, skills, confidence, and competence when dealing with challenging end-of-life care communication situations. A comparison of pre- and post-intervention scores revealed a statistically significant positive change in the students' perceptions about their level of knowledge ($P < 0.02$).

SIMULATION FOR PHYSICAL THERAPY STAFF

Now with early mobilization being implemented in major institutes, physical and occupational therapies are increasingly being followed by the ICU interdisciplinary team. More patients on ventilators are being mobilized out of bed. This could possibly result in more adverse events such as accidental extubations, circuit disconnects, hemodynamic compromise, and falls. So, it is essential that the rehabilitation services staff be trained to anticipate and act on these issues by calling for help early or taking more precautions with tubing and pumps attached to the patients.

Ohtake et al²³ showed that incorporating simulated, interprofessional critical care into a required clinical course improved physical therapist students' confidence in dealing with technical, behavioral, and cognitive performance measures, and was associated with high student satisfaction; using simulation to introduce students to the critical care environment may provide encouragement and increase their interest in this area.

SIMULATION FOR FAMILIARITY WITH EQUIPMENT USE

1. Pacemaker and defibrillator: Simulation training will enable health care professionals to better operate the machinery used in this field. Running a scenario on a simulator with different brady/tachyarrhythmias scenarios will give health care providers hands-on training with different equipment so that they are prepared and trained for real-life scenarios. Knowledge of resuscitation algorithms is not sufficient to help patients if operators are not familiar with how to use vital equipment.
2. Continuous renal replacement therapy (CRRT): With the technological advancement, there is also a need to train the involved staff in the operation of the new equipment, and the operator should be comfortable with troubleshooting alarms. Mencía et al²⁴ developed a device and proposed that it may be very useful for training health care

professionals in CRRT management, thus avoiding risk to patients.

3. Extracorporeal membrane oxygenator circuit (ECMO): The use of ECMO has increased in recent years. Simulation in ECMO can be used to train surgeons, anesthesiologists, critical care physicians and nurses, and perfusionists.

SIMULATION TO PREPARE FOR DISASTERS

Simulation with standardized patients during a mass disaster can be used to train health care professionals to be mentally and physically ready. Also with emergency rooms being overcrowded with many sick patients during a disaster, the ICU team should be ready to absorb the very sick patients and provide additional care in unfamiliar settings outside of the ICU. In order for the team to react properly to these kinds of emergencies, simulation training is necessary.

ROLE OF SIMULATION IN PATIENT SAFETY

A medical error is a preventable adverse effect of care, whether it is harmful to the patient or not. Medical errors are one of the main causes of significant morbidity and mortality. They incur a cost burden on the society and health care industry. Medical errors hurt patients physically, economically, and psychologically. They may also cause feelings of inadequacy and guilt in the provider. Decreasing medical errors to improve patient safety is of high importance.

Some of the measures to reduce medical errors and increase patient safety, as suggested by Kohn et al,²⁵ are to support projects aimed at achieving a better understanding of how the environment affects the ability of the provider to practice safely. Another recommendation is funding researchers and encouraging organizations to develop, demonstrate, and evaluate new approaches to improve provider education in order to reduce errors. Simulation training can be used to fulfill both these purposes. Errors may occur in a team care environment as a result of nontechnical factors (eg, communication), and specific simulation-based training

protocols have been developed for enhancing team performance.^{16,26}

With the age-old practice of apprenticeship training in the medical field being questioned in light of increased priorities for patient safety, simulation training seems to be a useful tool to help reduce medical errors through training and improve safety. Simulation training allows practitioners to make errors and learn from them in a controlled, simulated environment. This experience can prepare them to face real-life scenarios with confidence and minimize actual errors.

CRISIS RESOURCE MANAGEMENT

Crew resource management, defined as effective utilization of all available equipment and people to carry out safe, efficient flight operations,²⁷ is a term introduced in the aviation industry during a NASA workshop in 1979. It was designed as a training program to improve air safety and reduce the increasing number of fatal accidents attributable to human error.²⁸ When errors were analyzed, they were mainly attributed to failure of interpersonal communication, leadership, and decision-making. The same principle can be applied to the medical field where it is called crisis resource management (CRM). Health care industry has now recognized the importance of this training and is slowly and steadily incorporating it into different subspecialties. The traditional medical curriculum does not lay emphasis on nonclinical skills such as communication, leadership, and team building. Now, with human errors being linked to inadequate nonclinical skills, importance has been given for developing and maintaining these skills by simulation training.

How can one evaluate and measure CRM skills? Two validated scales in critical care are the Ottawa Global Rating Scale (GRS) and Mayo High Performance Teamwork Scale (MHPTS).²⁹ In their study, Kim et al³⁰ had first- and third-year residents participating in two simulator scenarios, recreating emergencies in acute care settings, and were evaluated using the Ottawa GRS by three different evaluators. With his results, Kim found acceptable inter-rater reliability and validated the Ottawa GRS to evaluate CRM performance during high-fidelity simulations.

Malec et al³⁰ performed a study to develop and evaluate a scale for assessing teamwork skills in simulated settings. He developed the MHPTS and found that it provides a brief, reliable, and practical measure of CRM skills that can be used by participants in CRM training to reflect on and evaluate their performance as a team.

CRM involves leadership, problem solving, situational awareness, resource utilization, and communication skills. CRM is extremely important for patient safety but is not covered in the traditional learning curriculum. In order to master CRM skills, one has to practice them repeatedly in simulated sessions. [Figure 75–6](#) illustrates how simulation helps improve different skill sets to achieve patient safety.

DEBRIEFING

Debriefing, a term used more often in military scenarios, is a very important component in simulation training. As shown in [Figure 75–7](#), simulation training first involves creating a simulation case scenario (with all pertinent medical details and specific educational goals), then introducing the learner(s) to the simulated scenario, giving them the time to perform a task, and then debriefing them after the scenario is completed. The debriefing should involve the learner's self-evaluation (ideally after viewing a video recording of their performance), and the instructor's feedback (a powerful educational tool). The aim of debriefing is to make learners realize both their strengths and areas that could be improved in an encouraging, healthy manner. Also, during this time the instructor should evaluate and address individual and team performances and gives positive and negative reinforcement as appropriate.

CONCLUSION

Critical care practitioners are increasingly using simulation training. Traditional learning with books and lectures continues to provide a basic fund of knowledge. Simulation helps reinforce and consolidate the knowledge gained from traditional learning. Additionally, simulation helps health care providers develop hands-on clinical and nonclinical skills such as CRM skills. CRM skills cannot be learned from a book or in a lecture hall. Due to the low prevalence yet high complexity of many

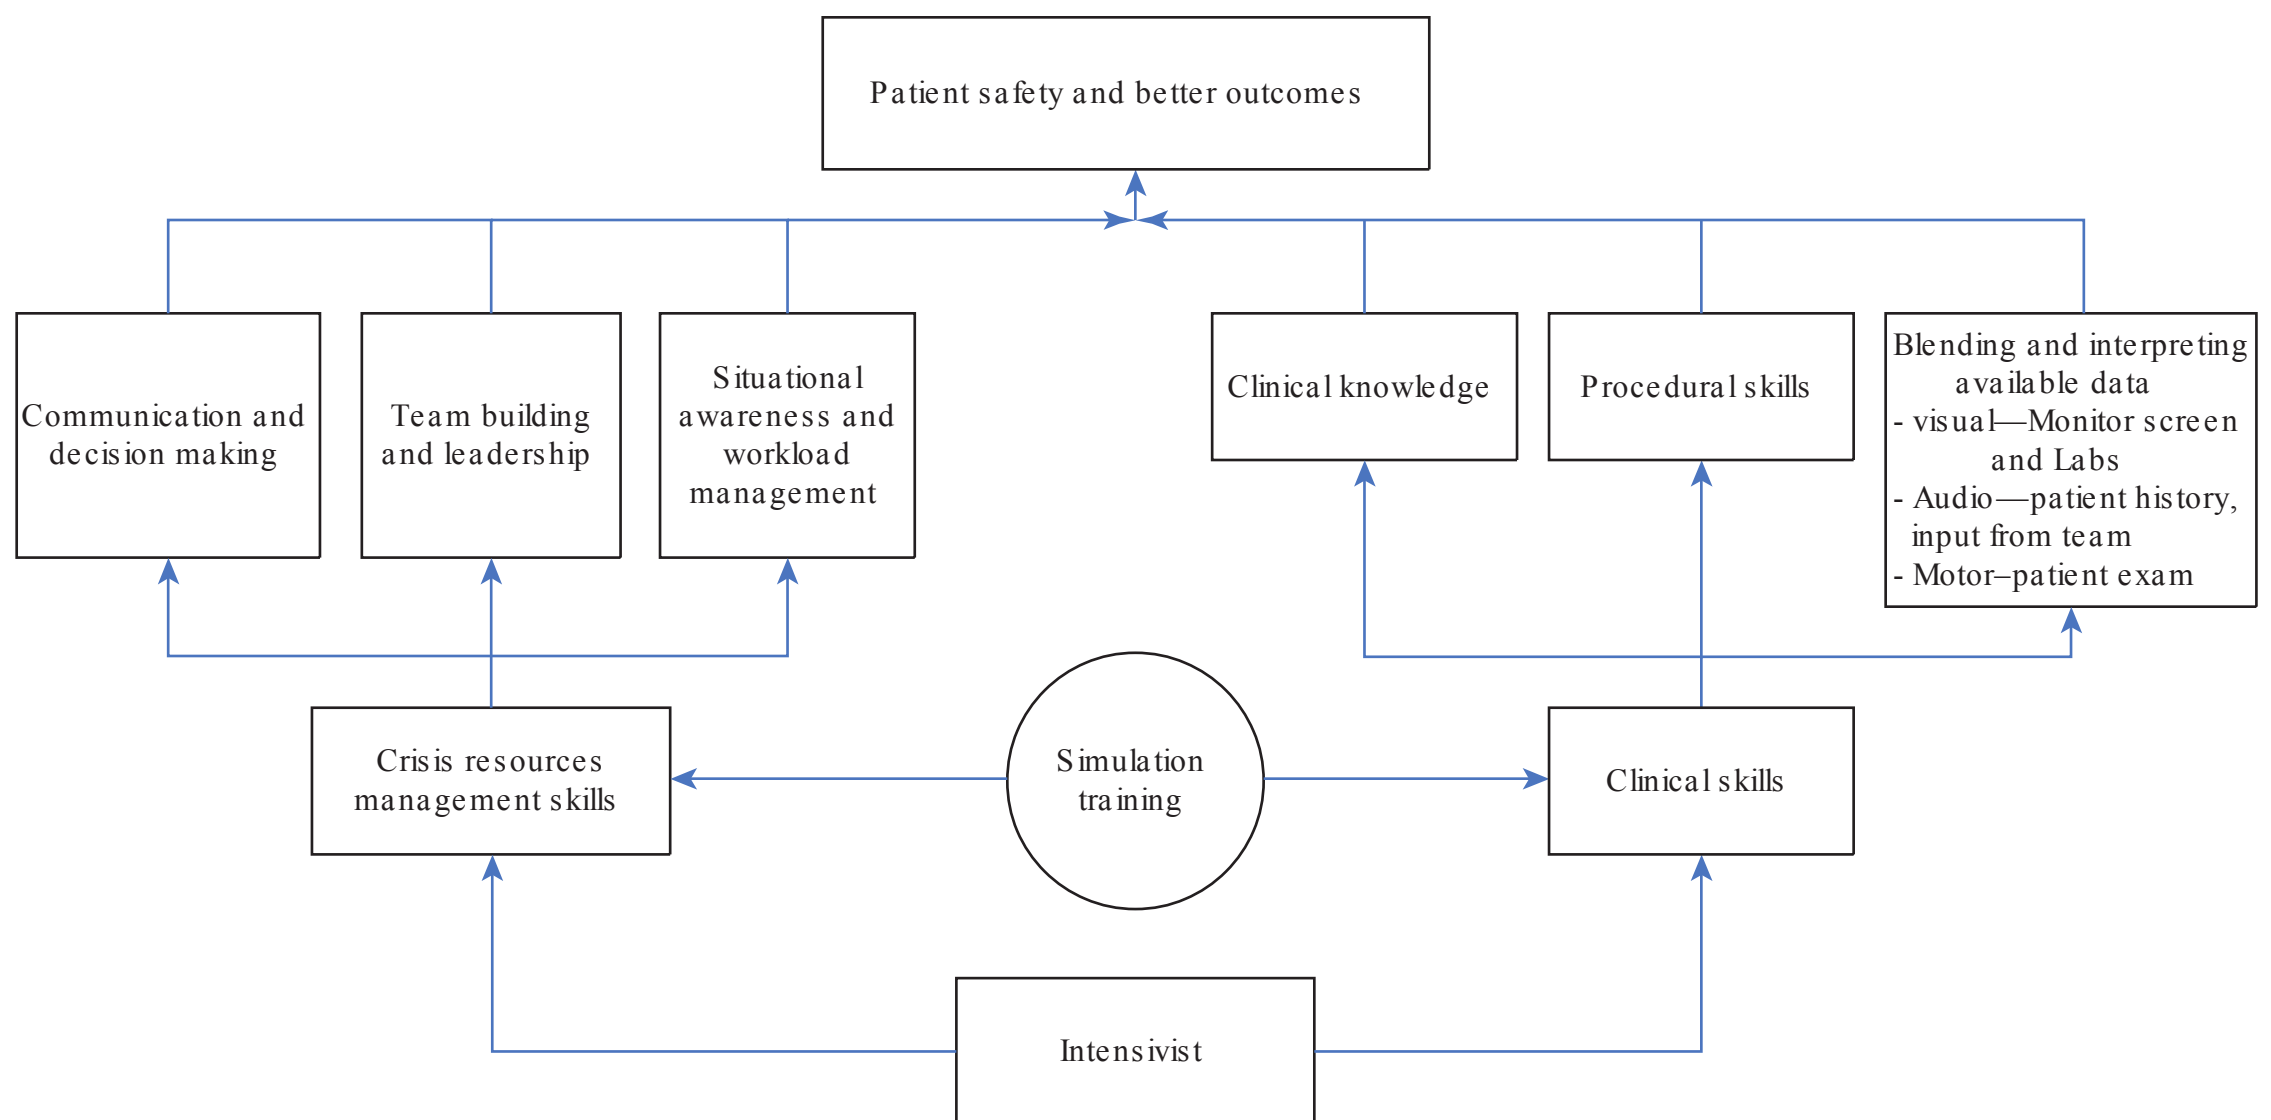

FIGURE 75–6 Combination of clinical and nonclinical skills for patient safety. (Data from Driskel JE, Adams RJ: Crew Resource Management: An Introductory Handbook, August 1992. U.S. Department of Transportation. Federal Aviation Administration.)

disease processes encountered in critical care, critical care performance depends on time-sensitive decision-making, safe procedural skills, and good staff teamwork to ensure positive clinical outcomes. However, the opportunities for young trainees to be present and actively participate during these critical moments are increasingly low. Training in critical care using simulation can make medical education more effective and interesting, providing real benefits to patients. Simulation training enables immediate self-evaluation and provides

critical feedback, essential for skill development. Simulation training, in all its forms, should be an integral part of the education of all providers who work in the ICU.

ICU Bed Utilization

Hannah Wunsch, MD, MSc

KEY POINTS

- 1 The lack of an agreed-upon definition of an ICU bed remains a barrier to understanding bed utilization.
- 2 Small ICUs or systems of ICUs are at a disadvantage due to their size, creating inefficient use of ICU beds.
- 3 Availability of intermediate-care beds may impact the flow of patients into and out of ICU beds.
- 4 The casemix of patients admitted to an ICU can vary dramatically. This may be driven by the overall availability of ICU beds, but will also be determined by the casemix of patients in a hospital or system.
- 5 Use of intensive care beds is often driven by the specific culture of a hospital regarding the “perceived” need of an individual patient, as well as the larger cultural expectations within a given society.
- 6 Optimization of ICU bed use may include decreasing the number of small ICUs operating separately, standardizing criteria for admission, and increasing alternate care options.

INTRODUCTION

Care of critically ill patients is an integral part of hospital care,¹ but ICU beds are a limited resource in many settings.^{2,3} How ICU beds are used has implications for the care of individual patients, as well as resource use and costs at the hospital and regional level. Some aspects of ICU bed utilization may be specific to individual hospitals, but others are more generalizable across hospitals and health care systems. This chapter reviews many of the factors that impact how ICU beds are used, and then discusses potential approaches to optimizing their use.

Definition of an ICU bed: The lack of an agreed-on definition of an ICU bed remains a barrier to understanding bed utilization. Some countries, such as the United Kingdom, have a clear definition, describing Level 3 care (ICU-level care) as patients

receiving advanced respiratory support alone, or having a minimum of two organs supported.⁴ Many countries do not seem to have any definitions. In the United States, there are no standard definitions, but a proposed system of categorization broadly defined the highest level of care as including “sophisticated equipment, specialized nurses, and physicians with critical care training.”⁵ Across developed countries, the majority of ICU beds have availability of mechanical ventilation and some form of renal support and other organ support. The meaning of an “ICU bed” in developing countries is much more questionable as it does not necessarily include resources to provide specific organ support.⁶ This chapter will discuss about the use of ICU beds in systems, with the ability to provide mechanical ventilation and other basic organ support as part of intensive care.

HOW ARE ICU BEDS USED?

The question of the utilization of ICU beds is ultimately one of triage: understanding who is to be admitted to an ICU bed and why, and looking to optimize the use of this expensive resource while providing appropriate care for individual patients. The use of beds is dependent on a number of specific factors: (1) the physical number of ICU beds in a specific ICU, hospital, or system; (2) the ICU bed to hospital bed ratio; (3) other options for care of patients, such as intermediate care units; (3) the casemix of patients cared for in a specific hospital or system, including specific elective surgical patients; (4) hospital culture; and (5) regional culture and norms.

The number of ICU beds: The total number of ICU beds available will clearly have an impact on the use of those beds.⁷ This may be due to a number of factors related to the absolute number of beds. First, a hospital with only a few (3-4) ICU beds will not have a high volume of critically ill patients and is likely to have a system for transferring their critically ill patients to larger centers.⁸ Some countries or systems may have a formalized regionalization system (such as for trauma),⁹ whereas others may be more informal.⁸ However, such systems mean that small ICUs may tend to care for patients with only a low severity of illness.^{10,11}

Small ICUs or systems of ICUs are also at a disadvantage due to their size, leading to inefficient use of ICU beds. This is due to the concept of queuing theory, which demonstrates that the likelihood of a patient admission being delayed is a function of the occupancy and the total number of ICU beds.¹² For example, an ICU that has only 4 beds must operate at 75% occupancy in order to ensure an available bed for the next patient. In contrast, an ICU with 100 beds operating at 75% occupancy has 25 beds available for patients.

The potentially large implications of high occupancy for ICU bed utilization have now been documented in a number of studies. A study by Stelfox et al¹³ from Canada demonstrated that when beds are not immediately available, more patients have alterations in their goals of care, with no detectable difference in overall mortality, suggesting that occupancy may drive physicians and patients to choose

appropriate alternative care paths. However, the knock-on effect of high occupancy may also depend on the country and the overall availability of beds. For example, data from the United Kingdom suggest that many patients are discharged prematurely due to chronic high occupancy and intense pressure regarding new admissions, with worse hospital mortality for the patients discharged prematurely.^{14,15} In contrast, data from the United States suggest that premature discharges associated with “strained” ICUs do not result in increased mortality, and may consequently represent more efficient use of ICU beds.¹⁶

The ICU bed to hospital bed ratio: Little is understood about the ICU bed-to-overall hospital bed ratio and how this affects ICU bed use. We do know that most systems/countries operate on a relatively fixed ratio of ICU beds to hospital beds of approximately 2 to 5 ICU beds for every 100 hospital beds in total, while the United States operates with a very different ratio of 9 to 10 ICU beds per 100 hospital beds in total.⁷ This high ICU bed to hospital bed ratio in the United States may impact ICU bed utilization by decreasing the threshold for use, particularly if other lower acuity beds become the scarce resource. Data from the United States suggest that 40% of patients admitted to an ICU have monitoring needs only (no active treatment), and that only 35% of these patients are considered at high risk of needing active treatment during the ICU stay.¹⁷ Similarly, a study by the Veterans Affairs system in the United States found that many patients (up to 50%) admitted through the emergency room with a predicted risk of death of less than 2% were admitted to ICU beds.¹⁸ This is enabled by an overall high availability of ICU beds and a generous ICU bed to hospital bed ratio, as described above, but also may be driven by inadequate nursing or other resources in other parts of the hospital.

Other options for care of patients: The question of other care options for patients is an important one to understand ICU bed utilization. Intermediate care (also called stepdown care, or high-dependency care) has received little attention in the ICU literature. Yet in a survey of 40 hospitals as far back as 1995, 63% of hospitals reported at least one intermediate care unit.¹⁹ These types of units provide care at a higher level than available in a general ward, but usually without the ability to provide full organ

support, such as mechanical ventilation. Evaluation of their use has mostly focused on elective surgical patients,²⁰⁻²² but, clearly, the utilization of ICU beds in a system depends on the availability of such beds. The availability of intermediate-care beds may impact both the time patients need to spend in an ICU bed prior to discharge and also the need to admit a patient to an ICU bed at all, particularly when the focus is on better monitoring and/or nursing care, rather than full organ support.

Casemix of patients: The casemix of patients admitted to an ICU can vary dramatically.²³ This may be driven by the overall availability of ICU beds, but may also be determined by the casemix of patients in a hospital or system. This point is related to the one above regarding intermediate care beds, as some individual patients are more amenable to care in alternate settings. One large driver of the routine utilization of ICU beds is specific surgical programs in a hospital. For example, a hospital that routinely performs liver transplants will use ICU beds for the care of those patients (sometimes) before and (always) after the surgical procedure. Similarly, a hospital that has a large population of oncology patients may expect a certain requirement for ICU beds for patients developing complications from chemotherapy or surgery.²⁴

Specifics of the hospital culture: Use of ICU beds is often driven by the specific culture of a hospital regarding the “perceived” need of an individual patient. For example, in a study of patients admitted to hospitals in New York State with diabetic ketoacidosis, anywhere from zero to 100% of patients received intensive care during the hospitalization.²⁵ Although much of this variation may be driven by the factors described above, such as availability of other appropriate care settings and high-level nursing on wards, at least some of this variation is likely attributable to accepted practices. There are similar findings for other diagnoses, such as patients with carotid endarterectomy.²⁶ One study examined outcomes using their standard practice of admitting almost all (98%) of the patients to the ICU for monitoring after a carotid endarterectomy versus admission based on assessment of risk (22%) and found no difference in outcomes, reinforcing the idea that practices regarding ICU bed utilization may be based on the perceived, rather than actual, need.²⁶

Regional culture and norms: Use of ICU beds may be driven not only by the culture or expectations for care within a specific hospital setting, but also by larger cultural expectations. For example, data from the ETHICUS study carried out in Europe found a large variation in the practice of withholding or withdrawing of treatment before death, depending on the region of Europe,²⁷ and comparison work of cultural expectations in the United States and United Kingdom shows stark differences in expectations and experiences.²⁸ Some of these cultural norms may be codified into laws that then underpin patterns of ICU bed utilization. In some countries, physicians may make decisions regarding escalation of care and/or end-of-life care choices, such as the placement of a do-not-resuscitate order, without much input from families, while other countries or regions mandate that patients or families must agree to the proposed care plan.³

OPTIMIZING ICU BED UTILIZATION

Guidelines: Within the specific culture and laws of a region, a number of approaches may help to optimize ICU bed utilization. The first is to have clear guidelines for admission or refusal. While this approach works well in theory, the reality of such guidelines is that they provide a lot of latitude regarding the appropriateness of admission.²⁹ For example, the guidelines from the Society of Critical Care Medicine state: “ICU admission criteria should select patients who are likely to benefit from ICU care,” going on to try to define groups who may or may not benefit.³⁰ While such guidelines may help in the most extreme circumstances, the documents themselves acknowledge that they are not particularly useful for individual decision-making.³¹

All guidelines or tools for individual or even diagnosis or procedure-specific decisions are hampered by the lack of data regarding the benefit received from admission to an ICU.³¹ Whereas patients who require mechanical ventilation or are in shock requiring systemic circulatory support may be admitted to an ICU and no one doubts the benefit of intensive care for those patients,³² there are many other circumstances when it is not so

straightforward. For example a patient may be too sick to be rescued by the maximal support offered in an ICU or may be too well to benefit from the additional care.³³

Gatekeepers: Another option that may improve the utilization of ICU beds is designation of appropriate caregivers to act as “gatekeepers.” Many ICUs do not have clear designees for this role; particularly for “open” ICUs, this may mean that every physician in the hospital has admitting privileges to the ICU and can decide for themselves whether a patient should be admitted if there is a bed available.³⁴ Such an approach is clearly problematic, as ICU beds are part of a system, and appropriate use of those beds involves understanding of competing interests and ability to triage based on experience with critical illness and the likely course of an individual’s illness. One study has examined the impact of a medical ICU director on resource use, finding that the presence of an active medical ICU director in US ICUs was associated with a lower average occupancy rate and lower probability of patients being “misallocated” to the ICU.³⁵

Minimizing small ICUs and specialty ICUs: Along with having appropriate decision-makers, understanding queuing theory (mentioned above)^{12,36} and designing a system to minimize the number of small ICUs and maximizing the utilization of available ICU beds are paramount. Cities in England have very few ICU beds, but their utilization is optimized in places such as London by essentially creating a network of all ICU beds across London using the London Ambulance System to track available ICU beds and shift patients to the nearest available bed when needed.³⁷

The related problem of many specialty ICU beds may occur particularly in large academic medical centers, with 4 to 5 specialty ICUs (such as a “transplant” ICU). Patients may be left waiting for admission to the “appropriate” specialty ICU, rather than gaining admission to any available ICU bed. Data suggest that for most types of patients, specialty ICUs (compared with general ICUs) may not offer benefit for outcomes.³⁸ However, with the presence of specialty ICUs, patients who are “boarders” (i.e. admitted to an inappropriate ICU) may also have worse outcomes.³⁸

Alternative care options: Another way to optimize the use of ICU beds, particularly in systems such as that in the United States where many patients in ICUs are admitted solely for monitoring purposes, is to create or increase other care options, such as intermediate care areas. This type of approach may also involve such options as increasing the hours a recovery room is open to allow patients to remain in a monitored setting without full admission to an ICU.^{39,40} Hand-in-hand with this option is the improvement of nursing on general wards.

High-quality and experienced nursing staff on wards: A large barrier to keeping patients in lower levels of care may often be the perceived lack of quality nursing, rather than the need for any specific interventions provided by an ICU. Many studies suggest that aspects of nursing care, such as the nurse-to-patient ratio, and the level of education of nursing staff, can have a large impact on outcomes for patients.⁴¹⁻⁴³ Therefore, another approach to optimizing the use of ICU beds may be to ensure quality nursing care in other areas of the hospital so that ICU beds do not become the default destination for any patient who requires good nursing care.

Removing financial misalignment: Finally, in certain systems, such as that in the United States, optimal use of ICU beds may only be achieved once competing financial incentives are removed. For example, a physician who has a salary based on the number of critical care bills generated has a strong incentive to keep patients in the ICU, or admit marginal patients. Similarly, a hospital that is paying nursing staff based on the number of ICU beds in the unit would prefer to have patients in all of those beds to offset the fixed costs of the staff.⁴⁴ Or there may be financial penalties for an institution that keeps patients waiting for beds in the Emergency Department, forcing them to use ICU beds for patients who would otherwise go to ward beds. Only once these incentives are removed can other aspects of ICU utilization be optimized.

With the goal of efficient, patient-centered care in hospitals, ICU bed utilization is an important area for further research. Many of the approaches to improve efficiency remain speculative, and warrant further investigation with rigorous study designs to determine optimal approaches.

The ICU in the Global Hospital Environment

Hayley B. Gershengorn, MD

KEY POINTS

- 1 Critical care is not and cannot be completely standardized across all institutions; the local hospital and regional health care environment necessarily impacts the role of the ICU.
- 2 Critical care administration is often siloed, but may benefit from centralization into a service line, division, department, or institute.
- 3 Staffing of critically ill patients must be flexible and depend on the hospital environment; intensivists may be asked to care for patients outside of the ICU and physicians without traditional intensivist pedigrees may be trained and then appropriately tasked with caring for patients in the ICU.
- 4 Critical care is not just care within the ICU; rapid response/medical emergency teams, telemedicine, and regionalization of critical care can be used to advantage in certain institutional settings.
- 5 ICU resources—specifically, ICU beds—are limited; optimal use of this scarce resource in each hospital environment depends on understanding the capabilities outside of the ICU, both within an individual institution and regionally.

INTRODUCTION

While the “intensive care unit” (ICU) is a distinct location to which patients with critical illnesses are transferred, in order to optimally manage the ICU and care for the critically ill, it is important to understand the ICU as it functions within the global hospital environment. ICUs in the United States originated during the polio epidemic of the 1950s as a place to cohort patients in need of mechanical ventilation.¹ Over time, however, patients classified as critically ill have become far more heterogeneous and the potential to care for them has increased dramatically.² As a result, the role of the ICU in the hospital environment

has necessarily changed. Currently, ICUs cannot be viewed as standalone units that operate in silos. Instead, they must be well integrated into the hospital system to maximize the benefit of what is often a sparse resource—the ICU bed.³⁻⁵

In this chapter, four aspects of ICU management—(1) the administration of critical care, (2) staffing for critical care, (3) the structure of critical care, and (4) resource utilization for critical care—will be discussed. Some of these topics are addressed in detail in other chapters; herein, I will highlight how they are integral to situating the ICU well within the broader hospital environment.

ADMINISTRATION OF CRITICAL CARE

Critical care medicine has, traditionally, been a specialty without a home. ICU physicians have come from multiple backgrounds (eg, internal medicine, surgery, anesthesiology) and, in larger institutions, the units in which they work have, historically, been separately managed by their individual clinical departments.⁶ To make matters more complicated, the administration of nonphysician ICU staff (eg, nurses, respiratory therapists, nonphysician providers) is further fragmented. Instead of having a department unto themselves, critical care practitioners have been scattered throughout the organization. This type of fragmented or “siloed” structure has known drawbacks; silos can detract from teamwork and worsen communication with patients and families.^{7,8} An alternate strategy that is gaining favor is that of “service lines” where all aspects of care pertaining to a given clinical entity are grouped under one organizational unit. This organizational methodology has proven beneficial in widely varying clinical settings.⁹⁻¹² Administering critical care as a service line is of potential benefit to patients and the hospital as a whole.¹³

Creating a critical care service line can be accomplished through the development of a separate critical care division or department or through the appointment of a director of critical care who helps to oversee a critical care administration that remains housed within distinct clinical departments. While the former is a more drastic change for an institution in which the traditional model is in place, it allows for a more centralized system and, potentially, economies of scale and scope¹⁴ and flexibility in resource use.^{15,16} The latter option may not reap the same benefits, yet can make standardization of protocols—known to improve critically ill patient outcomes¹⁷—more feasible. In either case, all aspects of critical care delivery are managed together. With this model, the mission of the service line may be made clearer and resources may be more easily optimally allocated to achieve consistent goals.

This strategy of collaborative critical care administration has the potential to be beneficial to the hospital. First, if all providers operate under the same administration, collaboration among them is

simplified. If a patient in a hospital with more than one ICU is critically ill and in need of an ICU bed at a time when none is available in the ICU most well suited to him/her, coordinated management may facilitate the admission of that patient to another ICU. Additionally, transfer of that patient to the better suited ICU may be more feasible when bed availability permits. In the extreme, ICUs operating under this paradigm can have beds that are flexibly allocated to different care teams (eg, medical or surgical) and/or different care levels, depending on the day-to-day needs of the hospital.^{15,16} Second, there is a single person/administration who is responsible for addressing all issues pertaining to critical care delivery. For example, in New York State, a regulation mandating compliance with and documentation of adherence to sepsis bundles of care has been recently passed.¹⁸ With a centralized critical care administration, one single sepsis protocol can be developed and rapidly disseminated. Third, integration across clinical departments within critical care may foster integration outside of it as well. Lines of communication among providers within medicine and surgery, for example, may be bolstered through the existence of an integrated critical care department.

STAFFING FOR CRITICAL CARE

Staffing has become a topic of much focus in intensive care medicine recently. Leapfrog recommendations and Society of Critical Care Medicine (SCCM) guidelines require high-intensity staffing models where intensivists are available and/or onsite 24 hours a day.^{19,20} These mandates are difficult to meet for many institutions. Strategies to improve critical care coverage are discussed in detail in the chapter “Alternate Staffing Models in the ICU.” As staffing pertains to the ICU as a part of the global hospital environment, two main questions for staffing arise: Is the responsibility of an intensivist only to care for patients in the ICU? Are there advantages and/or disadvantages to having physicians from other service areas be primarily responsible for the care of ICU patients?

An intensivist is a physician with board certification or extensive experience in critical care medicine.²⁰⁻²² Traditionally, such a physician may

be involved in triage for the critically ill before ICU admission but cares, primarily, for patients within the confines of an ICU. Recently, however, the role of the intensivist has been expanded under the rubric of an “ICU without walls.”²³⁻²⁵ Under this paradigm, the intensivist is expected to consult upon and provide care to critically ill patients prior to, following, and, sometimes, in the absence of, an ICU admission. Rapid response/medical emergency teams are the most commonly used method of delivering critical care expertise to non-ICU patients who become critically ill.²⁶ While there is no standard structure for these teams, many include an intensivist and/or a critical care nurse.²⁷⁻²⁹ In essence, therefore, these teams can be viewed as expanding the ICU. Data on their impact is mixed,³⁰⁻³³ yet ward staff satisfaction is improved^{34,35} and these teams are being used with increasing frequency.³⁶

Rather than waiting for a clinical deterioration that merits activation of such emergency response teams, some institutions provide critical care consultation by intensivist-led teams for patients who are either not critical enough to be transferred to an ICU or have been recently transferred out of one.^{25,37} These services can create a degree of critical care coverage that, while often lacking in the nursing and monitoring capabilities of an ICU, can benefit less critically ill patients. Staffing these services requires a commitment of an expanded workforce, however. Depending on the specifics of a given institution—available staff, ICU capacity, ICU occupancy, etc—staffing such teams may improve care for the critically ill throughout the hospital.

Bringing the intensivist out of the ICU may be one way to improve care throughout the hospital and another may be having appropriately trained clinicians from other departments work in the ICU. Most ICU patients in the United States do not receive care by an intensivist.^{21,38} Instead, many are cared for by physicians with no training in critical care medicine; care often falls to hospitalists³⁹⁻⁴¹ and emergency medicine physicians.⁴² Recently, the SCCM and the Society of Hospitalist Medicine issued a joint position paper on the potential merits of accelerated training of experienced hospitalists in critical care.^{40,41} Such training is not currently available, but may be possible in the near future. Over the past several years, emergency medicine physicians have

been granted permission to enter critical care medicine fellowships and sit for the critical care medicine certification examinations administered by the American Boards of Internal Medicine, Surgery, and Anesthesiology.⁴³ Together, these actions promote an integration of critical care medicine with other disciplines. Hospital administrators can capitalize on the impact of this expanded pool of providers by hiring physicians trained in critical care, whose background makes them well suited to work in non-ICU environments as well. A critical care trained hospitalist will improve care delivery to newly critically ill patients on the general ward; additionally, if he/she also works in the ICU, he/she may enhance communication between the ICU staff and providers in noncritical care areas. Similarly, a critical care trained emergency medicine physician whose responsibilities extend into both environments can bridge care gaps and improve interactions between the ICU and the emergency department. Finally, in times of lower staffing (eg, overnight²¹), having someone available who is willing and able to cover an ICU and another clinical care area may be cost-effective. Critical care staffing can, if done thoughtfully, improve patient care throughout the hospital.

In planning for potentially more diversified ICU staff, hospital administrators must be mindful of competing responsibilities pulling intensivists away from the ICU, however. Most American ICUs have an “open” staffing structure in which there is no unified critical care team of providers looking after all patients in the ICU.^{6,39,44} The most common ICU staffing model practiced in other places in the world is a “closed” model in which the primary responsibility for care of all ICU patients is transferred to an intensivist for the time that the patients are in the unit.⁴⁵⁻⁴⁷ Leapfrog and SCCM advocate for high-intensity staffing, which is more often met by a closed ICU structure, but can be attained using an open model with mandatory critical care consultation. Data on the impact of a high-intensity staffing model on patient outcomes is mixed.^{48,49} Most intensivists split time between ICU and other responsibilities.³⁸ In an open model, almost by definition, the primary physician caring for each patient has simultaneous non-critical care responsibilities—to care for either non-critically ill hospitalized patients or outpatients in the office setting. This set-up is

often the case even for practitioners in closed model units. A potential disadvantage to having intensivists who have multiple additional skills is that they may be asked to multitask across disciplines; in so doing, needed focus may be inadvertently drawn away from ICU patients. Care must be taken to balance this potential negative consequence with the benefits of diversified staff.

STRUCTURE OF CRITICAL CARE

ICU occupancy is often high^{4,5} and patients who are in need of an ICU bed may experience delayed transfers, which are known to result in poor outcomes.^{50,51} As touched upon in the section on “Staffing for Critical Care,” expansion of critical care services outside of the walls of the ICU itself may be desirable to improve the presence of critical care within the hospital environment. As aforementioned, one method for accomplishing this goal is the creation of rapid response/medical emergency teams or consultation services; others may include telemedicine and/or regionalization of critical care.

Telemedicine involves the use of technology to allow for patient monitoring, review of data, order entry, and, at times, clinical examination using robotic assistants by clinicians not onsite.⁵²⁻⁵⁴ In the ICU, this technology has taken off as a method for expanding coverage of critical care patients nationwide.⁵⁵ Numerous studies have been conducted to evaluate the impact of this strategy; a recent meta-analysis demonstrated that while implementation improves ICU mortality and length of stay, hospital mortality and length of stay are unchanged by the introduction of telemedicine.⁵² This strategy is often considered as a means of bringing critical care expertise to underserved populations. From a hospital’s perspective, however, there are additional potential benefits to offering telemedicine ICU (tele-ICU) services to outlying hospitals. First, ICU patients are often transferred to regional centers from smaller community based institutions when expertise for care is not available at the smaller facility.^{56,57} Sometimes the lacked expertise is a subspecialist’s opinion or intervention, which can only be provided at the larger center; such transfers likely result in favorable patient outcomes and can be financially attractive to a referral hospital.⁵⁸ When patients are transferred

simply for the provision of high-quality critical care, the transfers may overburden the referral center and are less likely to be financially beneficial to it.⁵⁹⁻⁶² Creation of a tele-ICU service may minimize the need for these latter transfers. Second, despite inconsistent data on its benefits,⁶³⁻⁶⁷ many hospitals have adopted the Leapfrog standard of 24-hour onsite intensivist coverage. For hospitals employing such a model, there may be significant downtime for the in-hospital intensivist in a less busy ICU environment. Consequently, having such providers additionally providing tele-ICU care to outlying hospitals may be a revenue-generating proposition for the hospital. The cost-effectiveness of such a strategy has not been studied, however, and would likely vary greatly across institutions.

Regionalization of critical care is a topic being discussed at the national level.⁶⁸⁻⁷¹ Often compared to the regional trauma systems in place in the United States,⁷² the purpose would be to identify clear critical care referral centers to which appropriate patients would be triaged by emergency medical personnel prior to hospital arrival. In a survey of physicians who provide acute care, a majority felt such a system would improve patient care (52%) and efficiency (66%); however, 66% also felt that it would place strain on families.⁷³ Concerns have also been raised about such a system at the national level over (1) the financial implications for referral centers and smaller hospitals as well as (2) the fact that critical illness (unlike trauma) often develops in patients already admitted to the hospital.^{62,72} A hospital system may benefit from regionalization of critical care on the more local or even system level, however. In fact, this type of system-based regionalization exists in some instances.⁷⁴ Hospital system administrators may be able to use interhospital transfers for critical care expertise as a means to provide better patient care (through optimization of volume-outcome relationships⁷⁵⁻⁷⁹) and achieve financial optimization.

RESOURCE UTILIZATION FOR CRITICAL CARE

Resources for critical care include personnel and equipment. Strategies to optimize personnel use are discussed in the section on “Staffing for Critical

Care.” Borrowing from economics, equipment can be broken down into “fixed” and “variable” resources where “fixed” resources are those that are permanent/semipermanent and independent of patient volume and “variable” resources are those that are used only when patients are in need of them.⁸⁰ Put simply, “fixed” resources can be viewed as ICU beds and large equipment (eg, mechanical ventilators). ICU bed utilization is discussed in detail in the chapter “Utilization of ICU Beds.”^{***} Suffice it to say here that it is important to the hospital’s care delivery, operational efficiency, and financial success to consider how many ICU beds and in what configuration (eg, in one mixed specialty unit, spread amongst specialized units, etc) is best to meet the needs of the hospital as a whole. Similarly, the purchase of large mandatory equipment (eg, mechanical ventilators) must be similarly thought through to optimize the return on investment while providing appropriate care to the patients in need.

Allocation of variable resources can often be adjusted more frequently than fixed resources and the potential impact for the hospital environment can be significant. First, decisions must be made about what types of resources to accrue; for instance, there are advanced care devices (eg, continuous veno-venous hemodialysis/filtration, extracorporeal membrane oxygenation) that can be expensive to acquire, but may reap clinical and financial benefits for an institution. Specifically, the possession of such technologies may funnel patients with higher level care needs to the hospital.⁸¹⁻⁸³ Second, decisions about the availability of “critical care resources” outside of the ICU can impact the hospital as a whole. For example, hospitals with intermediate care/step-down units that allow for higher monitoring than on general wards may improve patient flow out of ICUs.⁸⁴⁻⁸⁶ In so doing, care for patients in need of ICU beds and costs of patients too ill for the general floor and not sick enough for the ICU may be optimized. Also, there is variability between hospitals in the need for ICU admission for certain illnesses.⁸⁷⁻⁸⁹ Decisions to determine resource availability throughout the hospital (eg, the ability to administer continuous insulin infusions for patients with diabetic ketoacidosis in settings other than the ICU) can help maximize critical care bed availability for others more in need. The up- and downsides

of these strategies may be different for each hospital and should be evaluated at each institution prior to resource allocation decisions.

CONCLUSIONS

ICUs are often viewed as well-circumscribed units. A simplified model of critical care focuses only on the care delivered by traditional critical care clinicians within the confines of an ICU’s walls. Envisioning critical care in this limited fashion, however, benefits neither the critically ill nor the hospital as a whole. Innovative administrative models, staffing strategies, structural plans, and resource allocation can benefit a hospital’s patients (both those who are critically ill and those who are not), its ICUs, and the hospital itself.

Alternative Staffing Models in the ICU

Jibran Majeed, ACNP-BC, CCRN; David Keith, PA-C, MS and Rhonda D'Agostino, ACNP-BC, FCCM

KEY POINTS

- 1 The nationwide shortage of intensivists has prompted US hospitals to effectively develop and integrate alternative staffing models into their intensive care unit (ICU), including the use of nurse practitioners (NPs), physician assistants (PAs), and hospitalists.
- 2 Patients managed by NPs, PAs, and hospitalists have been shown to have similar outcomes in hospital mortality and length of stay and greater compliance with evidence-based practice guidelines when compared to those cared for by residents.
- 3 Hospitalists may serve as the primary providers in ICUs without critical care consultants or assist in the co-management of patients with intensivists.
- 4 With the myriad of ICU practice models available, additional studies are needed to help sculpt styles based on the particular needs and preferences of an institution.
- 5 Regardless of the chosen staffing model, the key determinants for the success and growth of the critical care workforce will rely heavily on organization, strategic planning, and communication.

INTRODUCTION

Historically, physician providers in the form of intensivists, critical care fellows, and housestaff trainees delivered care in adult intensive care units (ICUs). In recent years, alternative staffing models, including advance practice providers (APPs) [mainly nurse practitioners (NPs) and physician assistants (PAs)], nonintensivist physicians (hospitalists), and telemedicine, have been increasingly used to manage the critical care physician supply and demand gap.¹ The reasons for this gap are well documented and include an aging and growing population of the chronically ill requiring ICU care,² workforce shortage of intensivists,²⁻⁴ and increasing work-hour restrictions on resident duty

hours by the Accreditation Council for Graduate Medical Education (ACGME).⁵ A survey of internal medicine housestaff also showed that less than 5% will choose to pursue a career in critical care medicine (CCM) partially as a result of the well-documented intensivist burnout⁶ and the sensed mismatch between a heavy work schedule and monetary compensation.⁷

The nationwide shortage of intensivists has been occurring in the midst of ongoing increases in the number of critically ill patients and ICU beds.^{8,9} In 2005, there were approximately 94,000 ICU beds in nearly 6500 ICUs in approximately 5000 US acute care hospitals.⁸ In order to deal with these realities, institutions need to effectively develop

and integrate alternative staffing models into their ICU.

This chapter will focus primarily on the use of advanced practice providers and hospitalists in the adult ICU setting. (Telemedicine is covered elsewhere in a separate chapter of this textbook.)

ACUTE CARE NURSE PRACTITIONERS

The acute care nurse practitioner (ACNP) specialty evolved in the late 1980s¹ and is considered the best fit for adult critical care based on the competencies and scope of standards set by the American Association of Critical Care Nurses.^{1,10} There are currently more than 192,000 NPs in the United States.¹¹ In 2012, approximately 14.2% of NPs were prepared in acute care, and 51% of them reported working in an inpatient hospital setting.¹¹ Their role is not defined necessarily by location but by the patient care needs. The patient population they care for ranges from young adults to the elderly with acute, critical, and complex chronic illnesses.¹² The extent of autonomy and physician oversight for ACNPs in relation to diagnosing and prescription writing privileges vary from state to state.¹³

Perquisites to becoming an NP include obtaining a bachelor's degree in nursing, although some bridge programs from a nonnursing bachelor's degree do exist, and a registered professional nurse license. Completion of an accredited graduate level education program is mandatory.

PHYSICIAN ASSISTANTS

The concept of PAs evolved in the early 1960s in response to a shortage of general practice physicians.¹⁴ PAs are nationally certified, state-licensed, and practice medicine as part of a physician—PA team.¹⁵ The fundamental principle of PA practice is physician-dependent delegated autonomy, defined accountability, and reciprocal responsibility for providing supervision and seeking physician consultation. Supervision is defined by state law and hospital policy, but all states have laws allowing off-site supervision by physicians

via telecommunications.¹⁶ In mid-2013, there were 84,064 clinically active PAs (those who held a valid state-issued PA or medical license), and 2% overall were ICU/critical care based.^{17,18}

PA programs are based on the medical model, average 27 months in length, and provide broad-based general medicine education with an emphasis in primary care.¹⁹ Most PA programs award a master's degree on completion of the entry-level curriculum.²⁰ Unlike NP education, PAs do not have different tracks. The expectation is that entry-level PAs will broaden their medical knowledge and clinical skills with practice-based physician teaching and formal continuing medical education programs. A trend in the PA workforce distribution towards specialization is documented.²¹ Clinical postgraduate PA programs, in the form of residencies, are available for PAs who want added experience in preparation for practice in a medical or surgical specialty.²²

HOSPITALISTS

Hospitalist medicine has been the fastest growing specialty in medicine for the past decade. In 2009, 89% of hospitals with over 200 beds had hospitalist presence.²³ Hospital medicine focuses on general medical care for hospitalized patients, allowing primary care physicians to assume responsibilities in the community.²³ The initial intent was to improve patient outcomes and decrease hospital length of stay and costs. Approximately 85% of current hospitalists are board-certified in internal medicine.²³ In 2009, the American Board of Physician Specialists developed the first board certification for the practice of hospital medicine.^{23,24}

Hospitalists have mostly replaced primary care physicians as the manager of ICU patients in nontertiary hospitals.²³ In community hospitals, about 87% of the hospitalists are providing care for patients in the ICU, and 30% are providing critical care services in academic medical centers.²⁵ The primary models of hospitalist care in the ICU include hospitalists serving as primary ICU providers in centers without critical care consultants or assisting in the co-management of patients in collaboration with intensivists.²⁵

ROLES AND RESPONSIBILITIES

Delineating the roles and responsibilities of APPs and hospitalists will depend on the institution’s needs. The general roles and responsibilities of APPs (Table 78–1) include various levels of autonomy that are dependent on the individual practitioner’s experience, capabilities, and granted privileges. In some institutions where ICU staffing is in-house 24/7, their roles may include that of the code team and rapid response team leader.

Hospitalists’ roles and responsibilities in the ICU vary depending on the institution policies, whether the ICU is an “open” versus “closed” unit, as well as their own level of experience and competency in providing critical care. Issues such as billing and obtaining credentialing and privileges for critical care are also institution-specific. In some institutions, the hospitalist practices as the sole ICU attending with admitting privileges. In other settings, the hospitalists will follow and provide critical care for their ward patients who are transferred to the ICU. Many hospitalists also seek

consultation with intensivists to help manage patients with mechanical ventilatory needs or to manage more complicated critically ill patients.²⁶ In some institutions, hospitalists are also being utilized as the initial responders of the rapid response team.²⁷

BENEFITS

Nonphysician or nonintensivist models in the ICU can offer several institutional benefits. First, these providers can help overcome the current intensivist and resident shortages as well as become a consistent workforce that can positively impact patient care.¹ Regular exposure and practice will help these providers gain knowledge and expertise in CCM and become proficient in performing invasive procedures.¹ A recent national survey of program directors of ACGME-approved critical care fellowship training programs demonstrated that integrating NPs and PAs can positively impact critical care training for the fellows because it allows greater focus and time on fellow educational needs while the NPs/PAs assume daily clinical responsibilities.²⁸ Additionally, patients managed by NPs, PAs, and hospitalists have been shown to have similar outcomes in hospital mortality^{24,29,30} and length of stay^{24,29-31} when compared to those cared for by residents. NPs have also been shown to have better communication with nurses³² and greater compliance with evidence-based practice guidelines¹⁰ that have resulted in decrease in days on mechanical ventilation,³³ rates of urinary tract infections, and skin breakdown.³¹ Finally, besides improving the quality of patient care, some studies also suggest that the use of NPs and PAs in acute care may decrease hospital costs^{31,34} and improve the financial productivity of the institution.¹⁰

INTEGRATING ALTERNATIVE STAFFING PROVIDERS IN THE ICU

Due to the shortages of the traditional ICU workforce, it is evident that APPs and hospitalists are providing care in the ICU. The question then becomes not if but how to successfully integrate them into the ICU. Adding hospitalists, NPs, and PAs into the ICU team as “intensivist extenders” effectively increases

TABLE 78–1 CCM NP/PA responsibilities.

<p>Clinical daily responsibilities</p> <ul style="list-style-type: none"> Obtain history and perform physical examination Participate in daily rounds Order and interpret diagnostic test Prescribe medications Document in daily progress notes Manage ventilators Formulate plan of care with CCM attending Communicate with patients and families Communicate with other multidisciplinary team members

the availability of adult critical care services.¹⁻²³ However, successfully establishing these alternative providers into an ICU team is not as easy as advertising, hiring a few, and scheduling shifts. Integration of these alternative staffing providers needs effective planning with thoughtful consideration and discussion of many factors, including institutional expectations, financial considerations and rationalization, administrative support, current staff acceptance, governance, recruitment, and retention (Table 78–2).

HOSPITALIST ISSUES

Individual hospitalists’ knowledge and skills for managing the critically ill may vary based on differences in training and clinical practice experience prior to becoming a hospitalist.²³ The costs for educating hospitalists in CCM may at times become an employer’s expense. A competency-assurance process based on an education and skills training process leading to acquisition of competencies beyond those obtained in internal medicine residency training has been suggested.²⁵ However, formal opportunities to broaden general critical care knowledge

and obtain skills are reportedly few. Therefore, a traditional critical care fellowship is recommended for those hospitalists who primarily want to work with critically ill patients.²³ In 2012, a position paper endorsed by the Society of Hospital Medicine and the Society of Critical Care Medicine proposed the creation of an expedited ACGME-sanctioned and accredited critical care certification pathway, with the goal of attracting practicing hospitalists to critical care fellowship training.²³ This proposal is still under consideration by the ACGME.

ADVANCE PRACTICE PROVIDER ISSUES

Unlike hospitalists, APPs do not have the preparation and training provided in medical school and residency. They receive less stringent education and therefore have different challenges.¹ However, with a careful selection of motivated individuals and on-the-job training, they can be trained to provide services traditionally performed by ICU physicians. A recent survey showed that NPs and PAs provide care in greater than 50% and approximately 25%, respectively, of adult ICUs in academic medical centers in the United States.^{10,35} Thus, teams including APPs or exclusively consisting of APPs, with appropriate physician leadership, can provide critical care that is equivalent to that delivered by traditional teams built around housestaff in a high-intensity ICU setting.^{25,28}

INITIAL PLANNING

Integration of APPs into the ICU will require diligent planning and many considerations. These should include the program model one chooses to incorporate APPs into. Will the APPs be integrated into an existing intensivist-led, resident-based team, or as a stand-alone intensivist-APP team? Especially for the novice APPs, the availability of in-hospital physician backup for management decisions and procedural assistance has to be considered.

Staff buy-in is required. This includes the ICU nurses and physicians, hospital staff physicians (particularly if the ICU is transitioning to a “closed” unit), respiratory therapists, dietitians, and pharmacists.

If integrating APPs occurs in a teaching institution, the effect on housestaff and CCM fellow training should be considered. The APP's role and responsibilities need to be clearly defined to avoid any conflict with other team members. The APPs must be presented to all as partners, not competitors.³⁶

Organizationally, which department(s) will be responsible for clinical and administrative oversight must also be defined. Generally, NPs fall under the department of nursing and report to nursing leadership, while PAs typically fall under a clinical department and report to the departmental leadership. Dual governance for NPs in the ICU has been described.³⁷

ORIENTATION AND MENTORING OF APP

All APPs require orientation and mentoring, regardless of their previous experience and competence. New NPs may have prior experience as ICU nurses, but the transition to a CCM NP can be quite demanding, as described below. New PAs are expected to broaden their knowledge and skills with on-the-job education and training, so experience in a hospital medicine position prior to seeking a CCM PA position is suggested.³⁸

Knowledge deficits in basic critical care principles, procedural skills, ultrasonography, and management skills are universal. Thus, a comprehensive, competency-based preparation course, as part of a mentored orientation, is necessary. This will require significant work on the part of the intensivists, consultant attendings, staff APPs, respiratory therapists, nutritionists, physical therapists, and other multidisciplinary team members to ensure success. Several samples of orientation programs are available in the literature.^{18,37-39} For programs with less available teaching staff, outsourcing APP training to a regional program has been reported.^{40,41}

BUDGETING

Establishing or expanding the multidisciplinary ICU team with APPs requires financial considerations. In 2010, the average salary for an APP working in a hospital-based unit ranged from \$93,943

to \$94,680 plus 33% benefits totaling ~\$125,000. The expense for a postgraduate year-1 resident in 2014 in New York City was \$55,900 salary plus 32% benefits, totaling \$73,788 dollars, which was reimbursed by Medicare. Using a formula in which 30% of a resident's 80-hour workweek is for educational activities, 56 h/wk is required to replace the resident service hours or ~1.5 full-time equivalents (FTEs) [42]. At an average cost of \$125,000/year (salary + 32% benefits) for an APP, this translates to an additional expense of \$187,500 to cover one resident's service time for 1 year. Allowing 5.5 FTEs to cover one 12-bed unit (1:12 provider/patient ratio) each shift (24/7/365), the total expense is \$687,500 dollars per unit/year. The cost will vary with geographic location, years of experience for each practitioner, and ratio of providers to patients.

Salary expense may be partially recovered if the APP is on the hospital cost report as an employee, and their services are reimbursed under part A of Medicare. Alternatively, the APP can bill for their services if they are qualified to do so, and not on the hospital cost report, as will be discussed in the Billing section.

Cost rationalization based on potential benefits as discussed below may include cost savings in the long run by improving patient satisfaction, quality, length of stay, and staffing.

BILLING

Billing has to be considered when integrating APPs into the ICU. The Balanced Budget Act of 1997 officially recognized APPs as health care providers. This allowed them to be eligible for their own provider numbers and to submit bills to Medicare Part B for evaluation and management (E/M) services and procedures.⁴³ As outlined by the Centers for Medicare and Medicaid Services (CMS), qualified APPs can bill for critical care services under their national provider identifier (NPI) at 85% allowable of the physician rate.⁴⁴ Billing requires documentation of the encounter and must validate the need for critical care service. For services or procedures that are not regularly part of the critical care services bundle, such as insertion of an arterial line or central line, the provider who performs the procedure bills them separately.⁴⁴

CMS requires a physician supervision agreement for PAs and a collaborative practice agreement for NPs. Individual health insurance companies may have different coding methods and rules for reimbursement when it comes to nonphysician providers. However, most companies follow CMS dictations as a basis for reimbursement.⁴⁵

CREDENTIALING AND PRIVILEGING

APPs have to obtain credentialing and privileges. This process ensures that they have the necessary qualifications to provide safe and quality care in conjunction with federal and state laws, regulations, and standards set by the Joint Commission. Credentialing and privileging are administrative processes driven by the medical staff bylaws and involve obtaining, verifying, and assessing a provider's credentials, based on education, clinical training, certification, licensure, and other professional qualifications for appointment to the medical staff and providing patient care in or for the hospital. Most states require NPs to have a collaborative practice agreement with a supervising physician, and all states require PAs to have a supervising physician agreement. For billing purposes, the APP's scope of practice must include critical care and procedural privileges, and the supervising physician agreement should stipulate that the NP or PA is authorized to provide critical care services.⁴⁵

The evaluation of a practitioner's performance is now an ongoing process that involves an evidence-based approach. The Joint Commission mandates that the hospital attain an initial Focused Professional Practice Evaluation (FPPE) for a nonphysician provider who is new to the hospital or an existing one who seeks new privileges. FPPE can also be done when existing credentials and privileges are questioned. The Joint Commission also mandates that providers maintain competence and require periodic review by abiding to the requirement of Ongoing Professional Practice Evaluation (OPPE). The OPPE process consists of periodic evaluations, peer review, quarterly chart review by the collaborating physician, demonstrating ongoing competence for procedures, participating in morbidity and mortality rounds, and reviewing any issues that may be substandard.^{43,46}

OVERCOMING COMMON OBSTACLES

Moving from a standard to an alternative ICU staffing model may bring on various issues due to the obstacles naturally associated with a dynamic process and an overall general resistance to change. Although extremely limited, there is literature that describes some of the common obstacles that may occur after a new ICU provider staffing model has been introduced.³⁷

RECRUITMENT AND SELECTION

Searching for the right ICU provider can be overwhelming. For example, finding experienced candidates is complicated by the fact that only 2% of PAs and 14.6% of NPs work in acute care settings.³⁵ Conversely, while 75% of hospitalists are already covering ICUs, many are tied into contracts for their services.²³ As a result, recruitment of these alternative ICU providers must rely on setting up relationships or programs to develop internal candidates. An APP residency/fellowship program, clinical/mentorship rotation, or more recently the emergency medicine and internal medicine pathway into critical care fellowships can help to bridge gaps in employment during the transition year(s) of the staffing model. Regardless of the recruitment method, successful candidates are usually those who demonstrate modesty, flexibility, and eagerness. Typical ideal candidates in the APP track include those with critical care experience (either as a nurse or an NP), PAs who have at least 2 years of in-patient hospital experience (although critical care experience is preferred), and hospitalists who have at least 1 year of practice.^{37,47}

Ironically, experience in critical care, although routinely preferred, may have several drawbacks. An "experienced" APP may find assimilation into a new ICU environment, with various degrees of autonomy, different from what he/she may be used to, challenging their comfort level. Experience has shown that objectives for new hires should be predetermined, with weekly goals being outlined and highly structured. If a new candidate fails to meet the objectives or does so with unacceptable delay,

the program must have sufficient structure to recognize and support the transition of the new hire out of the ICU setting.^{37,48}

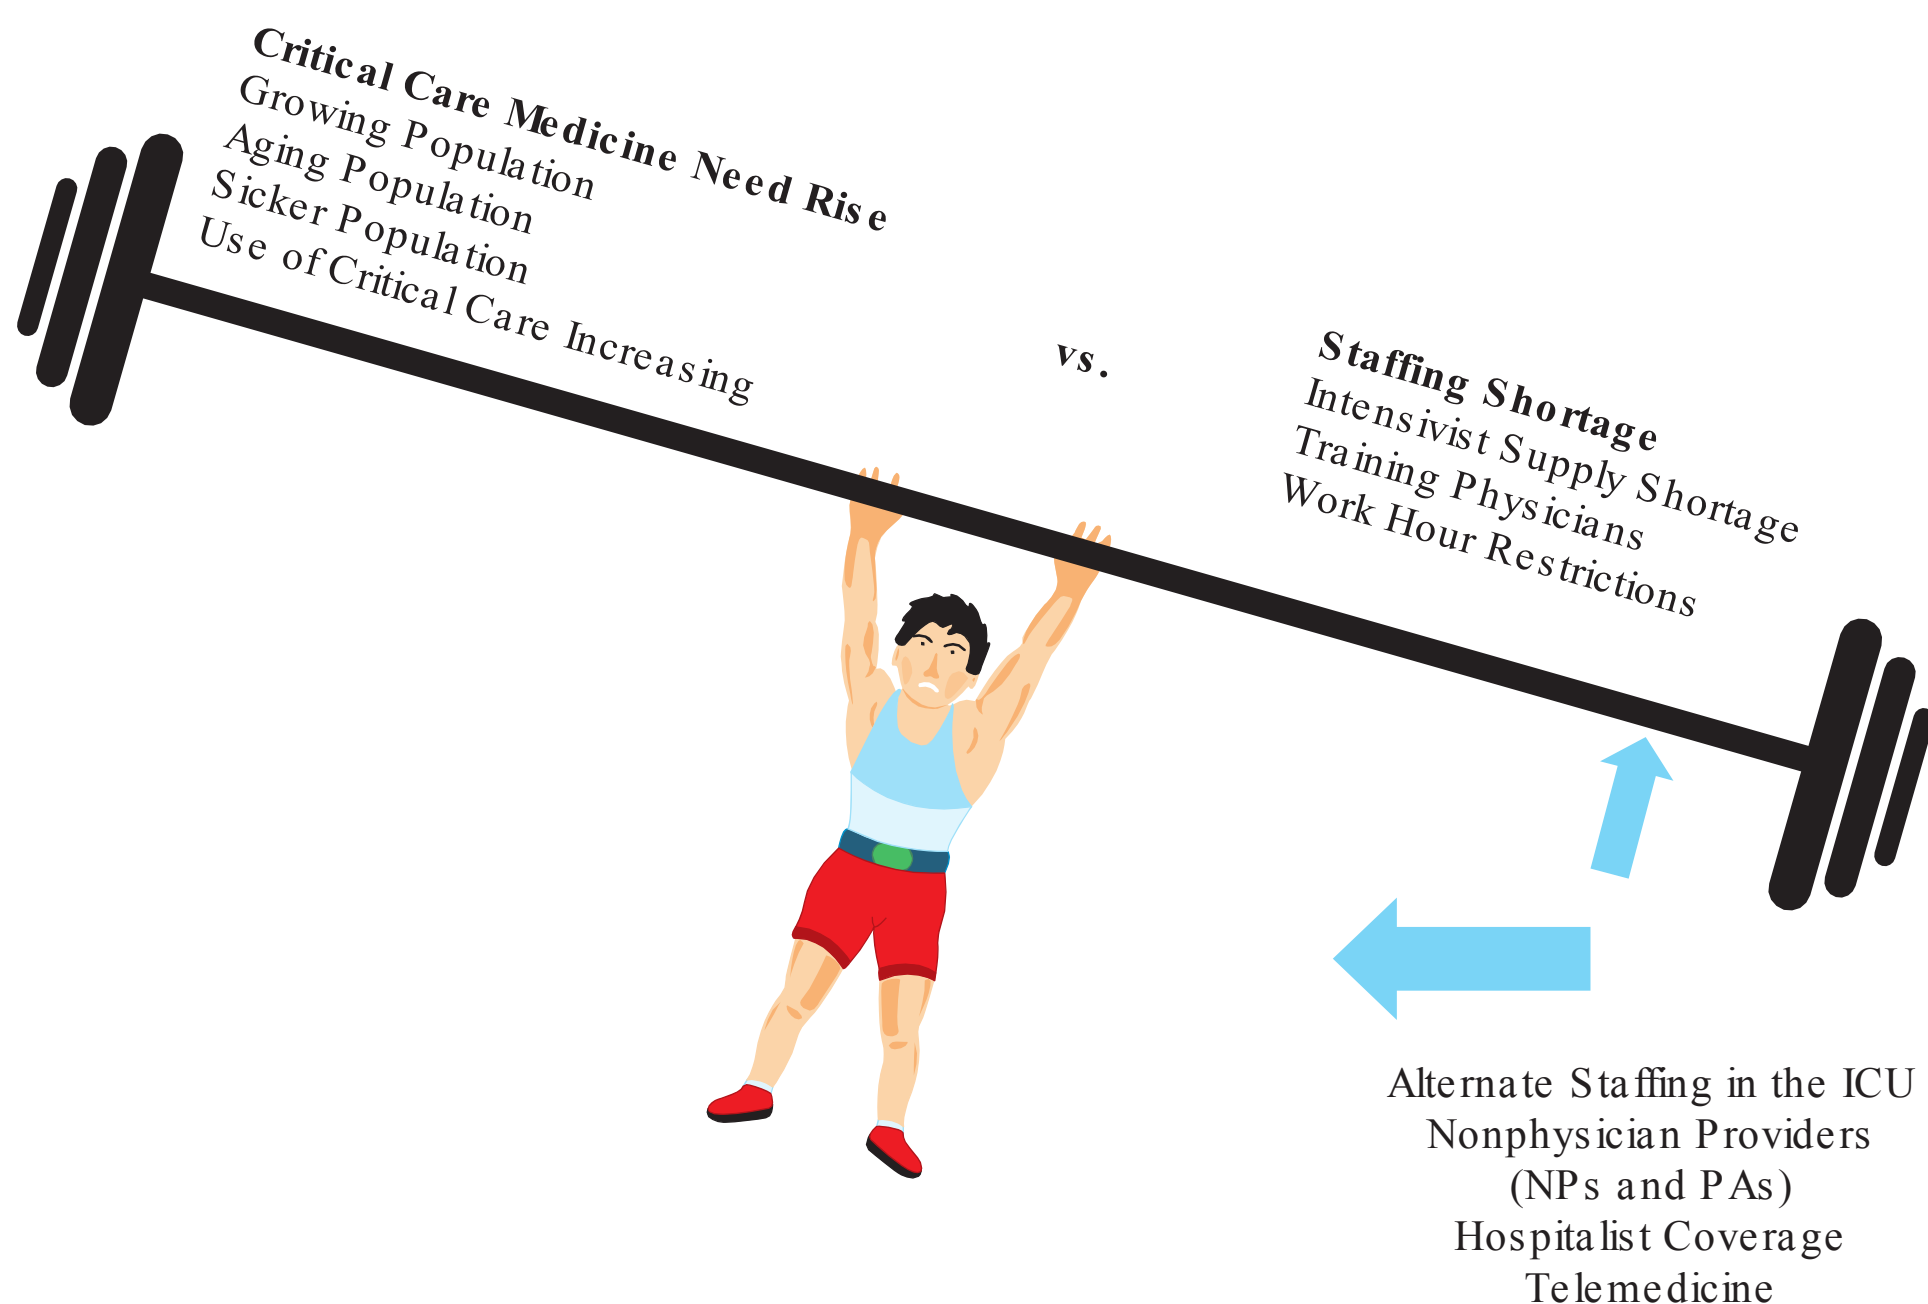

RETENTION

ICU “burnout” is well documented; thus, it is not surprising that alternative staffing providers suffer from this similar affliction. It is estimated that 50% of CCM physicians and 33% of critical care nurses suffer ICU burnout.⁴⁹ While the implementation of additional alternative staffing, in conjunction with intensivist staff, has helped to reduce burnout, it should be done with caution (Figure 78–1). The majority of burnout is multifactorial, including working long hours (especially on the night shift), prolonged time without vacation, excessive workloads, sleep deprivation, and ICU conflicts. Consequently, it is important for institutions to consider methods to reduce “burnout” in an attempt to provide a stable ICU workforce. These methods may include providing 12 to 16 hour shifts with adequate staffing (ratios of 3-5 patients per APP have

been successful), rotation across various shifts, not reserving day positions for only senior staff, and 4-5 weeks paid and supported vacation. Ultimately, institutional support is mandatory for program success.⁵⁰

ADDRESSING CONFLICTS

Conflicts will arise at some point while implementing a new provider model. These common encounters exist within any discipline, but it has been described (although extremely limited) to occur mostly between the RN and NP, NP and PA, NP/PA and CCM fellow, or between the hospitalist and primary care physician. Regardless of the nature of conflict, structure and processes should be in place to mitigate and provide adequate resolution. Some centers have described preemptive meetings between nursing and medicine, advocating for an advance practice manager and or routine ICU unit meetings. Above all, communication is always of utmost importance in the prevention and resolution of conflicts.

The use of Alternative Staffing can potentially balance critical care supply and demand

FIGURE 78–1 The imbalance between critical care demand and staffing shortage.

SUMMARY

Integrating alternative staffing models into the ICU is a logical, safe, and necessary endeavor to curtail gaps in the workforce as critical care physician shortages increase and available replacements decrease. A recent prospective study showed that outcomes are comparable for critically ill patients cared for by ACNP and resident teams in a medical ICU.⁵¹ The evidence-based studies describe multiple uses of various models to augment staffing, yet there does not seem to be a “best practice” model. With a myriad of coverage and ICU practice models available, additional studies are needed to help sculpt styles based on the particular needs and preferences of an institution; no one model will fit all organizations. However, regardless of the chosen staffing model, the key determinants for the success and growth of the CCM workforce will rely heavily on organization, strategic planning, and communication.

Governance

Stephen M. Pastores, MD, FACP, FCCP, FCCM and
Vladimir Kvetan, MD, FCCM

KEY POINTS

- 1 The organization and management of critical care services are key to ICU performance and may impact patient outcomes and healthcare costs.
- 2 Critical care organizations with advanced governance offer several benefits including unifying all ICUs under one leadership with defined accountability; improved opportunities to reduce costs; standardization of technologies across ICUs; enhanced critical care research; and improved retention of faculty through a more stable environment.
- 3 Movement toward unification of governance commences with the education of intensivists during their fellowship training.

INTRODUCTION

Critical care medicine (CCM) has made significant strides since its inception as a unique specialty almost 50 years ago. In the United States, the use and costs of CCM continues to rise. Between 2000 and 2010, critical care beds increased 17.8% (88,235-103,900) in nearly 3000 acute care hospitals with intensive care unit (ICU) beds. In 2010, critical care in the United States accounted for 13.2% of hospital costs, 4.1% of national health expenditures, and 0.74% (\$108 billion) of the gross domestic product.¹ As critical care consumes significant portion of hospital beds and resources and plays a major role in throughput of emergency departments and operating rooms, it is of vital interest to hospital leadership to unify, standardize, and control this resource.

In response to the perceived shortage of trained intensivists in the United States,² proposals to mitigate this shortfall have been developed including tiered regionalization of critical care services³ and providing alternative coverage options with

hospitalists,⁴ advance practice providers (nurse practitioners and physician assistants),⁵ and ICU telemedicine in community hospitals.⁶

In recent years, there has been an increasing tendency for critical care services in academic medical centers to consolidate their staffing and resources, and to form advanced governance organizations, above the level of departmental divisions or sections.⁷ The designation varies greatly from service lines, systems, signature programs, centers, institutes, and clinical departments. To date, only one academic university department of critical care exists in North America at the University of Pittsburgh. Introduction of service line models to critical care, mandates to improve quality and safety of healthcare,^{8,9} and transparent public disclosure have added momentum to the health care industry recognizing the need for well-governed critical care as an important tool in business management of medical centers. Among the many aspects that need unified critical care governance include patient

management, protocol institution, technology acquisition, education, training, and interactions with other hospital areas.

ORGANIZATION AND MANAGEMENT OF CRITICAL CARE SERVICES

The organization and management of critical care services are key components that contribute to ICU performance and may impact patient outcomes and health care costs. The guidelines for critical care delivery, clinical roles, and best practice model in the ICU from the Society of Critical Care Medicine published in 2001 and updated in 2015 are excellent resources for how ICUs should be administered.^{10,11} The 2001 recommendations were based on 6 tenets: (1) Medical interventions should be provided by intensivists leading multidisciplinary groups; (2) Patient care should be directed by ICU teams using a “closed” format in which dedicated critical care teams take ownership of all aspects of care in the ICU; (3) ICU physicians should be available for medical and administrative tasks without competing clinical responsibilities; (4) ICU physicians and nurses should have critical care credentials; (5) Care teams should include critical care pharmacists and full-time respiratory care practitioners as well as ICU physicians and nursing staff; and (6) ICU governance should be conducted by multidisciplinary groups.

The most recent guidelines highlighted the importance of process of care and ICU structure to improved outcomes and offered four important recommendations (Table 79–1).¹¹ The task force

highlighted, among others, the importance of sustaining process improvements through education of all ICU staff and education of and support from hospital leadership as well as an understanding and use of process improvement methodology to assess the impact of changes in ICU structure.

CRITICAL CARE ORGANIZATIONS WITH ADVANCED GOVERNANCE

Within the past several years, critical care leaders at academic medical centers and large community hospitals have increasingly examined their ICU infrastructure and clinical staff and take on “battles” to pull the ICUs away from departments and place them into a hospital-based environment and political and administrative infrastructure. From the hospital’s perspective, a critical care organization (CCO) offers an excellent opportunity to bring together all ICUs under one leadership with defined accountability. Added advantages include improved opportunities to contain costs; implementation of local and national patient safety and quality initiatives through protocols, standardization of technologies across ICUs with resultant savings from volume-based equipment and supply purchases, warranties, and staff training; enhanced critical care research; and improved recruitment or retention of faculty through a more stable environment.⁷ We recently reported a descriptive multicenter study on the structure, governance, and experience to date of CCOs in hospitals in North American academic medical centers.⁷ We identified very few CCOs (n = 27). Of the 27 CCO physician directors from 23 institutions (19 sites in the United States and 4 in Canada), 24 (89%) completed the survey. Nearly 80% of the CCOs were created in the last 15 years. Majority of these CCOs were located in larger urban hospitals (> 500 beds) and 79% were primary university medical centers. The transition to a CCO was initiated by the hospital administration in 46% and/or existing critical care service or division in 42% and by consensus of department chairmen in 13%. There were various models of CCM governance, reporting structures, hospital support, and general satisfaction. Almost 90% indicated that their CCO governance structure was either moderately or

TABLE 79–1 Recommendations from the SCCM task force on models of critical care.¹¹

- An intensivist-led, high-performing, multidisciplinary team dedicated to the ICU is an integral part of effective care delivery.
- Process improvement is the backbone of achieving high-quality ICU outcomes.
- Standardized protocols including care bundles and order sets to facilitate measurable processes and outcomes should be used and further developed in the ICU setting.
- Institutional support for comprehensive QI programs as well as tele-ICU programs should be provided.

ICU, intensive care unit; QI, quality improvement; SCCM, Society of Critical Care Medicine.

highly effective, and are still evolving. On average, there were 6 ICUs per hospital with an average of 4 ICUs under CCO governance. In-house intensivists were present 24/7 in 49%, nonphysician advanced practice providers (nurse practitioners, physician assistants) in 63%, hospitalists in 21%, and telemedicine coverage in 14%. Nearly 60% indicated that they had a separate hospital budget to support data management and reporting, oversight of all ICUs, and rapid response teams. We attributed the relatively small number of CCOs that currently exist to several factors including, perhaps, the reluctance of department chairpersons to give their ICUs up to a CCO as they perceive potential loss of billing, triage, and patient and staffing control. Furthermore, CCM has been very intertwined with other disciplines in terms of fellowship training and attending staffs (ie, medicine, pulmonary, anesthesiology, surgery, neurosciences, and pediatrics) due to the absence of a unified critical care fellowship track and certification examination. Thus existing departments have come to believe that their ICUs and intensivists especially in specialty ICUs have little in common with each other. Finally, very few CCM graduates have the necessary skill set to champion the creation and lead CCOs despite CCM fellowship program training in management and team leadership.⁷

MANAGEMENT TRAINING FOR CRITICAL CARE FELLOWS AND INTENSIVISTS

Ideally, a properly structured fellowship training program should prepare physicians from any specialty eligible for Accreditation Council for Graduate Medical Education (ACGME)—accredited training to manage a medical, surgical, cardiac surgery, and neuroscience ICU without any problem. The barriers to operating critical care and deriving benefits from economies of scale by full-time intensivists in the United States are frequently derailed by the desire of physicians required to practice their primary specialty/subspecialty (eg, pulmonary medicine, surgery, anesthesiology) creating a system of many part-time intensivists devoting only a small portion of their clinical time to the dedicated care of ICU patients.² Other specialists are convinced that only

intensivists with specialized fellowship training are appropriate to work in specialty ICU, such as neurocritical care. Thus, intensivists in US ICUs often have multiple departmental appointments and may be full- or part-time ICU clinicians and hospital-based or voluntary staff members. Whereas large academic institutions have closed model ICUs (ie, intensivists have exclusive or primary authority for patient triage, ICU admission and discharge decisions, and patient care), in nonacademic hospitals, the majority of ICUs are open units with many requiring critical care consultation and intensivists co-managing patients with the primary attending physicians. In contrast, the traditional model of critical care as a division or service of a department is not typical for many European countries where freestanding critical care departments are commonplace. For example, in the United Kingdom, most ICUs are integrated medical-surgical ICUs and the vast majority of intensivists have an anesthesiology background. Similarly, in Canada, most ICUs are combined medical-surgical units; however, the intensivists in many AMCs come from varying training backgrounds (eg, anesthesiology, surgery, internal medicine, emergency medicine) similar to the United States.

Movement toward unification of governance starts with the education of intensivists during their fellowship training. Critical care fellowship programs should focus on administrative and business concepts, including cost containment, finance, and team leadership.^{12,13} A few advanced governance organizations have developed professionalism training series to prepare fellowship graduates to deal with the need for a sophisticated approach to budgets and job market needs as they enter the workforce and assume leadership roles.¹⁴

TOOLS FOR CRITICAL CARE GOVERNANCE

Among the most powerful tools that may be useful to new leaders of critical care in their hospitals are the outreach programs of having intensivists responding rapidly to medical and surgical emergencies outside of the ICU. In addition to expert resuscitation and stabilization, the intensivist controlling the admission to a higher level of care has the ability to select patients who would derive the highest benefit from a trial of

ICU management. In addition, though the opinions vary as to the effectiveness of medical emergency or rapid response teams in modifying outcomes,¹⁵ the clear institutional benefit in rapid decision by the most qualified physicians cannot be denied. The ability to rapidly institute comfort or palliative measures for the patients not likely to benefit from a trial of ICU care is also very important.¹⁶ At the same time, intensivists do have the skills to determine success or failure of a trial of ICU care and provide a time limit to the effort.¹⁷ Unfortunately, despite our best efforts and initiatives, the population of chronically critically ill patients in the United States runs into hundreds of thousands,¹⁸ with most of these patients suffering from prolonged cerebral and neuromuscular dysfunction and risk of early death after failure of a trial of ICU care. Access to, and benefit from, alternative sites, such as long-term acute care (LTAC) facilities, is being questioned¹⁹ and subject to moratoriums, state-level certificate of need, and demonstration of limited benefit to patients and the health care industry.

In conclusion, critical care leaders across the United States are increasingly faced with the rising patient demand for critical care services at a time of intensivist workforce shortage and mandates from external organizations to improve on the efficiency and quality of care. These leaders must also respond to the need to educate new generations of ICU physicians and nonphysician care providers (nurse practitioners and physician assistants); standardize care and technologies in hospitals with many ICUs; optimize ICU integration within the hospital; and participate in cost control, research, and fundraising initiatives. Movement toward unification of governance starts with the education of intensivists during their fellowship training. The creation of more advanced governance CCOs in acute care hospitals led by effective and successful leaders²⁰ can ensure not only the delivery of high-quality safe patient care but also more effective use of resources and assistance in organizational operations and development.

Managing the ICU from Afar: Telemedicine

Tzvi Neuman, DO and Baruch Goldstein, MD

KEY POINTS

- 1 The key to successful telemedicine is communication: telecommunication and interpersonal communication.
- 2 Telemedicine allows smaller hospitals to provide 24-hour continuity of care by an awake and alert board certified CCM physician, allowing access to an off-site intensivist at any time, day, or night.
- 3 Telemedicine allows hospitals to be compliant with current medical industry standards.
- 4 Improvements in delivery of care may lead to improved clinical and financial outcomes.

INTRODUCTION: ADDRESSING A NEED

Telemedicine was developed in the 1960s and 1970s by the US military and aerospace sectors by using information and communication technologies to provide medical care in remote areas.¹ More recently, as telecommunication technologies have significantly advanced, telemedicine can help alleviate the shortage of physicians in certain specialties by allowing instant access to specialists who are not physically available at the location of the patient. Consequently, telemedicine, and in particular, tele-ICU, may help offset several well-known health care delivery challenges within the critical care community. These challenges include the following:

1. A large deficit of board-certified intensivists staffing intensive care units (ICUs) during the day and, especially, at night. It is estimated that currently only one-third of ICU patients are cared for by board-certified critical care physicians.^{2,3} Halpern et al⁴ note that many intensivists are also certified in additional specialties and spend a portion of their time in those capacities, thereby reducing the time they spend in the ICU. Furthermore, staffing ICUs in smaller hospitals and those located in rural areas is very challenging. In smaller hospitals, the number of ICU beds is often not sufficient to support a dedicated on-site intensivist, and in rural hospitals, there may be limited access to critical care medicine (CCM) specialists due to issues related to commuting.
2. The aging population is increasing and although the number of trained critical physicians has increased in recent years, it is projected that by 2020 the demand for critical care physicians will exceed the supply.²
3. Another concern is the high cost of intensive care. Bartolini and King⁵ note that over six million of the sickest patients are treated in ICUs per year. This patient population has the

highest rate of mortality and contributes the most in terms of the cost incurred in health care, consuming \$107 billion dollars per year, which is 4.1% of the \$2.6 trillion dollars spent on annual health care in the United States.

To the extent that these challenges exist, research has shown that having an intensivist manage the care of ICU patients has significantly reduced mortality and length of stay (LOS) in the ICU.^{6,7} Furthermore, the Leapfrog Group, a voluntary employer-based coalition that advocates for improved quality, safety, and affordability in hospitals, notes that due to high mortality rates in ICUs, the quality of care in ICUs is of particular importance. The Leapfrog Group composed a safety standard indicating that intensivists (in particular those specifically trained in critical care medicine) should be present in the ICU during daytime hours and exclusively provide care to these patients and that when physicians are not in-house, the on-call doctor or tele-intensivist needs to return pages at least 95% of the time within 5 minutes and arrange for care to be delivered to a patient by a doctor, physician assistant (PA), nurse practitioner (NP), or registered nurse (RN) within 5 minutes. As of 2010, the Leapfrog Group noted that only 34.5% of the responding hospitals were compliant with this safety standard.

Tele-ICU programs offer one way to improve patient access to critical care specialists and address these issues. In specialized off-site command centers, critical care is delivered by CCM-trained doctors and nurses who provide coverage to patients in academic, community, rural, and critical access facilities. By using telemedicine, specialists can use their expertise to alter patient care plans while constantly monitoring patients with the help of the bedside RN and tele-RN.

Dr. Brian Rosenfeld and Dr. Michael Breslow, critical care physicians for over 20 years at the Johns Hopkins Hospital in Baltimore, developed the initial technology for the electronic ICU (eICU) in 1998. They utilized a physician-focused electronic medical record (EMR), coupled with clinical algorithms of best practices, an early vital sign warning system,⁷ and an audio-visual interface to deliver ICU care. The original tele-ICU program was adopted for use by a Virginia hospital system in 2000. As of late 2012, there were 54 tele-ICU monitoring centers

utilized by government and civilian health care systems covering over 350 hospitals.⁵

In essence, the tele-intensivist can be thought of as a doctor who is reviewing patients in an office adjacent to the ICU with access to the entire EMR, ICU waveform monitor, and radiologic imaging and who can approach the bedside when alerted by the RN. At night, the tele-intensivist may be better equipped than the day doctor who is on-call from home and is awakened to discuss a patient; the tele-intensivist is awake and alert with all the relevant information in front of him or her in real time. The tele-intensivist, whose only responsibility during a shift is to monitor ICU-level patients using a remotely located eICU workstation, may also be in a better position to provide care when compared to an on-site non-CCM physician who has a number of other responsibilities in the hospital, including those outside the ICU. Tele-intensivists work in different time zones during daytime hours, providing night shift coverage at the location of the patient. For example, the authors of this chapter are located in Israel; they are part of a group of US board certified CCM physicians providing night coverage to ICUs in the United States while working during the day in Israel.

As in all areas of medical care delivery, the key to any successful tele-ICU is proper communication, interpersonal and telecommunication between on-site and off-site staff—whether they are from medical or ancillary services. This includes proper sign-out between the in-house and off-site physicians and nurses, medical consultants, ER and admitting staff, anesthesiologists, and surgeons, and most importantly between the tele-ICU doctor and bedside nurse. Timely and effective communication yields the best results for the patient and their families ([Figure 80–1](#)).

TELE-ICU MODELS

There are various types of tele-ICU models ([Table 80–1](#)). Some models offer continuous monitoring and management of ICUs during night shift hours or 24 hours a day, where physicians and nurses in a monitoring center work in 8 to 12 hour shifts. During the shift, the tele-ICU team is exclusively dedicated to the care of the patients in the ICUs of that hospital system. In the tele-ICU consultant

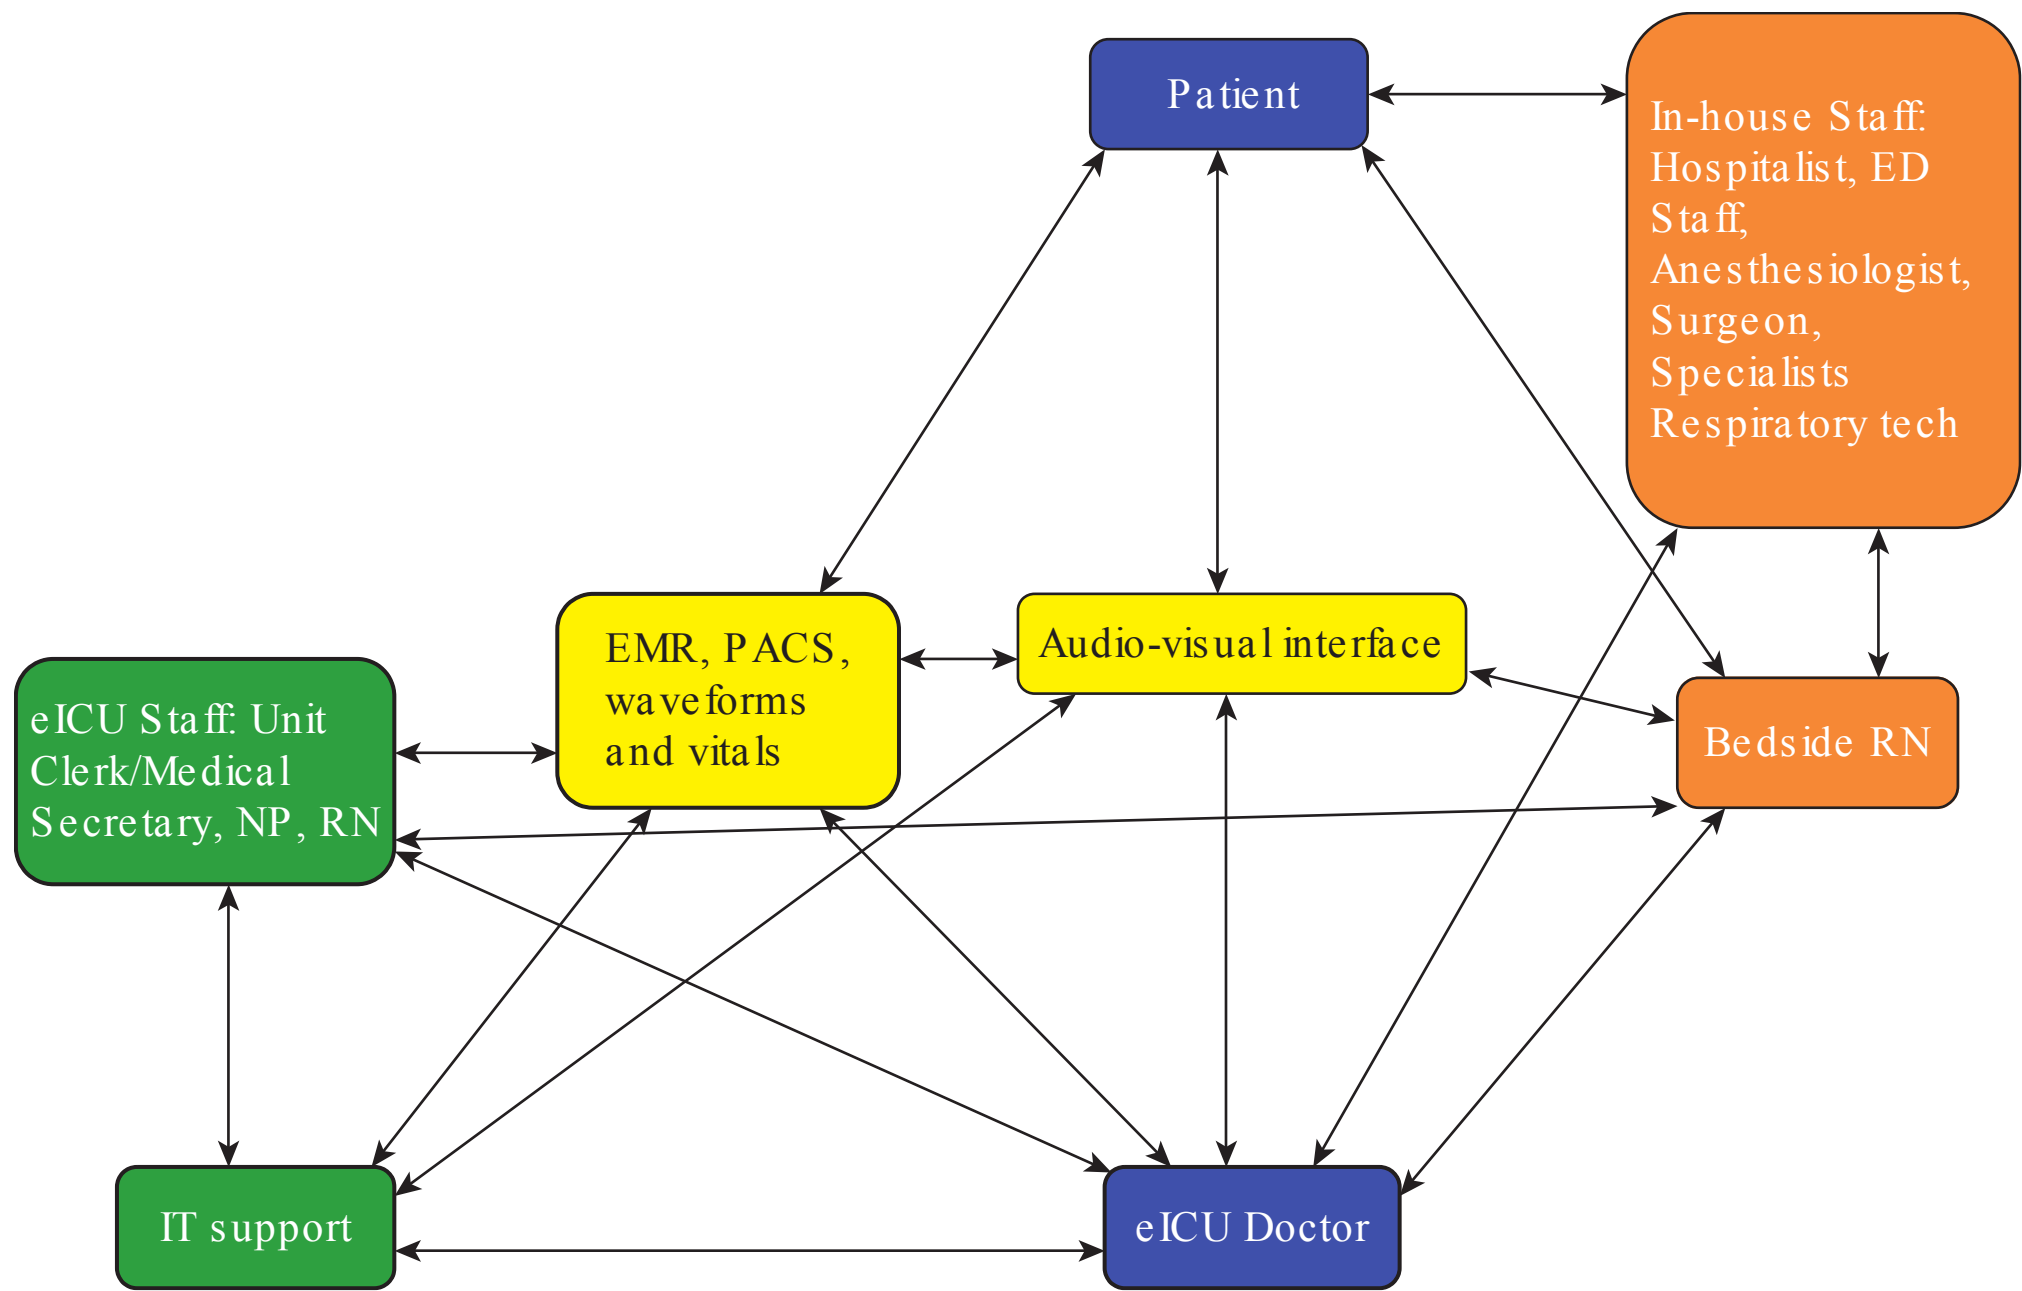

FIGURE 80–1 Schematic presentation of the lines of communication in the tele-ICU.

model, an intensivist provides critical care consultations upon request and is not responsible for continuous monitoring of entire units. Generally, in this model, a mobile cart with audio-video capabilities or a robot is commonly used to gather information followed by treatment recommendations given by the consultant.

There are other hospitals that use their own “home-made” tele-ICU monitoring systems by using various EMR programs, with or without audio-video capabilities, for patient assessment. The level of involvement of the tele-intensivist in the care of these patients varies between hospital systems based on the clinical job definition determined by the medical officers of each hospital system.

TABLE 80–1 Tele-ICU models and brief description of care provided.

Continuous monitoring	<ul style="list-style-type: none">• Ongoing 24-hour monitoring by a tele-intensivist and tele-RN in conjunction with in-house staff
Consultation-based monitoring	<ul style="list-style-type: none">• Monitoring based on CCM consultation• May be intermittent• Treatment is recommendation based care in conjunction with care plan developed by the primary medical service taking care of the patient
Hospital-defined monitoring	<ul style="list-style-type: none">• Uses various EMR programs• May be with or without audio-video capabilities• CCM involvement varies

TECHNOLOGY BASICS

Tele-ICU technology provides access to the hospital’s EMR, the radiology image archiving and communication system (PACS), and the ICU hemodynamic monitor, and is coupled with an audio-visual interface allowing the CCM physician to see and communicate with the patient, family, and hospital medical staff.

There are currently several vendors offering different types of ICU EMR systems. The Philips eICU system (Philips Healthcare, Andover, MA) is currently the most commonly used application by health systems that run large tele-ICU programs involving continuous care. This is the system that the

authors of this chapter have used in various health systems. When using the Philips eICU system, the ICU rooms are outfitted with high-definition Pan Tilt and Zoom (PTZ) cameras and servers. There is also an option of using a mobile cart with a camera that can be used for patients outside the ICU, such as in an emergency room awaiting ICU admission or during rapid response calls on the wards.

Various EMRs provide the tele-ICU staff with alerts such as sepsis alerts and best practice alerts regarding glycemic control, and DVT and GI prophylaxis, which need to be reviewed. The Philips Tele-ICU software has specialized algorithms that provide alerts when adverse trends in vital signs are noted.

NETWORK REQUIREMENTS

Since the tele-ICU team provides care for critically ill patients, it is crucial that the tele-ICU team is always immediately available for real-time communications and that connectivity with the remote staff is not lost due to technology failure. The tele-ICU center is generally connected to the hospital data center via redundant dedicated T1 lines. Back-up electricity with uninterrupted power supply (UPS) systems and electric generators is used as well to ensure continuous operation even during power failures. Full-time information technology (IT) support is required to address any technical problems that may arise.

STAFF AND SUPPORT

Staff is divided between in-house and off-site personnel, and medical and ancillary services (Table 80–2). The hospital staff available varies from facility to facility and the duties of the teleintensivist depend on the staff available for that particular ICU.

In-House Staf

Bedside Registered Nurse

The ICU nurse is present at bedside and provides most of the hands-on care to the patient. The bedside RN is the key provider with whom the tele-ICU staff interacts; they discuss any medical events that arise, such as a change in status, or hemodynamic or respiratory issues, and the care plan is delivered per recommendations and orders given by the tele-ICU physician.

TABLE 80–2 In-house and of -site staf .

In-house	Of -Site Tele-ICU Command Center
Bedside RN	Unit Clerk/Medical Secretary
Hospitalist	Tele-RN
Respiratory therapist	NP
Emergency Department physician	Teleintensivist
Information technologies (IT)	IT
Subspecialists, surgeons, and anesthesiologists may be called into hospital as needed	

Hospitalist/Managing Physician

In the majority of hospitals with tele-ICU programs, there is an in-house hospitalist available 24 hours a day. The hospitalist is often responsible for the care of patients admitted to the medical floor, the ICU, as well as any new patients admitted through the ER. In some institutions, there are private internists who are responsible for new admissions and the care of admitted patients; these physicians may not be present on-site all the time. Some hospitals do not employ an on-site hospitalist or internist during the night hours.

Respiratory Therapist

The respiratory therapist helps manage invasive and noninvasive respiratory support. At some facilities, the respiratory therapist is also certified in performing intubations for invasive ventilation. In recent years, some hospitals have expanded the role of the respiratory staff to include critical care procedures such as the placement of central IV access, arterial access, peripherally inserted central catheters (PICC), and conducting focused bedside echocardiography.

ER Physician

In many of the hospitals, there is an emergency medicine physician whose primary responsibility is the emergency room, but the physician can be called to help out on the floors and the ICU for codes, intubations, or other procedures.

Surgeons and Anesthesiologists

Hospitals generally have an anesthesiologist and surgeon on-call. Aside from working in the OR, the anesthesiologist or surgeon can be called to help manage an airway problem or perform other invasive ICU procedures.

Other Specialists

Specialists in other fields may be available for consultation; they generally round in the ICUs during the day and are on-call from home during the night. The types of specialists available vary from hospital to hospital; in some of the more rural facilities, there may not be access to specialists in certain fields of medicine.

Command Center/Tele-ICU Monitoring Site Staff

The off-site center may be located on the premises of one of the hospitals in the system or may be located off-site. The medical staff in these command centers has at their fingertips sophisticated EMR technologies, bedside ICU monitoring, PACS system for imaging, and audio-video access to the patient's room (Figure 80–2). The tele-ICU has medical secretaries, critical care nurses, and critical care physicians. Some tele-ICUs also have acute care NPs. Each member of the medical and nonmedical staff should be oriented, before starting to work in the service, to their own respective roles and duties as well as the roles of the other staff to ensure a cohesive and efficiently run service.

FIGURE 80–2 Command center tele-ICU monitoring.

Unit Clerk/Medical Secretary

The unit clerk or secretary triages phone calls from different hospitals and helps the medical staff communicate with on-site personnel such as the bedside nurses, hospitalists, ER physicians, and other on-call specialists. They also ensure that patient data are properly entered into the EMR. When necessary, they also help identify potential or current technical problems in software or hardware that arise with the network and communicate with the IT team.

Tele-ICU RN

The tele-ICU RN has several roles; the most important is to support the bedside RN with any medical concerns that arise. The tele-ICU RN is assigned patients to follow and monitors vital signs, hemodynamics and other tracings, laboratory values and other tests, and can also visually assess the patient using video cameras located in the patient's room. The tele-ICU RN is in close communication with the bedside RN and proactively involves the tele-intensivist with any problems or concerns that arise.

Another tele-ICU RN role is to monitor standards of care and the application of best practices. For instance, the off-site RN can confirm glycemic monitoring and control, GI and DVT prophylaxis, sepsis and delirium alerts, and the VAP bundle. The team is alerted to ensure appropriate protocol-driven care, which can help the hospital meet standards of care developed by national and international medical societies such as the Society of Critical Care Medicine, the American College of Chest Physicians, the American Association of Critical Care Nurses, The Joint Commission (TJC, formerly known as JCAHO), and the World Federation of Societies of Intensive and Critical Care Medicine.

The tele-ICU nursing team also includes a clinical manager, or team leader. The clinical manager, together with the medical director, models the workflow and assigns the specific tasks for the tele-ICU nursing team.

Tele-Intensivist

The tele-intensivist is a board-certified or board-eligible CCM physician who is licensed in the state(s) where the hospital(s) is located. The responsibilities of the tele-intensivist are similar to that of the bedside ICU attending physician. The tele-intensivist

is available to triage all matters of medical concern such as electrolyte replacement, pain management, sedation, ventilator management, titration of vasoactive agents, coordination and follow-up with consultants, as well as treat hemodynamic instability and respiratory distress. The tele-intensivist is in close communication with the bedside RN, respiratory therapist, and when applicable, the hospitalist or ER physician. Entering notes into the medical chart is a prudent form of communication and legal recording. Even minor details are recorded in a short note so the bedside staff will know the care provided by the tele-ICU staff.

Nurse Practitioner

Some of the larger or busier tele-ICUs also have acute care NPs, state licensed with specialty certification from the American Association of Critical Care Nurses. The NP, assigned to patients in a fashion similar to the off-site doctor, is responsible for patient care and is in constant communication with the CCM physician. The NP will generally take calls for laboratory orders, medication orders, and radiology requests. The NP may be asked to assist a physician who is attending to other patient care matters. A clear job definition for the NP should be outlined by the medical chief of staff together with the chief of service of each hospital system.

IT Support

IT support is an important component of telemedicine, ensuring that all telecommunications lines, hardware, and software are working reliably and smoothly. IT staff should be available 24/7, in-house and off-site.

PATIENT RATIOS

Monitoring critically ill patients can be labor intensive, especially when there are many high-intensity patients. It is incumbent on the medical chief of staff together with the chief of service and vice-president of nursing for each hospital, in conjunction with the medical director of the tele-ICU service, to find a safe ratio of medical personnel to patient load. The ratio for monitoring that has been recommended for an MD is between 50 and 120 patients, an NP is between 50 and 100 patients, and an RN between 35 and 45 patients.

GENERAL TELE-ICU WORKFLOW

The general workflow in the tele-ICU includes treating all active medical issues that arise and best-practice monitoring. Tele-ICU team involvement occurs when the bedside staff calls them, when they discover medical trends during proactive rounding, or when using the tele-ICU program algorithms.

FACILITIES WITHOUT INTENSIVIST SERVICES

In facilities without intensivist coverage, the tele-intensivist can play a crucial role in the day or night. In these facilities, the hospitalist or internist can review care plans of new admissions with the tele-intensivist by phone or via the audio-video interface from the patient's room. In many hospitals, there are regular daily morning rounds with the tele-intensivist. During the night, the tele-intensivist can be called by the physician or bedside RN to help just as an on-call physician would be called at home. The tele-intensivist can also assist the surgeon in managing patients postoperatively.

FACILITIES WITH AN INTENSIVIST AVAILABLE DURING A PORTION OF THE DAY

The majority of hospitals with a tele-ICU program have an intensivist or a pulmonologist available for consultation to help manage the ICU patients; however, they are not in house all the time. There may be a dedicated intensivist group but without enough staff to allow for in-house night time coverage. Other hospitals have a CCM physician who consults on a daily basis but is not always available to the ICU due to other responsibilities. In those facilities where a dedicated intensivist rounds during the day, the main role of the tele-intensivist is during night-shift hours. Ideally, the managing intensivist will sign out his or her patients at the end of the day to the tele-intensivist just as he would sign out to an in-house night intensivist taking over

continuity of care. In the morning, the tele-intensivist signs out major events that occurred over night to the day CCM physician. Should the need arise where the tele-intensivist feels that an intensivist is needed at the bedside, the on-call intensivist can be notified to return to the ICU. Alternatively, the hospitalist, ER physician, or an anesthesiologist, if available, can help at the bedside during the night as well. With more and more facilities having respiratory therapists who are certified in ICU procedures, the tele-intensivist is able, in most cases, to provide appropriate medical management without requiring the help of an on-site intensivist.

FACILITIES WITH 24-HOUR IN-HOUSE INTENSIVIST COVERAGE

Some facilities that have 24-hour in-house intensivist coverage are part of a broader hospital system that utilizes the tele-ICU program. The tele-intensivist is available to assist upon request. This generally happens when the in-house intensivist is covering a large number of patients in a particular ICU or is covering patients in other care areas within the same hospital.

OUTCOMES

Tele-ICU is a relatively new practice in medicine. The greatest theoretical impact that CCM specialists can have is on medical facilities with a deficit of intensivist coverage, facilities with a high severity-adjusted mortality and long LOS, and to facilities located remotely where safe transfer of a critical patient to a higher level care center may not be feasible.⁸ Lilly et al⁹ reported that early intervention by a tele-intensivist was associated with lower mortality and LOS. Wilmitch et al¹⁰ in their recent 3-year retrospective study found a statistically significant decrease in severity-adjusted hospital LOS by 14.2% and a decreased ICU LOS by 12.6%. The Philips Healthcare company reports,¹¹ according to company tracking data, that there has been a 37% to 64% decrease in patient mortality, as well as an \$8 million consumer savings attributed to reduced ICU days.

BENEFITS AND LIMITATIONS

The main benefit to using a tele-ICU model is real-time access to a CCM specialist who may otherwise not be available to care for ICU patients. The bedside nurses caring for patients who may potentially deteriorate while awaiting a call back from a doctor get an immediate response from the tele-intensivist. The tele-intensivist provides immediate care as orders can be entered efficiently into the medical chart and unnecessary delay is avoided. Implicit in this model is that the nurse is at the bedside while communicating concerns with the tele-intensivist. The patients and their families who are at the bedside, some of whom may have arrived in the middle of the night, can also access a physician upon request. Other benefits include adherence to best practice measures and improved nursing productivity.

Prior to implementing a successful tele-ICU program, there are various issues with cost and culture that need to be addressed. These barriers can be divided into system-based challenges or those related to the CCM specialist. System-based barriers include initial cost to implement a telemedicine program and a smaller hospital's difficulty in putting a program in place. The construction, installation, and training of staff can approach \$5 million, while the annual operation of a command center can approach \$1 to \$2 million for staff, hardware, software, and technology licensing.⁸ Although the implementation and maintenance of such a program can be costly, the overall benefit to patients and the hospitals entrusted with their care is tangible.

Another important barrier to implementation is the lack of third-party payer reimbursement for tele-intensivist care. Regarding this, the Leapfrog Group³ recommends that health care purchasers should encourage hospitals to implement changes and meet their standard by providing marketplace incentives. They call for education of the consumer and purchaser to create a greater demand for care by bedside and tele-intensivists to care for the sickest patients. Such innovations can create financial savings in the health care sector when community hospitals, with the help of telemedicine, can care for critically ill patients in their facilities, as opposed to transferring the patient to a tertiary hospital (unless the community hospital does not have adequate

resources, in which case it is appropriate and recommended to transfer care).

Other barriers include acceptance by the in-house CCM community who may be reluctant to have a tele-intensivist intervene in the care of their patients. The tele-ICU staff must be considered by the bedside staff as an integral part of the health care team in order for the system to work and to achieve its benefits.

Another limitation is the inability of the tele-intensivist to perform invasive bedside procedures (such as central access, arterial access, hemodialysis access, or tube thoracostomy) and the potential delay while waiting for another member of the in-house staff to complete these procedures in a timely fashion. Availability of certified staff to perform ICU procedures is an important factor that complements the benefit of having a tele-ICU program.

Maintenance of medical licensing throughout the different states where the tele-ICU service is used is necessary for each physician. This can be facilitated by a dedicated licensing and credentialing coordinator who can ensure continuity of certificates and hospital privileges.

FUTURE CONSIDERATIONS

As the use of focused bedside ultrasound and echocardiography grows in the world of critical care medicine, the tele-intensivist can also utilize this diagnostic modality. Specially trained respiratory therapists have conducted focused bedside trans-thoracic echocardiography while the tele-intensivist watches the real-time imaging on the high-definition/high-fidelity audio-visual interface, allowing early diagnosis of issues relating to the fluid status and other cardiac abnormalities. As the therapists become more comfortable with ultrasound, they can learn other ultrasound modalities such as lung, renal, and abdominal imaging, and can help diagnose dysfunction in these organ systems. In the future, intensivists may also be able to help stabilize patients being evacuated by mediflight, in dangerous battlefield situations, or conduct international consultations. They may also be able to work with other physicians, such as cardiothoracic surgeons or neurosurgeons, who have accepted patients onto their

service from outside hospitals, and help optimize these critical patients in concert with the surgeons prior to or during transfer to the accepting hospital.

Ethics and Palliative Care in the Intensive Care Unit

Aluko A. Hope, MD, MSCE

KEY POINTS

- 1 The four principles of biomedical ethics—beneficence, nonmaleficence, autonomy, and justice can provide a rubric through which clinicians can identify ethical dilemmas in clinical practice.
- 2 Informed consent is a process of mutual respect between a clinician and a patient that involves (a) ensuring that the patient has the capacity to make the specific medical decision; (b) the skillful disclosure of relevant information to the patient; and (c) ensuring that the patient's expressed choices are voluntary.
- 3 Advance care planning is a process by which patients, with facilitation by a trained professional, clarifies their current health state, goals, and objectives.
- 4 A living will is any document where the patient anticipates a specific set of medical circumstances and requests or refuses specific types of treatment under each of these medical circumstances.
- 5 A health care proxy form allows a patient to name a surrogate decision-maker in the event they become unable to make medical decisions for themselves.
- 6 In shared decision-making, clinicians are considered the experts on prognosis/treatment options, whereas the patient/family is considered the expert on the patient's values.
- 7 Palliative care is a multidisciplinary, patient-centered approach to care that focuses on (a) assessing and treating symptoms; (b) providing psychological and spiritual support to patients and families; (c) facilitating treatments that are better aligned with patients' values by ensuring skillful, proactive, and compassionate communication between the clinical team and the patients/families.
- 8 Most patients die in the ICU after the withdrawal or withholding of some life-sustaining treatments.
- 9 The withdrawal of life-sustaining treatments should be considered a clinical procedure that requires expertise, careful preparation, appropriate documentation, and ongoing evaluation.

INTRODUCTION

With the inevitable advancement in technological innovation and the aging of the population, more patients with chronic medical problems will face complex medical decisions in intensive care units (ICUs). Although most ICU patients survive, many deaths occur in or directly following an ICU stay.¹ Dying in the ICU has become a negotiated process, most often requiring some limitation of life-sustaining treatments.² ICU survivors struggle with physical and psychological symptoms, and functional and cognitive impairments, and their families struggle with caregiver strain in the face of an increasingly fragmented health care system.³ Patients come to the ICU with diverse expectations and values but are often too incapacitated to fully express them. Families, in the face of their own grief and bereavement, are asked to represent the patient, often weighing the possibility of impaired survival or death with the hope of recovery. All of these factors combine together to make the ICU a clinical arena rife with potential for conflict, making it increasingly important for the ICU clinician to be able to integrate the principles of bioethics and palliative care into the clinical care they provide their patients in the ICU.

This chapter will first discuss the key ethical principles and theories that provide a framework for medical decision-making in the ICU. Second, it will review the key legal cases in the United States that have informed the way in which care is negotiated in the ICU. Third, it will review medical decision-making, focusing on surrogate decision-making and the shared decision-making model in which the patient or the family play an active role in decision-making along with the clinical team. Fourth, it will define palliative care and discuss the integration of its principles into the care of the critically ill patient. Fifth, it will discuss futility conflicts in the ICU. Finally, it will review the principles and practice of withdrawing life-sustaining treatments in the ICU.

ETHICAL FRAMEWORK FOR MEDICAL DECISION-MAKING

Many different approaches to ethical analyses exist. This chapter will review the main approach—principlism—in depth and then briefly summarize other approaches that clinicians can consider.

Principlism

Beauchamp and Childress delineated four principles—beneficence, nonmaleficence, autonomy, and justice—that provide an ethical framework for moral deliberation in medicine.⁴

The principle of beneficence refers to the clinician's duty to act for the benefit of the patient. An extension of beneficence is the principle of nonmaleficence, which imposes an obligation on the clinician to not inflict harm on the patient (associated with the maxim: *Primum non nocere*, “above all, do no harm”). These principles of beneficence and nonmaleficence underlie the fiduciary relationship between the physician and the patient and are the two oldest ethical principles in medicine.⁵ Within the Hippocratic tradition, under the beneficence model, the physician relied exclusively on their own judgment to decide what was best for the patient and would exercise that authority over an obedient patient. In this model, the disclosure of information by the physician to the patient was strictly for the patient's benefit and physicians often practiced “benevolent deception,” whereby medical information was withheld or misrepresented to the patient for fear that it might adversely impact the patient's health.

The principle of autonomy in bioethics refers to the fact that the patient should be free of controlling influences and limitations that prevent a meaningful choice (ie, the right of self-determination). The word autonomy is derived from the Greek words *autos* (“self”) and *nomos* (“rule”). With the rise of autonomy as an important ethical principle of medical practice, medical decision-making changed significantly: The modern physician must now integrate the patient's choices with his or her own clinical judgment and the patient always has the right to refuse any treatment.⁵

Justice—the fourth ethical principle—is usually defined as the fair distribution of medical resources. This principle, by acknowledging the importance of treating similar patients in a similar fashion, is usually situated in a larger society or organization, rather than in an individual clinician—patient encounter. This principle provides a strong mandate to remove barriers of access to medical care and to eliminate health disparities within health care. In the era of rapidly rising health care costs, questions

about how to fairly allocate the expensive, resource-intensive treatments provided in the ICU are often asked under this ethical principle.

Ethical principles alone cannot guide clinical practice; rather, they provide a rubric through which clinicians can identify ethical dilemmas in clinical practice. Respect for autonomy may clash with beneficence when patients refuse treatments that the physician thinks are in their best interest. The ethical responsibility of the individual physician to use medical resources responsibly can put justice in conflict with autonomy when patients request scarce medical resources needed by others who are more likely to benefit from their use.

Other Approaches to Ethical Analysis

There are other approaches to ethical analysis—besides principlism—that may be relevant to ICU care.⁶ Casuistry approaches ethical reasoning incrementally through the analysis of the features of a specific case and looks to paradigmatic cases for the best resolution of current ethical dilemmas. Narrative ethics focuses on the specific story of the actors involved in the ethical dilemma and uses narrative methods to enhance the moral imagination of the clinician to help determine an ethically appropriate course of action. Virtue ethics focuses on the moral character of the clinician, his or her attempts to meet a particular standard of action. This theory provides impetus for the development of ethical wisdom in novice clinicians by improving their affective and intellectual reasoning skills. Relational ethics emphasizes the care of the whole person in clinical ethical deliberation. Specifically, the patient's personalities, values, pasts, hopes for the future, relationships, roles, and responsibilities are all considered in the ethical analyses.⁶ This theory's emphasis on the relational and emotional aspects of medical decision-making is particularly relevant to palliative care and the integration of its principles into the ICU.

INFORMED CONSENT, MEDICAL ETHICS, AND THE LAW

Informed Consent: Legal History

The legal doctrine of informed consent extends from the primacy of autonomy in medical practice. In one

of the foundational opinions that would plant the seed for the informed consent doctrine, Judge Cardozo, in *Schloendorff v. Society of New York Hospital* (1914), wrote that “every human being of adult years in sound mind has a right to determine what shall be done with his own body; a surgeon who performs an operation without the patient's consent commits an assault for which he is liable for damages....”⁷

After the travesty of the widespread experimentation on human subjects during World War II, the Nuremberg Code established the voluntary consent of the human subject as an essential step in the ethical conduct of research. With the unveiling of questionable research practices that continued in the United States through the 1950s and 1960s, there was an erosion of the public's trust of the physicians' capacity to ensure the well-being of their patients. Through the then emerging field of medical ethics, an array of voices—lawyers, policy makers, legislators, theologians, philosophers—entered the arena of medical decision-making with the hope of protecting the patient from the imbalance of knowledge inherent in the physician–patient relationship. These voices suggested that medical decisions should include technical as well as value-laden choices that reflect the moral views of the patient, their family, and society.⁸

In *Salgo v. Leland Stanford University Board of Trustees* (1957), the Court of Appeals of California found that the physician in obtaining consent must disclose “all facts which mutually affect his rights and interest.” In *Canterbury v. Spence* (1972), another U.S. court ruled that “true consent to what happens to one's self is the informed exercise of a choice, and that entails an opportunity to evaluate knowledgeably the options available,” which can only be accomplished when a patient is able to look to the physician “for enlightenment with which to reach an intelligent decision.” In the same year, the American Hospital Association published its Patients' Bill of Rights, which enshrined the informed consent doctrine into the lexicon of medical care by establishing that the patient had the right to make decisions about their treatment and the right to refuse any medical treatment.

Informed Consent: The Process

Informed consent is a process of decision-making that requires the participation of the patient and

strives for mutual respect between the clinician and the patient. Key elements of informed consent include (1) disclosure of relevant information to the patient; (2) the patient's ability to understand the information; (3) the patient's capacity to make a decision; and (4) the patient's ability to express their choice voluntarily (ie, free of coercion, manipulation, or deception). Patients are deemed to have decisional capacity if they have (1) the ability to communicate a choice freely; (2) the ability to understand the relevant information; (3) the ability to appreciate the situation and its consequences; and (4) the ability to reason and deliberate about the treatment options provided.⁹ In the critical care setting, the assessment of the decision-making capacity can be complicated by the need for rapid assessments because of the time pressure in emergency settings and the fact that critically ill patients often have an altered mental status that may make quick assessments difficult. In an emergency situation when the patient lacks any of the requisite abilities for decisional capacity, clinicians turn to surrogate decision-makers or legal documents detailing the patient's desires. If no surrogate decision-maker is found and there is an emergency, the clinician may intervene under the presumption of implied consent.

LEGAL ASPECTS OF END-OF-LIFE CARE AND PALLIATIVE CARE

Some broad understanding of the key legal cases involving the limitation of life-sustaining treatment and the provision of palliative care will help clinicians improve their practice in this important aspect of ICU care.^{7,10,11} The first and most important case was the Quinlan case decided by the Supreme Court of New Jersey in 1976. Karen Quinlan was a 22-year-old woman in a persistent vegetative state, who was receiving mechanical ventilation in a New Jersey hospital's ICU after presenting with a drug overdose and suffering a cardiac arrest. Her father felt that his daughter would not want to remain alive in such a state and he wanted to be named her guardian so that he could order the removal of the mechanical ventilator. The hospital and the physicians involved in her care refused, arguing that removing the ventilator

would be euthanasia. The Supreme Court of New Jersey reasoned that Quinlan would have refused further treatment and that she had the right to refuse any life-sustaining treatment. Since the patient was incompetent to exercise that right, the court further ruled that the only practical way for that right to be maintained would be for the family to render their best judgment as to whether she would exercise it in these circumstances.

By ruling in this way, the Quinlan court rejected any distinction between withholding and withdrawing life-sustaining treatment and acknowledged the importance of surrogate decision-making in end-of-life care. The Quinlan opinion also went further by acknowledging the limitations of the law in resolving future conflicts in this arena and encouraged the use of hospital ethics consultation as a more appropriate mechanism for resolving these conflicts in the future. By 1991, this recommendation for an ethics consultation was operationalized through the Joint Commission on Accreditation of Healthcare Organization's (JCAHO's) requirement that (1) hospitals follow ethical behavior in its care, treatment, services, and business practices, and (2) they establish and maintain structures to support patient rights; these include patients' right to refuse care and patients' wishes relating to end-of-life decisions.⁸

In the years following Quinlan, multiple court cases in the United States firmly established the right of the competent patient to refuse any medical treatment. However, there was considerable variation in how different state courts felt it best to exercise this right of refusal for life-sustaining treatments in patients without decisional capacity. The issue of how different U.S. states dealt with the patient's right to refuse life-sustaining treatment first came to the U.S. Supreme Court through the Cruzan case.

Nancy Cruzan was a young woman hospitalized in Missouri in a persistent vegetative state after an automobile accident, who required artificial nutrition and hydration to stay alive. The family requested that the feedings be stopped because they felt that Nancy would not have wanted to continue treatment in her health state. The Missouri State Supreme Court ruled in 1988 that since the state had a legitimate interest in preserving life, life-sustaining treatments could only be removed by surrogate decision-makers if there was "clear and

convincing evidence” confirming that the particular patient would have rejected such treatment.

The U.S. Supreme Court, in *Cruzan v. Missouri Department of Public Health* (1990), recognized the constitutional right of the competent person to refuse life-sustaining treatments of all types, including life-saving hydration and nutrition. At the same time, the Supreme Court affirmed the Missouri State Supreme Court by ruling that the United States Constitution did not prohibit a state from having a high evidentiary standard (clear and convincing standard lies somewhere between the civil standard of a preponderance of the evidence and the criminal standard of beyond a reasonable doubt) for surrogate decision-making regarding life-sustaining treatments.

In a concurring opinion, Sandra Day O'Connor suggested a larger role for advanced directives as a potential mechanism to safeguard the patient's interest in directing his or her medical care in the event that they become incompetent. Influenced by Sandra Day O'Connor's opinion, Senators Danforth (of Missouri) and Moynihan (of New York) enacted a law entitled the Patient Self Determination Act (PSDA), which became law in 1991 and required health care institutions to provide adult patients with information about advance directives upon admission.

In *Washington v. Glucksberg* and *Quill v. Vacco* (1997), the question presented to the U.S. Supreme Court was whether prohibitions against physician-assisted suicide offended the United States Constitution. The Supreme Court concluded that terminally ill patients do not have the right to physician-assistance in suicide under the United States Constitution.

However, the Supreme Court did rule in favor of a patient's constitutional right to obtain relief from suffering, including terminal sedation. Justice O'Connor in *Glucksberg* inferred a constitutional right to “obtain relief from suffering” and Chief Justice Rehnquist in the majority opinion in *Vacco v. Quill* invoked the doctrine of double effect in his affirmation of the practice by clinicians of relieving pain with medicines, even if those medicines come with the possibility of hastening death.¹¹ The doctrine of double effect is a Catholic moral argument that tries to make distinctions between intended effects and merely foreseen effects by permitting an act to be done that may have two foreseen effects,

one good (such as relieving pain) and another harmful (such as death), when the intent is to produce the good effect and the harmful effect is foreseen but not intended. This doctrine, although philosophically imperfect, provides justification for the use of opioids and sedatives to maintain the comfort of the patient, even if the clinician sees the potential that the drugs may shorten the time to death.

In general, when asked to resolve disputes between families who request potentially inappropriate treatment and physicians who oppose it, courts in the United States have been reluctant to withdraw treatment that would lead to death over the objection of the family.¹¹ In the case of Helga Wanglie, an 86-year-old woman was in a persistent vegetative state after a series of medical complications over the course of several months, and was chronically dependent on the mechanical ventilator. The hospital wanted to remove the mechanical ventilator citing that the respirator was nonbeneficial. The patient's family objected on moral and religious grounds. The hospital then went to the Court asking for an independent conservator to make medical decisions for the patient instead of the family, but the court rejected the hospital's request. On the other hand, courts have also been reluctant to punish clinicians who act carefully and within professional standard to limit life-sustaining treatments. In *Gilgunn*, a Massachusetts jury imposed no liability on the hospital or the clinicians after they removed the ventilator from a terminally ill patient over the objection of her family.

ADVANCED CARE PLANNING

In response to *Quinlan* and *Cruzan*, U.S. states began to pass laws providing for the use of advance directives in which people could state what they wanted to be done in the event they became seriously ill and could not participate in their own medical decisions. In the living will, the patient anticipates a specific set of medical circumstances and can request or refuse specific types of treatment under each of these medical circumstances. With the durable power of attorney for health care (or health care proxy) form, the patient can choose in advance a surrogate decision-maker in the event they become unable to make medical decisions for themselves.

Advance care planning is the process by which patients, with facilitation by a trained professional, clarifies their current health state, goals, and objectives. Since living wills cannot be expected to anticipate all of the specific circumstances the patient could face in the ICU, families and/or surrogate decision-makers still need to understand the patient's wishes and values. Studies show that when families are included more upstream in the advance care planning process, advance directives may be helpful in aligning care with patient's preferences and in supporting surrogates during their decision-making for the patient.^{12,13}

In the United States, a growing number of states have established templates that allow written directives to be translated into medical orders and can be accessible across multiple venues in the health care system.¹⁴ POLST (Physician Orders for Life Sustaining Treatment) and MOLST (Medical Orders for Life-Sustaining Treatment) are examples of these templates that allow patients with advanced illness or frailty and/or the surrogate decision-maker to have an advanced care planning conversation about whether they want specific life-sustaining treatments in the event of an illness exacerbation.¹⁵ Such forms usually enable a discussion of three categories of life-sustaining treatments: cardiopulmonary resuscitation in the event that the patient becomes pulseless; approaches to medical interventions in the event of an acute illness; and artificially administered nutrition and hydration in the event the patient cannot take fluids by mouth. Within "medical interventions," the POLST cues the clinician to three levels of possible intervention: "comfort measures only"; "limited additional interventions," which add to comfort measure treatments such as antibiotics, intravenous fluids, and cardiac monitoring but avoids mechanical ventilation or ICU level care; and "full treatment," which further adds a trial of life-sustaining treatments with no limitations in treatment (eg, intubation, advanced airway intervention, mechanical ventilation, cardioversion, transfer to the hospital, and ICU). When such forms are completed, they become medical orders immediately but can be changed or updated at any time.

SURROGATE DECISION-MAKING

Many critically ill patients are too sick or impaired neurologically to participate in their own health

care decisions, particularly in the complex decisions about life-sustaining therapies. When a patient loses capacity to make medical decisions, their right to informed consent for a treatment is extended to the surrogate decision-maker, who was either previously designated by the patient or is identified by applicable local laws. Wherever they practice, clinicians should be familiar with the applicable local regulations on how surrogate decision-makers are determined when patients have not previously designated someone as their surrogate decision-maker.

Surrogates experience significant distress, anxiety, and guilt in having to be involved in medical decision-making in the ICU and clinicians need to be prepared to give surrogates guidance on the ethical standards for surrogate decision-making.^{16,17} When a patient has completed a living will requesting or refusing specific types of care in specific medical situations, even if local laws do not make these requests legally binding, surrogates are expected to make decisions for the patient concordant with the patient's previously expressed wishes. When there is no evidence of the patient's prior wishes, surrogates are expected to make decisions for the patient based on what the patient would have wanted under the circumstances of the illness (ie, substituted judgment standard) by using what they know of the patient's philosophical, religious, and moral beliefs and values. When the surrogate does not have any way of knowing what the patient would have wanted or the patient has never had the capacity to make medical decisions, surrogates are then encouraged to make medical decisions in the patient's best interest, where they weight the risks and benefits of the treatment to the patient (ie, best interest standard).⁴

Some critically ill patients who lack decision-making capacity do not have a surrogate decision-maker or an advanced directive.¹⁸ In such cases, clinicians have an ethical responsibility to act in the patient's best interest, given their understanding of the patient's medical conditions and prognosis. Since there is a great variation in hospital policies and local laws regarding the decision-making process for these patients, clinicians need to be aware of their hospital policies regarding such cases and consider involving ethics consultation to help with complex cases.

SHARED DECISION-MAKING

Critical care guidelines endorse a shared decision-making model in which the patient, if able, and/or the family play an active role in the decision-making in the ICU.¹⁹ Shared decision-making is based on a relationship of mutual respect between the clinical team, who are considered the experts on prognosis and treatment options, and the patient/family, who are experts on the patient's values. The goal in medical decision-making is to reach a consensus regarding the value-laden treatments by discussing the nature of the decision, exchanging the relevant information, and discussing how each party prefers to make decisions. The clinical team shares the burden of the decision-making by being available to help clarify the patient's values and the impact of each option on the patient's goals and interests.²⁰ Patients and families vary widely in how they prefer to make the value-laden decisions in the ICU, ranging from a preference for complete control of the decision to deference to the clinicians' judgment. The shared decision-making model empowers clinicians to become skillful and flexible communicators who can disclose information, explore expectations, use narrative skills to make sense of complex medical situations, build relationships by explicitly providing emotional support, explore role preferences, and discuss concerns and conflicts openly.²¹

PALLIATIVE CARE IN THE ICU

With the rise of patients' rights movement, researchers conducted the Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT), a large multicenter clinical trial that sought to better understand how seriously ill patients were treated in U.S. hospitals. The study found that physicians were not asking seriously ill hospitalized patients about their preferences regarding life-sustaining treatments near the end of life, that a significant percentage of the patients who died spent 10 or more days in the ICU before death, and that the family members remembered significant symptoms, including severe pain in the dying patients.²² The results of the SUPPORT study generated a robust national discussion in the United States about the inadequacies of end-of-life

care in hospitals and, together with the increased polarization around the issue of physician-assisted suicide, helped to catalyze the palliative care movement in the United States.⁸

Palliative care is an approach to care that grew out of a long tradition of hospice care, which provided intensive treatments aimed at relieving suffering in dying patients. Initially, palliative care was seen as a sequel to failed intensive care, and its role was restricted to patients who were actively dying. Over time, ICU clinicians have come to understand that it is difficult to predict survival in the ICU, and that survivors of critical illness often develop profound physical and psychological symptoms and functional and cognitive impairments.³ Thus, clinicians have come to appreciate that both critically ill patients and survivors of critical illness may benefit from a multidisciplinary, patient-centered approach to care that aims at assessing and treating multiple sources of suffering.³

ICUs are increasingly integrating the principles of palliative care into the comprehensive care for all of their patients in an effort to increase the overall quality of care.²³ ICU palliative care focuses on the following principles: assessing and treating the patient's symptoms in the ICU; providing psychological and spiritual support to the patient and their families; facilitating proactive and compassionate communication between the clinical providers and the patient and their families so that treatments are better aligned with the patient's values and interests; planning transition; and support for both patient and family throughout the illness trajectory.²⁴ The hope is that by integrating palliative care principles into the care of all critically ill patients, the ICU environment will be better suited to support all patients with a high probability of death or impaired recovery.

Over the past decade, there has been a steady increase in the availability of palliative medicine specialists in acute care hospitals in the United States and the trend is seen in other countries as well.²⁵ Depending on the culture of the institution, some core elements of ICU palliative care can be provided as part of the routine care by members of the ICU team. In addition, a clinician champion in palliative care or use of protocols or order sets can also improve clinical practice in this area. For example, when ICU clinicians conduct routine, proactive meetings

within 72 hours of the ICU admission with families of patients at high risk of death, patients spend less time in the ICU without any change in hospital mortality. The reduced length of stay has been attributed to the families and the clinicians reaching a consensus more quickly regarding the plan of care for the patient.²⁶ Other elements of the ICU palliative care may require consultation from a palliative care specialist (eg, refractory symptom management, conflict resolution regarding goals of treatment, providing support to a family with difficult family dynamics). Specialty palliative care consultation in the ICU has been associated with reduced length of stay, earlier identification of patients who are on a dying trajectory, and more transfer of dying patients to lower intensity care sites when appropriate.^{27,28}

MEDICAL FUTILITY

Patients or their surrogates may request treatments in the ICU that the clinicians feel are futile. The root of the word futility (from the Latin *futis* for leaky, vain, or worthless) suggests a very narrow definition in which a futile intervention literally cannot achieve its goals.²⁹ The concept of futility can be considered in two different ways. The notion of quantitative futility refers to an intervention with a small probability of achieving its physiologic purpose (eg, an intervention might be called futile if it has not worked in the past 100 cases). Clinicians also use futility in a more qualitative sense when the treatment in question is being used to achieve goals that the clinician thinks are inappropriate (eg, prolonging an inevitable death or prolonging a minimally conscious state).²⁹

The principle of autonomy should not be interpreted to mean that the patient has the right to every requested medical intervention. However, when families or patients request a potentially futile treatment, clinicians should ask themselves what (or whose) goal is the intervention futile to achieve and be careful not to conflate their medical judgments with their value judgments. Clinicians are not ethically obligated to offer or provide treatments that they do not believe will achieve the patient's goals; however, sometimes a clinician's initial sense of what constitutes a benefit to the patient may be broadened by a culturally sensitive, empathic exploration of the

patient's values. In the ICU, since the care is interdisciplinary, it is especially important for clinicians to seek consensus among the clinical team members about the appropriateness of a particular treatment approach.

Futility conflicts are often about fundamental differences in values about what makes a life worth living and/or what are the appropriate goals of modern medicine. Other contributory causes of these conflicts may include a misunderstanding of medical facts, including prognosis and the goals of treatment; surrogates' emotional stress; conflicts of interest on the part of the patient/family or clinical team; and intrateam or intrafamily conflict.³⁰ In most cases, a process-oriented approach to these conflicts that focuses on the best communication practices opens up the possibility for consensus.³¹

When conflicts arise in the ICU over medical decisions, an ethics consultant may be helpful in facilitating an ethically justifiable plan that best integrates the values, perspectives, and interests of the relevant stakeholders. In several studies, proactive ethics consultation in the ICU was associated with fewer days in the ICU and more decisions to forgo life-sustaining treatments without any increase in mortality.³² Ethics consultants may also be helpful in developing and implementing hospital policies that allow for a "due process" approach to resolving futility conflicts.

PRINCIPLES AND PRACTICE OF LIMITING LIFE-SUSTAINING THERAPIES

Many patients who died in the ICU would have done so in the face of some limitation (withdrawal or withholding) of life-sustaining treatment, although there is a wide variability in this practice across the United States and in other countries.^{2,33} ICU clinicians need to be highly skilled and knowledgeable in this aspect of ICU care. Secular ethical principles do not distinguish between withholding (ie, refraining from starting) and withdrawal (ie, stopping a treatment that is already underway) of life-sustaining treatments. In practice, for clinicians and surrogates, stopping a treatment already in place often feels emotionally different from not starting a treatment.

However, when there is a significant uncertainty about prognosis, not starting a treatment may be more difficult and may leave the family with unresolved questions about whether the treatment could have benefitted the patient. The time-limited trial of a particular treatment may be especially useful when the prognosis is uncertain, allowing the clinicians and families to directly assess the benefits of a particular treatment with the recognition that the treatment may be stopped if it does not achieve the patient's goals.²³

The goal of withdrawing life-sustaining treatment is usually to remove treatments that are no longer wanted or are only serving to prolong the suffering or dying process of the patient.^{23,34} In general, guidelines suggest that once a decision has been made to withdraw one life-sustaining treatment (eg, renal replacement therapy or vasopressors), clinicians should carefully consider the utility of other forms of life-sustaining treatment. Clinicians should document the meetings leading up to the decision in the medical record. Interdisciplinary teams should aim for consensus among the team members with direct patient care about how the life-sustaining treatments will be withdrawn. Because the withdrawal of mechanical ventilation has the greatest potential for patient discomfort, some clinicians prefer to remove other life-sustaining treatments (eg, vasopressors, pacemakers, intra-aortic balloon pumps) prior to removing the mechanical ventilator in dying patients, with the hope that death will occur while the patient is on the ventilator.³⁵

The withdrawal of life-sustaining treatments is a clinical procedure like any other that is performed in the ICU and it requires expertise, careful preparation, appropriate documentation, and ongoing evaluation.^{23,36} The ICU room should be transformed from one equipped to rescue to one more conducive to comfort, dignity, and quiet. Most families will not know what to expect during the process of withdrawal so key information should be provided to alleviate fears, worries, and concerns. Clinicians should be prepared to discuss prognosis and time to death after the withdrawal of a particular treatment. Estimates based on the clinical situation of the patient can sometimes be helpful to families who need more guidance so that they can make arrangements. The possibility of transfer out of the

ICU is best discussed openly with families before it is initiated. Spiritual or emotional support should be offered and provided to the patient or family when appropriate.

The mechanical ventilator is the most common treatment that is withdrawn in the anticipation of death in the ICU.³⁷ There is no optimal strategy for removing the mechanical ventilator from the patient and there is considerable variation in practice. Some clinicians prefer to withdraw the mechanical ventilator and the endotracheal tube in one step, whereas others prefer to maintain the artificial airway to facilitate suctioning and prevent airway obstruction. Effective sedation and analgesia are crucial both before the ventilator is removed and afterwards. Some key steps to this process include ensuring that the patient is comfortable before initiating the withdrawal of the mechanical ventilator, assessing the likelihood of imminent death after the withdrawal of the ventilator, and being prepared with bedside medication for analgesia and sedation as appropriate for the clinical scenario.³⁸ Monitors should probably be turned off and, after the ventilator or endotracheal tube is removed, oral suctioning and intensive symptom management should be initiated. Neuromuscular blocking agents have no role in withdrawal of the mechanical ventilator or any other life-sustaining treatments.²³ Although patients may "look" comfortable during the process of withdrawal with the use of these medications, these drugs preclude any assessment of symptoms and do not have any analgesic or sedative properties. Therefore, their use cannot be justified as part of a comfort-oriented approach. ICU clinicians should become comfortable with the assessment and treatment of end-of-life symptoms (eg, pain, dyspnea, delirium, dry mouth) in patients who cannot self-report, so that the withdrawal of the mechanical ventilator is as comfortable for the patient and the families as possible.³⁹

Intensive Talk: Delivering Bad News and Setting Goals of Care

Dana Lustbader, MD and Negin Hajizadeh, MD

KEY POINTS

- 1 Offering palliative care is an integral part of good ICU care.
- 2 A script for running an effective family meeting in the ICU may include a format like ASK–TELL–ASK.
- 3 Provide important pieces of information one section at a time, then wait and listen for a response.
- 4 In addition to disease-targeted interventions, always provide palliative options when appropriate.
- 5 During a family meeting after you have elicited input from all participants, make treatment recommendations based on the values and preferences expressed.

INTRODUCTION

One of the most important responsibilities of health care providers in the intensive care unit (ICU) is effective communication with seriously ill patients and their family members. Generally, ICU patients are unable to participate in medical decision-making. Therefore, discussions about prognosis and treatments are often held with family members. In this chapter, the term family member will be used to describe related family members, loved ones, or legal surrogates responsible for medical decision-making on behalf of the patient. The ICU family meeting should generally occur within 72 hours of ICU admission. Family meetings are associated with increased patient, family and provider satisfaction with the type of care received, and more preference congruent care. We outline key strategies for conducting meaningful and effective ICU family meetings.

IMPACT OF EFFECTIVE COMMUNICATION

Patients with an advance directive, or patients who participate in discussions with their doctor about their preferences for care as their disease progresses, receive less intensive care in the final weeks of life, are less likely to die in the hospital or ICU, and have improved quality of life.¹ Unfortunately, most patients in the ICU have not had prior discussions regarding their treatment preferences in the outpatient setting or on the medical and surgical floors with health care providers. These difficult conversations are therefore often left to members of the ICU team. Although earlier conversations about treatment preferences is preferred, studies show that patients and family members respond well to anyone with good communication skills, even if the provider does not have an established relationship with the patient or family. In fact, an ICU provider

trained in effective communication may conduct a more successful family meeting than the primary physician.

Family satisfaction is directly impacted by effective communication strategies. Factors associated with increased satisfaction include high-quality communication, consistent information from all caregivers, use of empathetic statements, decision-making support, and family-centered care. Patient survival alone is not always correlated with increased family satisfaction.² The mnemonic VALUE has been developed to help providers better understand and manage family emotion during interactions and family meetings. The use of VALUE in a large ICU study during family meetings for patients who eventually died in the ICU showed that the surviving family members experienced less post-traumatic stress disorder, anxiety, and depression several months after the death of their loved one when these communication strategies were used. VALUE reminds us to value and appreciate what surrogates communicate (V), acknowledge emotion with reflective statements (A), listen (L), understand who the patient is as a person by asking open-ended questions (eg, “Can you tell me what kind of a person your mom was before she got sick?”) (U), and to elicit questions (E).³ This study highlights the importance of effective family meetings, not only for medical decision-making, but also for mitigating the suffering and bereavement of family members.⁴

IMPACT OF PALLIATIVE CARE

Regardless of the intensity of treatments, palliative care should be fully integrated with intensive care and not separate from potentially life supporting therapies. In fact, the marketing of palliative care as “an extra layer of support to the ICU care already being provided” has increased access to palliative care. In one groundbreaking study, patients with stage IV lung cancer, who had concurrent palliative care with cancer-directed treatment, were less likely to die in the hospital or ICU and had a better quality of life with less depression. Although the patients in the concurrent palliative care arm received less intensive care at the end of life, they lived three months longer than the control group receiving conventional cancer care alone.⁵

THE FAMILY MEETING IN 3 EASY STEPS: ASK–TELL–ASK

The skill of effective communication is as important as the ability to place a central line or treat sepsis and similarly requires practice. There are several key principles for effective family meetings. These include being prepared for the meeting, mindful listening, allowing time for periods of silence, verbal expressions of empathy, avoidance of medical jargon, and ensuring that family members understand the information. These are described below.

Prior to the family meeting, the clinician should review all pertinent information. Prognostic information should be clarified using medical data resources such as eprognosis.org.⁶ The physician should consult with the bedside nurse, who often has key pieces of information about the patient’s care and about any nuances of family politics that may become evident in the family meeting. The nurse also plays a crucial role in reinforcing concepts discussed during the meeting and answering questions later from family members. Other team members may also be useful during the family meeting such as the ICU social worker or chaplain. The location of the meeting should be in a private space without the concern for interruptions, and all participants should be seated. If a room is not available, the meeting could occur at the end of a hall or an empty waiting room. It is imperative that all participants have the chance to be seated. Most successful meetings last about 30 minutes and those that run beyond this time frame may in fact lose their effectiveness as the ability for family members to take in new information is exhausted.

Start the meeting by introducing everyone in the room and explaining the role of each provider. About half of the meeting time should be spent actively listening to family members. During a 30-minute family meeting, the clinician should be listening for 15 minutes and allow time for questions. This can be hard for some clinicians but listening rather than talking is critically important for an effective meeting and may even mitigate the risk of post-traumatic stress disorder, anxiety, and depression for survivors. Participants feel validated and suffer less guilt later. There may also be periods of silence when family members are grappling

with difficult news. The clinician should respect the need to absorb this information and allow time for silence before moving on with an empathetic statement such as: “I know this news is very difficult for you to hear.” Verbal expressions of empathy include statements such as: “I wish I had better news about your mom.” “I wish his condition could improve.” These verbal expressions recognize and legitimize the emotions being felt by family members while creating a relationship of trust with the provider.

Communication should also avoid medical jargon. Phrases like “the prognosis is grim” or “her ARDS is preventing weaning” are meaningless to most lay people and can hijack a well-intentioned family meeting. Instead a clinician could say: “I am worried he is beginning to die.” “The scarring in his lungs is preventing him from being able to breathe without the life support machine. I’m concerned his lungs may not get better. We will have to make some difficult decisions in the next few days about what to do.” Difficult news can be introduced with a sentence in preparation such as: “Unfortunately I have some bad news to share with you about your father.”

To ensure that family members have understood the information, a simple framework for the meeting is ASK–TELL–ASK.

1. **ASK**—Ask the patient and family member about their own understanding of medical condition and prognosis. This can be done with a question such as:
 - “Can you tell me what you know about your mom’s condition so far?”
 - “What have the doctors told you about your brother?”
 - “So I can better understand, can you tell me what you know about your cancer and what is likely to happen now?”
 - “What do you think is going on with your son?” “Can you tell me how you came up with this information?”
2. **TELL**—Provide information about the medical condition, treatment options, and prognosis. Deliver the news in language that is simple and easy to understand. Avoid all medical jargon. Generally, it is advised to summarize

the medical condition and major problems to be discussed during the family meeting. Keep in mind that family members are stressed and may have limited ability to understand large blocks of information at one time. Give two or three bits of information at a time and pause to allow families to absorb the information and in case clarifying questions arise. Provide information about treatment options, including risks and benefits for each treatment.

When discussing therapeutic options, it is important to include palliative options in addition to disease-directed therapies, if appropriate, and to frame palliative care as a treatment option. This can be done with statements such as:

“Since the dementia is very advanced, and your mom has not been able to come off the breathing machine, we have two options for our next steps. We can remove the breathing machine and keep her comfortable or we can place a more permanent breathing tube in her neck called a tracheostomy which would allow her to go to a nursing home on the breathing machine in about a week.”

When discussing prognosis, always include the range of possible outcomes, given the uncertainty with each individual patient. For example, one might provide information for life expectancy in hours to days, days to weeks, weeks to months, or months to a year at the most. This can be done with statements such as:

“Most patients who have cancer in the lung and liver who are in the ICU for serious infection and low blood pressure like your grandmother die within days to a week.”

3. **ASK**—Provide an opportunity for questions and expressions of emotion. Agree on a plan for next steps. Examples are:

Can you tell me what you’re most worried about right now?

Given what we’ve just talked about, what is most important to you now?

What do you think should be done now?

I wish I had better news for you. How can I help you cope right now?

Structure and reliability can be useful tools to better help families cope with grief and despair. To conclude the meeting, summarize the treatment plan and set up a time for follow-up discussions when appropriate. For example:

So we discussed that we will do a 48 hour trial on the breathing machine with antibiotics for the pneumonia and emphysema. We'll meet again here in two days at 4 PM to re-evaluate how things are going. Is that okay with you?

We will wait for the priest to come later this morning. We will remove the breathing tube and stop the kidney dialysis after his visit and when your other children arrive sometime later today. We will continue to do everything possible to keep your daughter comfortable.

We will start the artificial feeding today through the tube in the nose. We will also get another brain scan today to see if the size of the stroke and bleeding has increased. If so, we will call the neurosurgeon back to help us decide if surgery would be helpful. We will meet again tomorrow around 11 AM after morning rounds to discuss the results of the brain scan with you.

Finally, express empathy again at the end of the meeting. For example:

I wish things were different for your mom. We will work hard to make sure she is as comfortable as possible.

I can see how well you have cared for your dad in your home over the past three years as his dementia and heart failure progressed. Unfortunately this stroke was so large and so sudden, there was nothing anyone could have done to prevent it. We will continue to do everything we can for his comfort. I am so sorry.

MANAGING FAMILY EMOTION

A wide range of family emotions should be expected during family meetings. The clinician should be present emotionally (responsive to the emotions of family members), and mindful of the verbal and nonverbal responses from family members. When emotions escalate, often the best course of action is to listen and to recognize the emotion. If anger at a particular situation is being expressed, one might say: "Let me make sure I understand you correctly—you're angry

that the evening nurse did... is that right?" Or you might say: "Thank you for making me aware of that problem; I will speak with him about what you've mentioned." When a problem is brought up during the family meeting that can be validated, one should say something like: "You're right, I wish it didn't take two days for the CT scan to be performed. I can see why you're angry." Often validating or hearing what is of concern in the moment can open doors for a more productive meeting regarding the treatment plan and goals of care by establishing a relationship built on trust.

DISCUSSING PROGNOSIS

Providers are often afraid to discuss accurate prognostic information with patients and their families for fear of removing all hope or causing sadness. A study of hospitalized elderly patients showed that patient preferences for end-of-life care were not documented or incorrectly documented in the medical record 70% of the time.⁷ Most studies, however, indicate that discussions of prognosis lead to greater patient satisfaction, improved concordance between treatments wanted and those actually received, less aggressive care at the end of life, and improved psychological outcomes for patients and their families. In fact, inadequate preparation for death is associated with poor bereavement outcomes for survivors with complicated grief, post-traumatic stress disorder, and a sense of regret or guilt.

In providers who do discuss prognosis, survival is often overestimated. In one study physicians overestimated survival by 5-fold.⁸ In fact, the longer a physician knows a patient, the more likely they are to provide an overly optimistic survival rate. Therefore, providers should prepare for these discussions with tools that use evidence-based calculators to improve prognostication such as eprognosis.org.⁹

Despite prognostic communication, families may not "hear" what clinicians tell them. Surrogate decision-makers generally believe that their loved one has a better chance of survival than the odds being cited.¹⁰ For example, if a clinician says there is a 10% chance of survival, the family member may believe that their loved one has about a 50% chance. These optimistic biases may be due to the belief that the patient is stronger than most or

that the provider is misinformed and does not have all the information.

A family member may say: “My mother is a fighter. She had bad pneumonia before and walked out of here just fine last month.” A reasonable response to this may be to highlight why this situation is different from before and the outcome will likely be different as well. One might say: “I understand your mom is a fighter and survived the bad pneumonia last month. This time is different though because your mom is on a life support machine now and the emphysema has progressed. I’m worried she won’t be able to breathe on her own again.”

Optimistic biases are further reinforced by television shows that depict unrealistic survival rates following cardiopulmonary resuscitation (CPR) and create an expectation by family members of overly hopeful results and superior functional outcomes than are actually possible.¹¹ Here, the Ask–Tell–Ask framework of communication also allows for clarification.

A family member may ask a question: “How long does she have to live?” The provider should answer honestly if she knows. For example, one might give an accurate range and say: “Most people in her condition can live for days to a week.” A follow up might be: “Knowing that time is short, are there others we should call to be here now?”

It is equally important to discuss a patient’s likely functional outcome if they do survive their ICU or hospital course. This may significantly impact medical decisions. Uncertainty can be acknowledged with phrases such as:

I wish I could be more certain right now. Your mom is very sick and the stroke was quite large. We’ll have a better understanding of her chances of surviving this over the next two days as we follow her blood pressure. Right now it is dangerously low. In terms of knowing her outcome, it may take weeks to know if she survives.

We are going to do everything we can to help your daughter’s body recover from this serious infection. The kinds of things we’ll be looking for are improvement in blood pressure, the lung function and whether she wakes up in the next few days. We will communicate with you at each step along the way.

Finally, when decisions are made for patients to receive life-supporting technologies, they should include clearly defined markers of success or failure of the intervention, and an end-point if unsuccessful. This will facilitate discontinuation of unwanted life-sustaining therapies if the condition fails to improve or deteriorates. Time-limited trials may be warranted if there is uncertainty about the reversibility of the illness. For example, a 48-hour trial of mechanical ventilation and ICU care may be employed to assess whether the pneumonia resolves in an elderly patient with end-stage heart failure, and can be withdrawn if there is no clinical improvement or clinical decline.

It should be noted that the overall goal of effective communication strategies in the ICU is to align medically appropriate treatments with patient and family values. For some, every moment of life has value regardless of quality. For these patients, family members may believe that survival alone, despite the fact that the patient may be ventilator-dependent, comatose with a feeding tube, and discharged to a long-term care facility, is an acceptable outcome.

OFFERING PALLIATIVE CARE

Palliative care is an integral part of good ICU care. One strategy for involving palliative care consultants in the ICU is the use of screening tools to identify patients for whom consultation could benefit.¹² Several clinical triggers exist to prompt a palliative care consultation and include ICU patients with a hospital length of stay greater than 10 days prior to ICU admission, stage IV cancer, age greater than 80 years with two comorbidities, stroke and respiratory failure, terminal dementia, multisystem organ failure, and patients post cardiac arrest.¹³ Others have used the surprise question: “Would I be surprised if this patient died in one year?” If the answer to this self-addressed question is no, palliative options should be considered and discussed.¹⁴

THE DIFFICULT FAMILY— MANAGING CONFLICT

The difficult or hostile family presents unique challenges when leading a family meeting. It is generally advised to start by naming the emotion being observed and allowing the family member to express

their anger or frustration. One might say: “I see how angry you are about the care your daughter is receiving in the ICU.” “I can see how angry you are that the CT scan wasn’t done this morning. Let me find out what time it is scheduled for today?” On the other hand, some recommend to understate the emotion and to instead show curiosity, for example: “I’m wondering if you are concerned.” The argument being that “emotion naming” may make patients feel as though they were being labeled.¹⁵ With either style, practice and feedback will help the clinician master this particularly difficult skill.

The family that “wants everything done” in the setting of terminal illness is generally expressing intense grief and sadness at their impending loss. Rather than take the phrase to literally mean the family wants intubation, surgery, chemotherapy, or resuscitation during the dying process, it is best to explore what is medically appropriate for the patient, given the clinical condition, and discuss this with the family while acknowledging their intense pain. Clinicians should only offer and provide treatments that are medically appropriate. There is no medical, ethical, or legal obligation to offer treatments that will not work to benefit the patient and that violate accepted medical guidelines or ethical standards of care. One response to the family that “wants everything done” may be something like: “Can you tell me what you mean by everything done?” “What you are hoping the surgery will accomplish for your brother?” It is very important to understand what the family believes will happen if the requested treatments are done.

The expression of “I want everything done” may also indicate a lack of trust in the clinician or institution. With skillful communication by the clinician, trust is earned over time. Nonetheless, clinicians should only offer medically appropriate therapies that can include disease-directed treatments, palliative care, or both. A provider should feel comfortable making a therapeutic recommendation based on the values and goals expressed during an effectively run family meeting.

Examples of statements limiting the treatment options are:

Based on what you’ve told me about your sister, I suggest we do everything we can to treat the infection and keep her comfortable. We will not put her

on a life support machine if her breathing fails since this will not reverse the effects of the big stroke she had last week. You have shared with us that she would never want to live in a nursing home dependent on others and unaware of her surroundings.

And, “I know how much you want everything done for your dad’s bowel problem now. Unfortunately he cannot have surgery because he is too sick and would die during the operation. I wish there was something we could do to treat the perforation but his other organs have all shut down and his blood pressure is dangerously low right now. We will do everything possible for his comfort today. I wish things were different.”

THE DO-NOT-RESUSCITATE (DNR) DISCUSSION

“Getting the DNR” from a distressed family member for a terminally ill patient is a dreaded “task” often delegated to the most junior physician (the intern). This “task” can be very stressful, particularly when prior training has been limited. Several key strategies can make this discussion more effective. First, the clinician should recognize that this may be the first time anyone has addressed preferences for resuscitation with the patient or family member, despite the fact that the patient may have had the diagnosis of terminal illness for weeks or months prior to their current ICU admission. Second, the clinician should remember that resuscitation is a medical treatment aimed at restoring cardiopulmonary function when the heart or lungs stop working temporarily. CPR was never meant to be performed on a patient dying an expected death from a terminal disease. Third, the clinician should feel empowered to make a recommendation about the code status to the family member or patient based on what is known about their personally held values and beliefs:

As we’ve discussed, the lung cancer has spread throughout your mom’s body. Given what you’ve told me about the importance of independence and recognizing her grandchildren, I suggest we protect her from CPR if she dies. We will do everything possible to keep her comfortable during that time.

The dementia is very advanced. Your dad got the pneumonia from the terminal dementia that caused an inability to swallow and breathe safely. He is not

responding to the antibiotics for his pneumonia and his blood pressure is dropping now. We need to discuss how his death will be handled here in the ICU. We have two options. We can attempt resuscitation which will not likely work because of his underlying illness, or we can do everything possible to keep him comfortable while he begins to die.

The trauma injuries from the car accident have severely damaged your son's lungs and brain. It does not look like he can survive. I'm worried he may die tonight. We need to discuss how we will handle his death. We can attempt resuscitation which very likely will not work since he is already on a life support machine, or we can keep him very comfortable and do everything possible for your son until that point.

I understand from what you and your rabbi shared with me that every moment of life is valued by your grandfather regardless of quality. Knowing this we will attempt resuscitation when his heart or lungs stop and perform whatever may be medically appropriate at that time. I am afraid those efforts will not likely work to bring your grandfather back, but I understand this resuscitative attempt is important to your grandfather and family.

When a patient suffers cardiopulmonary arrest, the clinician is required to perform resuscitative measures in accordance with medical standards, unless there is a DNR order. These efforts should be medically appropriate and the clinician should not perform medically inappropriate interventions on a patient simply because they are asked to do so. Additionally, there is no legal or ethical obligation to run a code for an arbitrarily defined period of time if the return of spontaneous circulation is unlikely. In situations where there is no DNR order for a terminally ill patient dying of their disease, only appropriate resuscitative measures should be attempted. In addition, the moral distress imposed on providers who are asked to perform procedures that are not medically indicated and are highly unlikely to reverse the disease process in a dying patient must be recognized. This moral distress is felt especially by the youngest team members who are not actively engaged or in control of the decision-making, such as interns, trainees, and new nurses.

Every effort should be made to ensure that treatments align with patient and family preferences, rather than just simply left to chance. Thoughtful

advance directives and DNR conversations ideally should occur in the outpatient setting when a diagnosis of a terminal disease is made.¹⁶ In the absence of advance directives, opportunities often exist during the hospitalization prior to the ICU transfer for less rushed DNR discussions. Since the advent of the rapid response teams nationwide, there has been an increase in DNR discussions occurring and possibly protecting patients from being admitted to the ICU to die. This outcome of rapid response teams may in fact result in reduced intensity of treatment during dying, which may be more closely aligned with patient values and preferences.

CONCLUSION

Nearly 1 in 5 Americans die during or immediately after ICU-level care, often with pain, suffering, and isolation. Intensity of care at the end of life has also increased over the past decade with ICU use in the final 30 days of life in 2009 occurring at a rate of 29.5% for Medicare beneficiaries.¹⁷ Family members of loved ones who die are at risk of experiencing post-traumatic stress disorder and depression. Clinicians should practice conducting effective family conferences as they would for any other ICU procedure. Several websites are available to enhance communication in the ICU with seriously ill patients and their family members, such as Improving Palliative Care in the ICU (IPAL-ICU)¹⁸, Oncotalk Videos,¹⁹ and IntensiveTalk.²⁰

Skillfully led family meetings that focus on mindful listening and effective communication increase satisfaction and ensure that patients receive the ICU care they want and value.

Can Intensivist Performance Be Measured?

Sharon Leung, MD, MS, FCCP

KEY POINTS

- 1 CMS launched Physician Compare in December of 2010, and it expanded to include information on the quality of physicians' care in 2013. Measuring and reporting on the performance of doctors represents an effort to move to a more transparent healthcare system.
- 2 The strategy the IOM recommended to improve quality of care was to pay for performance (P4P) or financial incentives to transform behaviors to achieve greater value.
- 3 Process measures are more highly sensitive to differences in the quality of care and are easier to interpret. However, a process measure is only of value if it is assumed to have a link to a meaningful outcome. By itself, it has little intrinsic value.
- 4 One advantage of outcome measurement, for example, mortality rate, is that it is a measure that is important on its own, even if the differences have nothing to do with the quality of care.
- 5 One of the main issues of measuring intensivist performance is physician attribution. Each episode of care would involve multiple intensivists and other physicians.
- 6 Using ICU LOS as a process measure would discourage intensivists from providing time-consuming, yet important, end-of-life care for ICU patients, leading to more fragmentation of care.
- 7 Even though risk adjustment applies, using hospital mortality as a quality-outcome measure would not account for the impact of palliative care and the ability to transfer to LTACs.
- 8 The current system has not yet been made to link the fragmented entities caring for these patients with critical illnesses around accountability for value.
- 9 To improve service productivity, measuring and monitoring performance and its variance is a fundamental requirement for identifying efficiencies and best practices and for spreading them throughout the system or organization.
- 10 Advancing performance measurement at the physician level is the vital strategy on the policy agenda when considerable unexplained variation exists in practices that lead to poor quality, inefficient care delivery, and waste of resources.

INTRODUCTION

The US health system is the most expensive system in the world, and yet numerous developing countries outperform us.¹ Patients with critical illnesses account for the majority of healthcare expenditures per capita. According to a 2009 study by the Medicare Payment Advisory Commission (MedPAC), the top 5% of spenders account for 50% of all healthcare spending, totaling \$623 billion, or nearly \$41,000 per patient.² Since the population is aging and medical technology is advancing, this group of patients is growing rapidly. Managing patients with critical illnesses presents considerable challenges: high-cost care, frequent readmissions, and dissatisfaction of care among them.³

ICU care is labor- and resource-intensive. The focus on quality performance and maintaining quality processes is vital to critical care. In the United States, the major players monitoring ICU quality performance include the Agency for Healthcare Research and Quality, the National Quality Forum (NQF), the Volunteer Hospital Association, the Institute for Healthcare Improvement, the Leapfrog Group, and the Joint Commission. In 2010, the NQF endorsed hospital mortality and intensive-care-unit (ICU) length of stay (LOS) as quality indicators.⁴ Usually when the NQF measure is endorsed, an exploration of policy around these measures is anticipated. Also, the growing emphasis on processes of care and outcomes is pushing providers to broaden the focus of ICU metrics beyond LOS and mortality to include readmission rates, core measures, and patient satisfaction.

However, can performance indicators such as ICULOS, ICU mortality, and readmission rates be used to measure intensivist performance? If so, what about intensivists working in safety-net hospitals with a high percentage of patients who are uninsured? On the other hand, how can accountability be spread among physicians since each ICU patient is likely to be treated by multiple intensivists and other physicians? What would be the financial implications and consequences of using such measures? The aim of this chapter is to appraise whether these performance measures are appropriate and unbiased in measuring intensivist performance.

BACKGROUND

The ACA

Most of the health systems are now facing the same fundamental challenge: how to deliver broad access to health services while improving quality of care and controlling costs. Greater competition has often been proposed as a solution that addresses each element of this challenge. The performance failures of our healthcare system are largely invisible and will continue to be invisible as long as we do not have systems that allow us to track quality performance of the providers that are the central suppliers of our health care.

The landscape is changing. CMS launched Physician Compare in December of 2010, and it expanded to include information on quality of physicians' care in 2013. Measuring and reporting on the performance of doctors represents an effort to move to a more transparent healthcare system. In the near future, Physician Compare will provide information on physicians whether they provide recommended care to patients or not. New recommendations from the Joint Commission and CMS mandate the tracking of individual provider's competency through the following methods: Ongoing Professional Practice Evaluation on appropriateness of privileges, procedural volume, patient satisfaction, and professional interactions.

The Institute of Medicine (IOM) recognized that payment influences provider behavior. The strategy the IOM recommended to improve quality of care was to pay for performance (P4P) or financial incentives to transform behaviors to achieve greater value.^{5,6} Physician Quality Reporting System (PQRS) was a first step in this direction.⁷ Value-based purchasing (VBP) is a strategy that links payments to value of care over the entire continuum of patient treatment and hinges on recognizing and rewarding shared accountability among providers.⁸ CMS is working to transform the Medicare program from a passive payer to an active purchaser of high-quality healthcare services by linking payment to the value of services delivered.⁹

Quality Indices to Measure ICU Care

The aims of using performance indicators are to inform policy making or strategy at a regional and/or national level, to improve the quality of care, to

monitor performance of healthcare funders, to identify poor performers, and to protect public safety. The main issue is which performance indicators are able to differentiate a genuine difference in quality. Process and outcome measures are frequently used in assessing quality care in the ICU. Process measures are more highly sensitive to differences in the quality of care and are easier to interpret. One advantage of outcome measurement, for example, mortality rate, is that it is a measure that is important on its own, even if the differences have nothing to do with the quality of care.¹⁰ It has been used frequently in the critically ill population, but it is important to bear in mind that outcome measures are not a direct measure of quality of care. On the other hand, a process measure is only of value if it is assumed to have a link to a meaningful outcome. By itself, it has little intrinsic value.¹⁰ Thus, robust case-mix adjustment systems are needed before a raw number is evaluated. While it is tempting to use mortality to identify poor performers, its appropriateness needs to be considered for each specific disease and operation.

Quality Performance Tied to Reimbursement

Starting October 1, 2012, the Centers for Medicare and Medicaid Services (CMS) began reducing payments to hospitals with excess 30-day, all-cause, risk-adjusted, hospital readmission rates for pneumonia, acute myocardial infarction, and heart failure. According to MedPAC in 2007: “Readmission is generally more likely the more severely ill a patient is—even within the same diagnosis-related group (DRG).” Severely ill patients whose LOS exceeded the applicable DRG by a factor of two were 26.6% more likely to be readmitted.¹¹ Patients with a number of co-morbidities are at an increased risk for readmission. Also, patients discharged to an SNF or long-term care facility had twice the risk of 30-day hospital readmission.¹¹

QUALITY PERFORMANCE CANNOT BE MEASURED IN INTENSIVISTS

Physician Attribution

One of the main issues of measuring intensivist performance is physician attribution. Each episode of

care would involve multiple intensivists and other physicians. How should accountability be spread among all specialists? This issue is especially germane to the ICU population because a majority of patients have multiple conditions and may be treated by multiple physicians. Moreover, nearly three-quarters of the care by intensivists in the United States is delivered in what is considered an “open” or “low-intensity” ICU staffing model: An intensivist makes treatment recommendations but has no authority over patient care.¹² Only in a small percentage of ICUs—mostly medical ICUs and ICUs in teaching hospitals—is critical care provided in a “high-intensity” or “closed” staffing pattern, in which treatment decisions are cohesively managed under the guidance of one intensivist.^{12,13}

Therefore, intensivists in the open system more often treat episodes with multiple physicians and to the extent that efficiency varies among the physicians. Intensivists could be unfairly penalized or rewarded if the other physicians are more inefficient or more efficient. Also, multiple attributions could increase the number of episodes attributed (at least partially) to physicians, increasing the statistical precision of performance measures for them.

ICU LOS

ICU LOS is a process measure that can be independent of quality and is easily manipulated. Encouraging earlier transfer out of the ICU could increase the risk of patient harm and increase readmission rate. On the other hand, in states that have access to LTACs, patients can be transferred to LTACs early in their course of treatment. Thus, without another measure, looking at ICU readmission, there may be pressure for clinicians to discharge ICU patients prematurely. There is potential, however, for adverse consequences that may harm patients and ultimately increase healthcare costs. Furthermore, ICU LOS should always account for ICU mortality and ICU readmission. The measures together balance concerns regarding transferring patients faster because, while the LOS measure may improve, the mortality measure is unlikely to improve and may even worsen.^{14,15}

There is the potential that hospitals will be rewarded unfairly by transferring a large number of patients to LTACs and encouraging the overuse

of post-acute care facilities, which would drive up overall costs. At the same time, the safety-net hospitals will be penalized because the uninsured have no other option for care. Thus, in states without LTACs, both safety-net and non-safety-net hospitals would have increased ICU LOS.

Another issue is coordination of care. In the United States, critical care and palliative care are mutually exclusive entities.¹⁶ After failing a prolonged treatment in the ICU, intensivists are often the first to discuss the goals of care with patients who have reached their end-of-life and their caregivers. Using ICU LOS as a process measure would discourage intensivists from providing time-consuming, yet important, end-of-life care for ICU patients, leading to more fragmentation of care. Having the potential penalty in mind, a goals-of-care conversation is often difficult; intensivists may find it easier simply to transfer the dying patient out of the ICU or into the LTACs.

Hospital Mortality

Even though risk adjustment applies, using hospital mortality as a quality-outcome measure would not account for the impact of palliative care and the ability to transfer to LTACs. Mortality, in general, is higher in safety-net hospitals. Deaths from medical errors and deaths resulting from the decision not to pursue aggressive care are very different things. More than 90% of deaths are unrelated to unsafe care. Most other publicly available quality measures refer only to the in-patient mortality, creating an incentive to move patients to LTACs and other facilities when an end-of-life circumstance arises, an option that is not feasible in a safety-net hospital. Indeed, prior research shows that benchmarking-based in-hospital mortality simply delays death or shifts the site of death to an LTAC, without actually reducing overall mortality.¹⁵

Readmission Rates

Hospitals that serve economically disadvantaged populations, which presumably have less access to care in the community and lower levels of self-efficacy in navigating a complex, fragmented healthcare system, are going to be penalized the same as hospitals serving populations that do not

struggle with these complexities. On the one hand, the safety-net hospitals cannot afford any reduction in resources. Generally speaking, states with LTACs would have lower readmission rates compared to states without LTACs. These measures reflect a process of care that is independent of quality and that can be misleading.

PERFORMANCE CAN BE MEASURED IN INTENSIVISTS

Physician Attribution

Most stakeholders recognize that even with perfect information it would be difficult to equitably divide responsibility for complicated mixtures of resource utilization among multiple physicians treating a single patient in an episode. Therefore, the best way is to try to arrive at a reasonable approximation to reality in these situations. Instead of using single attribution, multiple attribution acknowledges that the decision maker, if there is one, has incomplete control over treatment by intensivists and other physicians, even if the decision maker referred the patient to those other physicians.

ICU LOS

One benefit of performance measurement is to encourage changes—particularly systemic changes—that improve patient outcomes. Public reporting of ICU outcomes can provide the stimulus for needed system changes and appropriate use of resources. The ICU mortality measure has been publicly reported in California since 2007. Developers and implementers of the measure have not received feedback from hospitals identifying unintended consequences. According to MedPAC in March 2011, since reporting of the measure began, patient risk profiles are basically unchanged, but ICU mortality has declined by 0.5%—a statistically significant difference.¹⁷ There has also been excellent engagement in benchmarking and quality-improvement strategies across the ICUs in California as a result of the public reporting of the mortality measure.

The noisy, active ICU is probably not the best environment for end-of-life care, and transfer to other units may be appropriate and desirable. The transfer will only affect the LOS measure since an

in-hospital death is still included in the mortality measure.

Hospital Mortality

The suggestion that a 30-day mortality measure would be an alternative to avoid discharge bias has been studied.¹⁸ Comparing in-hospital and 30-day mortality, there was little change in performance, particularly at the high- and low-performance levels. The data from the National Death Index required for 30-day mortality measures is expensive, and its availability is delayed by at least 2 years. On balance, the in-hospital measure provides good data in a timely manner.

Readmission Rates

CMS has gone on record as stating that there are several safety-net hospitals that do not show evidence of higher-than-expected readmissions rates. This implies that it is not an unaccomplished act that these hospitals are unable to make improvements in care delivery and services to reduce avoidable rehospitalization.

DISCUSSION

For patients with critical illnesses, improving care coordination does not necessarily mean the index hospitalization would have a shorter LOS and a lower mortality. Whichever variables are chosen must satisfy several preconditions. They must be relevant to deciding whether high-quality care is delivered. Mortality and LOS are simple to measure, but they are only one piece of a larger puzzle. Measuring one process without understanding other processes may be misleading. The current system has not yet been made to link the fragmented entities caring for these patients with critical illnesses around accountability for value. Implementing performance measures such as ICU LOS would only widen the gap between safety and non-safety-net hospitals.

ICU LOS and hospital mortality may be good surrogates for an adverse event: medical errors and hospital-acquired infections; however, there are certain conditions that require longer LOS with better patient outcomes that may lead to reduced

cost overall. The more appropriate indicators should include the total cost of care, outcomes of each chronic disease management separately, management of adverse events, as well as patient and caregiver satisfaction.

To improve coordination and decrease fragmentation of care, intensivists should be encouraged to broaden care beyond the acute episode and to weigh in on quality of life post-ICU care.¹⁶ There should be greater responsibility and accountability placed on physicians to discuss the prognosis and goals of care. Using ICU LOS as a process measure would adversely affect the quality of care in patients with critical and terminal illnesses. On the other hand, if a hospital has a lower mortality rate, it could mean a greater proportion of its discharged patients are eligible for readmission. To some extent, a higher readmission rate may indicate successful care.¹⁹

To improve service productivity, measuring and monitoring performance and its variance is a fundamental requirement for identifying efficiencies and best practices and for spreading them throughout the system or organization. Although some variance is inevitable, much of it can be controlled if each system properly accounts for differences in the type of patients they serve and then defines and collects data uniformly across different patient populations.²⁰ To do so, the intensivists in each critical-care service need to compare themselves against their own performance rather than against poorly defined external benchmarks, which only compounds the difficulties for accurate assessment.

Advancing performance measurement at the physician level is the vital strategy on the policy agenda when considerable unexplained variation exists in practices that lead to poor quality, inefficient care delivery, and waste of resources. To move the physician measurement and reporting agenda forward, there is a need for continued development of evidence-based quality measures that can be applied to gauge individual physician performance on a deeper array of medical conditions and specialties. There is a need for research to assess the optimal ways to construct reproducible and unwavering performance scores (eg, levels of aggregation) to assess the optimal ways to provide feedback to physicians and patients to facilitate their understanding and use of the information.²¹

Complications: Never Never or Never Ever

Effie Singas, MD and Dana Lustbader, MD

KEY POINTS

- 1 The ICU can be a dangerous place for patients.
- 2 Many ICU patients experience hospital acquired infections, medication errors, and procedure related complications.
- 3 Complications increase morbidity and mortality.
- 4 ICU complications may be preventable with structured patient handoffs, use of computerized physician order entry, good hand hygiene, ultrasound guidance for procedures, remote ICU monitoring, use of checklists and standardized treatment protocols.
- 5 When an error occurs, physicians should disclose the error, document the error in the record and promptly treat any complications arising from it.

INTRODUCTION

Hospitals are a dangerous place. Experts estimate that nearly 100,000 people die every year from medical errors that occur in hospitals, more than die from breast cancer, AIDS or car accidents. The ICU is especially challenging. There are multiple medical personnel including the primary ICU team and usually one or more consultants caring for patients. Critically ill patients are treated with multiple medications and often undergo procedures, thereby increasing the risk for adverse events and drug interactions. Recent trends in medical education have reduced the number of hours that house officers can work each week thereby increasing the number of handoffs, creating more opportunities for communication failures.

In this increasingly complex environment, there will be complications. The stakes are high. Complications increase morbidity and mortality in the critically ill. Furthermore, they erode public trust

in physicians and the medical system as a whole. As a result, physicians may experience stress and loss of confidence in an increasingly complex medical system. One study estimated two serious errors per day for a 10-bed critical care unit. Medication errors accounted for 78% of the serious errors in this study.¹ Medical error is generally defined as the failure of a planned action to be completed as intended (eg, error of execution) or the use of a wrong plan to achieve an aim (eg, error of planning) and an adverse event as an injury caused by a medical intervention rather than the underlying condition of the patient.² A recent study reported 1,192 medical errors for 1,369 patients; 27% of patients experienced at least one medical error. Patients experiencing two or more adverse events had a threefold increase in overall mortality.³

The landmark report “To Err is Human” published by the Institute of Medicine highlighted the magnitude of the problem and the far reaching

cost of medical error. The report heralded an era of patient safety and the development of quality initiatives for the care of hospitalized patients, especially patients in the ICU.² Critically ill patients are subject to intensive therapies that are most often associated with highest risk and therefore untoward events. This chapter describes common ICU complications and risk mitigation strategies.

HOSPITAL-ACQUIRED INFECTIONS

Hospital acquired infections (HAIs) are a frequent complication of intensive care accounting for prolonged intensive care unit (ICU) length of stay, morbidity, suffering, and death. According to the Centers for Disease Control and Prevention (CDC), about one in every 20 patients will develop an HAI. Such infections were long recognized by clinicians as an inevitable hazard of hospitalization and are most often associated with invasive medical devices or surgical procedures.³

Central line associated bloodstream infections (CLABSI) are common in the United States accounting for nearly 100,000 bloodstream infections annually with half occurring in the ICU setting. While one third of these infections are attributable to gram negative organisms, other organisms like coagulase-negative staphylococci, *Staphylococcus aureus*, and *enterococcus* predominate. Host factors associated with increased risk for CLABSI include neutropenia, immunosuppression, total parenteral nutrition (TPN) use, chronic illness, and burn. Prolonged catheter use, conditions of insertion, and catheter site care also play a role in the development of CLABSI. For patients with suspected or confirmed CLABSI, the indwelling catheter should be removed and cultured with the institution of empiric antibiotic therapy. The initial selection of antibiotic depends on the severity of the infection, but generally vancomycin is used because of its activity against coagulase negative staphylococci and *Staphylococcus aureus*. Ceftazidime or cefepime may be needed for severely ill or immunocompromised critically ill patients.

Urinary tract infections account for more than 15% of infections reported by hospitals. Virtually all health care associated UTIs are caused by instrumentation of the urinary tract. A catheter-associated

UTI (CAUTI) is a UTI where an indwelling urinary catheter was in place for more than two days. The majority of cases are caused by *Escherichia coli* followed by *Pseudomonas aeruginosa*, *klebsiella* species, and *enterobacter* species. Cefepime, ceftazidime, piperacillin-tazobactam, aztreonam, ciprofloxacin, and meropenem are generally first-line agents. In addition to sterile unobstructed closed drainage systems, prompt removal of urinary catheters is the single best strategy for CAUTI prevention.

Ventilator associated pneumonia (VAP) is a hospital acquired pneumonia that occurs 48 hours or more after the institution of mechanical ventilation. It is the most common nosocomial infection affecting patients with respiratory failure and accounts for nearly half of all antibiotics used in the ICU setting. Nearly 20% of mechanically ventilated patients will get a VAP during their ICU course. VAP is caused when the normal host defense mechanisms are bypassed with the endotracheal tube and microaspiration of contaminated oropharyngeal secretions occurs. Rapid colonization of the oropharynx with gram negative bacteria occurs following antibiotic use and illness secondary to resultant compromise of host defenses such as ciliated epithelium, mucus, and glottis. Patients are unable to cough and the contaminated secretions pool above the endotracheal tube cuff and migrate along the airway. Biofilm, impervious to systemic antibiotics, forms along the endotracheal tube and serves as a breeding ground for bacterial growth which ultimately leads to infection.

The CDC National Healthcare Safety Network (NHSN) implemented a ventilator-associated events (VAE) surveillance program in 2013.⁴ This surveillance algorithm uses objective elements to identify complications associated with mechanical ventilation. VAP is included in the algorithm, which starts with the presence of a ventilator-associated condition (VAC), a period of respiratory deterioration following a sustained period of stability or improvement on the ventilator (eg, changes in PEEP or FiO_2). The second tier definition, infection-related ventilator-associated complication (IVAC), requires that patients with VAC also have an abnormal temperature (temperature $> 38^\circ\text{C}$ or $< 36^\circ\text{C}$) or white blood cell count ($\text{WBC} \geq 12,000 \text{ cells/mm}^3$ or $\leq 4,000 \text{ cells/mm}^3$), and requires the initiation of a new antibiotic

for treatment of presumed infection. The third-tier definition is probable VAP and requires that patients with IVAC also have purulent respiratory secretions or laboratory evidence of respiratory infection. For quantitative cultures, a bacterial density of at least 10^6 CFU/ml for endotracheal aspirate, 10^4 CFU/ml for bronchoalveolar lavage, and 10^3 CFU/ml for protected specimen brush and for semiquantitative cultures, at least moderate growth of bacteria.

Risk factors for VAP include a supine position, previous broad spectrum antibiotic exposure, reintubation, acute respiratory distress syndrome (ARDS), prolonged mechanical ventilation, and trauma. The most common pathogens to consider for VAP are *Pseudomonas aeruginosa*, methicillin-resistant *Staphylococcus aureus* (MRSA), *Klebsiella pneumoniae*, *acinetobacter* species, *Streptococcus pneumoniae*, and *Haemophilus influenzae*. Polymicrobial pneumonia is common and one should note that multi drug resistance is increasingly frequent in the ICU setting, particularly for patients with prolonged intubation, prior hospitalizations or ICU admissions, immunosuppression or those requiring hemodialysis. All ventilated patients without contraindications should be maintained in the semi recumbent position with the head of the bed raised 45° and be weaned from mechanical ventilation as soon as possible.

Hospital hand hygiene protocols have been shown to reduce the risk of certain HAI. The World Health Organization estimates that nearly 2 million patients each year are affected by poor hand hygiene practices in hospitals. A shocking number of health care providers fail to embrace hand hygiene. Health-care workers should wash their hands for 15 to 30 seconds with soap and water or an approved alcohol based hand rub before and after patient contact.

MEDICATION ERROR

Medication errors consistently make up the largest group of medical errors. Risk factors include the use of continuous intravenous infusions, polypharmacy with the potential for drug interactions and complex dosing regimens. Medication errors in one study were most commonly associated with treatment, but were also related to prevention (eg, heparin prophylaxis for thromboembolic disease), diagnosis (eg,

intravenous contrast) and monitoring (eg, glucose monitoring). Cardiovascular drugs, anticoagulants and anti-infective agents were most commonly associated with medication errors.¹ Ensuring that medications are used appropriately is a complex process involving professionals from many disciplines. Errors can occur at any stage in the process—from prescribing the correct drug, properly ordering, processing and dispensing the drug, administering the right drug to the right patient, informing the patient about the medication, monitoring the patients response, and identifying adverse events.² Errors of omission were most common in both ICU and non ICU settings, whereas errors caused by improper dose or incorrect administration technique were more common in the ICU setting in a national study of voluntarily reported medication errors.⁵ In an observational study involving a surgical ICU in a tertiary care hospital, 87.5% of doses for weight-based infusions were calculated based on estimated or unreliable admission weights.⁶

The most common medical error reported in an observational prospective multicenter cohort study of 70 ICUs was related to insulin administration, 186 errors per 1,000 days of insulin treatment.³ During the time of this study, tight glucose control was advocated in ICUs.⁷ Subsequent studies examined the risk-benefit of tight glucose control and the practice remains controversial in ICUs today.⁸ Other medication errors included administering anticoagulant medication, prescribing anticoagulant medication, and administering vasoactive agents.³ A recent review of medication errors in the ICU found substantial differences in medication error rates, varying from 18.6 to 146.1 per 1000 patient care days. Studies that reported higher medication error rates included observation methods and did not rely on voluntary reporting alone suggesting an under reporting of error when self reporting is the only tracking method.⁹

While the use of computerized physician order entry (CPOE) has reduced errors in medication dose, route, substitution, and allergy and has intercepted adverse drug events, its use in the ICU can potentially increase the rates of certain medication errors, or result in entirely new error types. These include medication discontinuation failures, antibiotic renewal failures, unreliable reinstitution of

medications following surgery and problems with nonformulary medications.¹⁰ Alert fatigue is another common problem created by computerized entry of orders as the number of cautionary alerts increases, so too does the provider ability to tune them out.

PROCEDURAL COMPLICATIONS

Many ICU patients will be mechanically ventilated at some point during the course of their critical illness. Mechanically ventilated patients can experience complications from the initiation of mechanical ventilation all the way through to their extubation. These complications include esophageal intubation, hemodynamic instability in the peri-intubation period from sedation, hypoxemia, or delay in intubation. Once patients are intubated, endotracheal tubes can become dislodged, clogged or inadvertently removed by the patient. The rate of self-extubation has been reported to occur in about 5% to 15% of intubated patients.

Mechanical ventilation and the positive pressure patients are exposed to can lead to barotrauma and further complications. Use of a video laryngoscope can significantly reduce the number of esophageal intubations and increase first pass success during intubation.¹¹ The adoption of a combined team approach to urgent endotracheal intubation with designated roles for team members, a mandatory checklist and back-up plan, can minimize peri-intubation complications.¹²

Critically ill patients often require central venous lines for access, monitoring and therapy (eg, dialysis, ECMO). Complications can occur from start to finish—wrong site, improper sterile technique, poor procedural technique, including poor knowledge of the anatomy, resulting in bleeding, local trauma including injury of vessels or underlying lung (eg, pneumothorax), and infectious complications. The presence of a central venous catheter and mechanical ventilation were among the factors independently associated with having at least one medical error in a recent study.³

The use of ultrasound to guide invasive procedures such as central line placement and thoracentesis has made them much safer as the anatomy can be directly visualized. A multidisciplinary approach

employing a “time out” can make it difficult for errors of site or identification to occur.

Nasogastric tubes for enteral feeding and medication access can be dislodged or incorrectly positioned, entering the airway instead of the esophagus, resulting in trauma to the lung. Furthermore, patients must be positioned in a semi-recumbent position to minimize the chances of aspiration. Careful monitoring of positioning, securing of these tubes and appropriate sedation of the patient can avoid many complications.

Intern fatigue has been linked to serious medical errors in ICUs. One prospective, randomized study compared the rates of serious medical errors made by interns working a traditional schedule with an every third night call schedule versus an intervention schedule that eliminated extended work shifts and reduced the total number of hours worked per week. Interns made 35.9% more serious medical errors during the traditional schedule than during the intervention schedule. The total rate of serious errors was 22% higher during the traditional schedule.¹³ As a result of studies like these, the Accreditation Council for Graduate Medical Education (ACGME) restricted trainees to 16 consecutive hours of work. Shorter work shifts have resulted in a significant increase in the frequency of transitions of care (eg, handoffs) in the ICU. Improving the hand-off process with the use of a structured note and face-to-face handoff can reduce medical error.

OH NO, WE HAD A COMPLICATION. NOW WHAT?

Truth telling in the setting of medical error or complication is generally the best approach. Interestingly a recent study showed that one fifth of physicians reported not fully disclosing medical error or mistakes to patients for fear of malpractice lawsuits.¹⁴ The first priority is always to promptly diagnose and treat the complication. Careful documentation in the medical record is a critical next step. Informing the patient, family or surrogate is often difficult but part of good medical care. When discussing the situation, it is helpful to describe the situation, how it happened and the course of action to be taken to resolve the problem whenever possible. Never lie about or cover up a mistake.

CONCLUSION

The ICU is a complex and dangerous place for our patients. Patients are critically ill, require many medications, invasive lines and procedures, and 24/7 multidisciplinary care. This chapter outlines the most frequently encountered complications in ICU patients. Many hospital complications are preventable with good communication, oversight and education. Borrowing from other industries including the airlines and restaurant chains, hospitals have adopted methods and safety checklists to improve the reliability of the health care environment.¹⁵ The use of medical response teams for a faster response to a critically ill patient, remote ICU monitoring for greater oversight (eg, tele-ICU), and the adoption of critical care bundles and protocols are some of the methods being used to improve the safety of our patients in ICUs. The critical question is when will effective quality health care measures be available to every patient every time.

Controversies: Noninvasive Ventilation at the End-of-Life—Useful or Not?

Katerina Rusinova, MD; Alexandre Demoule, MD and Elie Azoulay, MD

INTRODUCTION

Noninvasive ventilation (NIV) has been well described as effective in different patient populations, for example, hypercapnic respiratory failure due to exacerbations of chronic obstructive pulmonary disease (COPD),¹ hypoxic respiratory failure in immunocompromised hosts,² or cardiogenic pulmonary edema in the absence of acute coronary ischemia,³ to cite the most common indications.

Conceptually, the use of noninvasive ventilation can be divided into the following three categories⁴:

1. NIV as a part of “full-code” treatment (life support without preset limits)
2. NIV in patients with do-not-intubate orders (life-support with preset limits)
3. NIV as a comfort measure in patients at the end-of-life (NIV ensuring comfort while dying)

Each category has specific goals of care, response to failure, and main points to communicate with the patient and/or family. Categories 2 and 3 can be defined as palliative NIV.⁵

The goals of NIV in patients in category 1 are to alleviate symptoms of respiratory distress, improve oxygenation and/or ventilation, avoid intubation, and reduce the risk of mortality. Endotracheal intubation is performed if necessary.

Patients in category 2 are those who decline endotracheal intubation or patients in whom clinicians feel that intubation would not meet the goals of care. In this group, the use of NIV achieves the same goals as it does in category 1, except that

endotracheal intubation is not an option in cases where NIV is ineffective.

The only purpose of NIV in category 3 is symptom palliation and patient comfort.

SYMPTOMS OF RESPIRATORY DISTRESS AT THE END OF LIFE

Respiratory distress is one of the most common symptoms seen in patients approaching the end-of-life. It leads to restrictions in quality of life and increases anxiety and fear.⁶

Terminal dyspnea is a manifestation of an irreversible process, such as carcinomatous lymphangitis in malignant diseases or advanced degenerative neuromuscular disease (amyotrophic lateral sclerosis).

The vast majority of patients with terminal cancer experience symptoms of respiratory distress at some point during the last 6 weeks of life, and they commonly report significantly increased dyspnea during the last two weeks.⁷ In patients with a non-cancer terminal diagnosis, such as COPD or chronic heart failure (CHF), the severity of respiratory distress can be greater; however, the severity remains relatively stable until death.

RESPIRATORY DISTRESS RELIEF BY USING NIV

The mechanism underlying the relief of respiratory distress through noninvasive ventilation remains the same in all clinical situations.⁸ NIV reduces the work of breathing by increasing transpulmonary pressure

and reducing inspiratory muscle workloads. Gas exchange is improved by increasing alveolar ventilation, functional residual capacity, opening collapsed alveoli, reducing shunts, and improving the ventilation/perfusion (V/Q) ratio. Altogether, these mechanisms result in a lower respiratory rate, reduced CO₂ retention, and an overall improvement of symptoms of respiratory distress.

RESEARCH FINDINGS

Recently, studies focused on the use of palliative noninvasive ventilation have provided descriptive data, new evidence, and qualitative appraisals of palliative NIV.

A prospective cohort study by Azoulay et al.⁹ reported outcomes of patients undergoing NIV in the context of “do-not-intubate” (DNI) orders (ie, category 2). A DNI order is present in about 20% of all patients receiving NIV in intensive care units (ICUs). A substantial hospital survival of 56% was observed, which was most obvious in the COPD patient subgroup. Importantly, for those who survived up to 90 days, health-related quality of life did not significantly change compared to baseline. Moreover, anxiety, depression, and posttraumatic stress disorder (PTSD)-related symptoms in patients and their families were similar to those seen when NIV was used in category 1 (full code) patients. These recent data, together with previously published reports,^{10,11} thus support the use of NIV in this clinical context.

A study by Nava et al.¹² that focused on patients with end-stage cancer (ie, category 3 patients) assessed the acceptability and effectiveness of NIV versus oxygen therapy in decreasing dyspnea and its effect on the use of opioids. The study showed that NIV is faster and more effective compared to oxygen in reducing dyspnea and offers the potential to reduce the dose of opioids. Hospital mortality was similar in both groups. NIV was well accepted and well tolerated, again, with the best response in cases of hypercapnic respiratory insufficiency.

Finally, NIV has been evaluated in patients suffering from terminal phase motor neuron disease who are at the end-of-life. A qualitative study by Baxter et al.¹³ revealed important variations in patient wishes regarding the use of NIV toward the end-of-life and also a

TABLE 85–1 Expected benefits and possible risks of end-of-life NIV: factors to be considered before NIV initiation (on an individual basis).

Expected Benefits	Possible Risks
Prompt relief of respiratory distress	Discomfort from tight-fitting mask (facial necrosis)
Maintained cognition	Noise exposure (up to 65 dB)
Time to finalize personal affairs (strategy to “buy time”)	Possible unnecessary prolongation of the terminal phase of life
Dose of opioids diminished (with fewer or reduced opioid side effects)	Nasal/oral dryness, nasal congestion
Improved ability to communicate due to diminished use of opioids and higher level of consciousness	Limited ability to communicate imposed by the face mask
Reassurance, reduced end-of-life anxiety	Stressful fixation on technology at the end-of-life
Say goodbye to loved-ones	Symptoms of PTSD in family members Complicated grief ¹⁵

degree of uncertainty concerning NIV management among healthcare teams. Nevertheless, end-of-life use of NIV was generally perceived as beneficial, allowing a more peaceful end-of-life, free of choking or struggling to breathe during the final moments.

Even if current research findings support the use of noninvasive ventilation in palliative situations (categories 2 and 3 of the conceptual framework), important questions/objections have been raised, concerning possible discomfort and unnecessary prolongation of the terminal phase of life.^{14,15} Some aspects of the current controversies are summarized in [Table 85–1](#).

PRACTICAL CONSIDERATIONS

Prior to NIV Initiation

Palliative noninvasive ventilation, incorporated into a strategy of continuous patient care, should be discussed early, along with the patient’s other

preferences regarding advanced or terminal stages of their disease. Specific goals of using NIV in the clinical setting should be carefully explained and thoroughly understood by the patient and their family with particular emphasis on concrete measures that can and, if approved, will be taken to quickly achieve patient comfort in cases when NIV fails to achieve the desired results.

Monitoring During NIV

It has been reported that NIV targeted at control of respiratory distress (ie, category 3) can also be successfully used outside the ICU, for example, wards, hospices, and even at home. Monitoring should be oriented toward continually reassessing whether NIV is succeeding or failing to meet therapeutic goals (in category 3, eg, the only monitored aspect would be relief of symptoms).

Discontinuing NIV at the End-of-Life

NIV used to aid patients through the end-of-life should be discontinued when patients feel that the NIV is not making them more comfortable or when patients are no longer able to communicate. This is probably the moment when the benefits of NIV have ceased, since patients have lost control over the decision to continue NIV support.

UNANSWERED QUESTIONS

There are important questions regarding the use of noninvasive ventilation during the end-of-life period that have not yet been addressed. There are no data assessing the quality of NIV–assisted end-of-life care. We also do not have a full appreciation or analysis of life support resource utilization or the effectiveness of palliative NIV on survival.

CONCLUSION

Noninvasive ventilation can and should be considered as a feasible palliative therapeutic option as well as a comfort measure during the dying process. However, there is only limited evidence about what type of patients and what diseases would mostly benefit from palliative NIV. To date, few studies have been published that address this important issue.

Presently, decisions about palliative NIV have to be evaluated carefully and on a case-by-case basis, and oriented on the potential benefits for a given patient.

Post-Intensive Care Syndrome

86

Leonard Lim, MD and Graciela Soto, MD, MS

KEY POINTS

- 1 The number of patients who survive acute critical illness has increased over the last few years and PICS is more common than previously thought.
- 2 PICS is new or worsening impairment in physical, mental, or cognitive status arising after critical illness and persisting beyond the acute care hospitalization.
- 3 These impairments are frequently under recognized and adversely impact daily functioning and the quality of life.
- 4 Decline in lung function parameters and ICU-acquired weakness are some of the physical impairments that can affect health care resource utilization and short- and long-term outcomes.
- 5 Neurocognitive impairment spans a wide range of dysfunction and is associated with metabolic abnormalities, hypoxemia, fever, sepsis, pharmacological agents, organ dysfunction, and disrupted sleep.
- 6 The neuro-psychological impairment encountered after ICU care (eg, anxiety, depression, and PTSD) is not associated with an increased severity of illness but rather to both the subjective and objective aspects of the ICU experience.
- 7 Strategies to minimize or prevent PICS should start during the ICU stay and address those modifiable risk factors known to be associated with the different aspects of PICS (eg, glycemic control, minimizing sedation, early exercise and mobilization, liberation from mechanical ventilation).

INTRODUCTION

Over the past decade, survival from critical illness has dramatically increased due to a better understanding of the pathophysiological mechanisms of disease, improved treatment strategies and advancements in medical technology. Several studies have shown improved survival and long-term outcomes in

survivors of critically illness. However, surviving the intensive care unit (ICU) stay is just the start of a long road to recovery for a majority of these patients. The discharge from the ICU opens the path to a long journey of challenging physical rehabilitation, mood disorders, cognitive impairment, psychological distress, financial hardship, and caregiver burden and burnout.

In recent years there has been a growing recognition of impairments that affect the physical, psychological, social, and emotional aspects of the individual after ICU discharge that may adversely impact daily functioning and quality of life (QOL). Recently, the term “post-intensive care syndrome” (PICS) is used to describe any new or worsening impairments in physical, cognitive, or mental health status arising after critical illness and persisting beyond the acute care hospitalization.¹ PICS may persist for months to years after hospital discharge. Most impairments will diminish with time but some may linger on until the patient’s actual demise. This chapter will explore in detail the different domains affected in PICS, its impact on the individual and society, and offer insights into future developments.

PHYSICAL IMPAIRMENT

Probably the most obvious and readily recognizable changes in patients immediately after discharge from the ICU are the physical impairments that are the result of the actual critical illness or the direct or indirect side-effects of interventions to treat the disease. An individual patient may lie at a particular point in the spectrum of physical disability according to the patient’s age, level of functioning prior to the onset of critical illness, and the burden of co-morbid conditions. At one end of this spectrum, clinicians encounter young, previously working and highly functional patients who develop a severe catastrophic illness. The middle range includes patients who are older and have a greater burden of comorbidities than the previous group. Finally, the opposite end of this spectrum includes those patients who have experienced chronic critical illness, or the very elderly, in whom ICU-level of care may not alter their ultimate outcome but may instead contribute to incremental disability and constitute part of a downward functional trajectory driven by progression of chronic illness.

Lung Function

It has been shown that in critical illness leading to respiratory failure, particularly in acute respiratory distress syndrome (ARDS), that lung function is decreased soon after recovery but improves to

normal or near-normal over 6 months to 5 years. The diffusing capacity for carbon monoxide (DLCO) is the lung function parameter that seems to be mostly affected as DLCO values still remain mildly reduced or low-normal even after 5 years of follow-up.² This persistent impairment in gas transfer is probably due to injury at the capillary level, which promotes thickening in alveolar capillary interfaces, pulmonary fibrosis, and pulmonary vascular remodeling.

Anatomical changes in the lung are also observed in follow-up imaging studies of ARDS survivors. Localized changes in the nondependent lung zones including reticular changes, ground-glass opacities and minor pulmonary fibrosis are seen on high-resolution computer tomography (CT) scans.³ The association between the severity of lung injury and length of mechanical ventilation may reflect ventilator-associated lung injury. However, the relationship between the development of lung fibrosis after ARDS and any possible risk factor is not straightforward. Some studies have found significant correlation between CT scan impairment and duration of mechanical ventilation, level of positive end-expiratory pressure (PEEP), and oxygen fraction. These data may only reflect greater severity of ARDS, which can be responsible per se for lung fibrosis.

It is interesting to note that the severity of the patient’s dyspnea after recovery from ARDS does not seem to correlate with actual lung dysfunction but may reflect extrapulmonary muscle weakness and sometimes psychological impairments.

Chronic Respiratory Failure

The onset of respiratory failure requiring prolonged mechanical ventilation is associated with increased morbidity, mortality, and health care costs. ICU admission for pneumonia, ARDS, neuromuscular disease, head trauma, or postoperative intracerebral hemorrhage is one of the strongest predictors of prolonged mechanical ventilation.⁴ ICU-acquired weakness (ICU-AW) has also been shown to be a predictor of failure to be liberated from the ventilator. The mechanism that is responsible for a majority of ventilator dependence can be explained by an increase in respiratory load coupled with decreased respiratory muscle performance. Chronic ventilator

dependence may result in complications similar to those receiving short-term mechanical ventilation. These include infections, tracheal bleeding or malformations, renal failure, pneumothorax, volume overload, ileus, and seizures.

The overall mortality in patients with ventilator-dependent chronic respiratory failure is high and up to 52% at one year from the initial hospitalization.⁵ Chronic irreversible neurologic diseases and presence of skin breakdown has been associated with increased risk for mortality. These patients may be discharged to home, long-term acute care (LTAC) facilities, skilled nursing facilities or hospice care centers. The QOL tends to be low but may improve over the years. In particular, ARDS survivors who require prolonged mechanical ventilation have poorer QOL than other ARDS survivors.⁶ Health care resource utilization in these patients have been shown to be exceeding high and much of this is spent on ongoing and recurrent medical care.

Weakness

Another important aspect of the physical impairment after recovery from critical illness is weakness. Potential contributors to weakness in survivors of critical illness are listed in Table 86–1. Risk factors for the development of weakness after critical illness are enumerated in Table 86–2. Several contrasting

TABLE 86–1 Contributors to weakness in survivors of critical illness.

Chronic disease
Acute neurologic syndrome, eg, Guillian-Barre syndrome, myasthenia gravis
Persistent organ dysfunction, eg, heart failure, chronic respiratory failure, acute kidney injury
Neuro-muscular pathology, eg, CIP, CIM, ischemic or compression mononeuropathies
Muscle atrophy from prolonged immobility
Deconditioning
Pain
Psychological disturbances

TABLE 86–2 Risk factors for weakness.

Female sex
Advanced age
Severity of illness
Hyperglycemia
Corticosteroids
Neuromuscular blockers

studies have shown variable association between the development of weakness and the severity of illness on ICU admission (eg, SAPS-2, APACHE II/III, SOFA). High blood glucose has been identified as a risk factor through an unknown mechanism while intensive insulin therapy has been shown to be a preventive factor against critical illness-associated weakness and to decrease the risk of critical illness polyneuropathy. The data on the association of corticosteroids with the development of weakness has been conflicting; however one study reported decreased neuromuscular dysfunction in patients on intensive insulin therapy while on corticosteroids, suggesting that when euglycemia is maintained, the anti-inflammatory effect of steroids may benefit the neuromuscular system.⁷ Low doses of neuromuscular blockers (eg, paralytics) do not seem to be associated with weakness but larger doses may be independently associated.

Formerly described by different entities such as critical-illness polyneuropathy (CIP), critical-illness myopathy (CIM), and critical-illness neuromyopathy, ICU-AW is the prototypical functional impairment that has been the subject of intense research even prior to the recognition of the other domains of PICS. The incidence of ICU-AW varies from 30% to 90%. It may be missed during the acute phase of critical illness when the patient is sedated, restrained and unable to communicate. Difficulty liberating from mechanical ventilation may be the first indication of an impairment.

CIP is an axonal polyneuropathy that affects both sensory and motor nerves. The causes of axonal degeneration include the systemic inflammatory response syndrome (SIRS), ischemia to nerves

from hypotension, microthrombosis, changes in microcirculation, endoneural edema, inflammation, mitochondrial dysfunction causing bioenergetic failure, neurotoxic meds, and metabolic abnormalities. Physical examination may reveal distal sensory deficits, distal weakness, and preserved deep-tendon reflexes (DTRs). Electromyography-Nerve Conduction Velocity (EMG-NCV) studies demonstrate decreased amplitudes of sensory and motor nerve action potentials with normal motor unit potentials and excitability. Pathologic evaluation reveals fiber loss and primary axonal degeneration of both motor and sensory nerve fibers, most severe distally.

CIM includes flaccid tetraparesis with depressed or absent DTRs but sensory function is not affected. The causes include increased muscle breakdown, decreased protein production and abnormal muscle repair, derangement of energy delivery, changes in the muscle membrane with primary inexcitability of muscle fibers, inflammation, steroids, and immobility. NCV studies reveal decreased amplitudes of compound muscle action potentials with preserved sensory nerve action potentials. Direct muscle stimulation demonstrates reduced or absent muscle excitability. Pathology most commonly reveals loss of thick filaments with atrophy of the type II fibers.

In terms of assessing weakness, the six-minute walk test (6MWT) is most widely used as it is an integrated outcome parameter that is dependent on the motor, pulmonary, and circulatory function. This test has proven to be a simple but useful test of global physical recovery in former ICU patients.

NEUROCOGNITIVE
IMPAIRMENT

Neuro-cognitive impairment spans a wide range of dysfunction in critically ill patients. From those who are comatose to patients with minor, sometimes subtle dysfunction that may only be revealed using specific tests of cognitive dysfunction, although close relatives may have already recognized behavioral changes in these patients. Among survivors from general, medical and surgical ICU, the incidence of cognitive impairment ranges from 4% to 71%, while the incidence of cognitive impairment in ARDS survivors ranges from 4% to 56%.³ Two studies in

elderly critically ill patients have reported a prevalence of cognitive impairment varying from 17% to 56%.^{8,9} Cognitive impairment is associated with a reduced QOL and is a major determinant of societal health care costs and care-giving needs. The elderly are prone to developing cognitive impairment; however, it appears that younger, relatively healthy patients are also at risk of cognitive impairment following critical illness. Risk factors for the development of cognitive dysfunction after critical illness are listed in Table 86–3. It is unclear whether a low performance on neuropsychological tests reflects impairment in cognitive functioning related to critical illness and ICU admission, or whether it is perhaps merely a marker of patients with poor health and an increased risk of ICU admission. However, studies that include premorbid cognitive data show that at least part of the measured cognitive impairment is related to the ICU admission and critical illness.

Memory, attention, verbal fluency and executive functioning are the domains most frequently impaired after critical illness. The pathogenesis is not fully understood but may represent an accelerated neurodegenerative process that develops in vulnerable patients. Cognitive impairments can also be associated with newly acquired brain damage due to insults from critical illness such as hypoxemia, hypotension, anemia, fever, hyper-/hypoglycemia, systemic inflammation, severe sepsis, pharmacologic agents, disrupted sleep, renal failure, and liver failure. Severe sepsis can lead to a neuroinflammatory response, resulting in increased levels of

TABLE 86–3 Factors associated with neurocognitive impairments in critical illness survivors.

Advanced age

Severe sepsis
Lower cognitive reserve

cytokines in the brain.¹⁰ Elevated cytokine levels are associated with impaired memory in healthy volunteers, and neuroinflammation is associated with the development of Alzheimer's disease. Long-term cognitive impairment in patients may therefore represent a maladaptive version of cytokine-induced disease. Delirium in the ICU can cause long-term complications such as cognitive impairment and can also significantly decrease short-term and long-term survival and worsen QOL after critical illness. Increased duration of delirium likewise is associated with worse neurocognitive outcomes in a "dose-dependent" manner.¹¹

Radiologic and pathologic findings associated with cognitive dysfunction associated with critical illness include ischemic and hypoxemic hippocampal lesions, brain atrophy, ventricular enlargement, decreased superior frontal lobe and hippocampal volumes, and loss of white matter in the corpus callosum and internal capsule. At 1 year, these anatomical findings were associated with worse overall cognitive performance and worse executive functioning. Left hippocampal volumes on MRI were likewise markedly reduced in a cohort of patients with septic shock.

Individuals who are hospitalized for a critical illness have a greater likelihood of cognitive impairment, even after adjusting for premorbid cognitive screening scores and comorbidity. It has been suggested that critical illness may cause an abrupt loss of cognitive function rather than accelerate the decline in cognitive functioning. Cognitive dysfunction is probably very frequent in the immediate short period after intensive care but tends to normalize in most patients with time. Time to improvement varies from different studies. Improvement towards normal cognitive functioning has been reported to occur as early as 9 months after ICU discharge. Other studies have shown no improvement from 1 up to 5 years of follow-up.

Studies have so far been unable to identify patients at higher risk of cognitive impairment using brief cognitive screening tools at time of hospital discharge. One candidate predictor for cognitive impairment might be quantitative electroencephalogram (EEG). A recent study of sepsis survivors found EEG to be a potential predictor of cognitive impairment in these patients. Deficits in

verbal learning and memory were associated with a significant reduction in left hippocampal volume and low-frequency activity on routine EEG. EEG may be able to provide prognostic information, possibly in combination with other modalities. Serum biomarkers may also be useful in predicting cognitive impairment. Elevated serum interleukin (IL)-6 and c-reactive protein (CRP) concentrations are associated with reduced cognition and contribute to accelerated functional decline in both the elderly and in post-operative cardiopulmonary bypass patients. Given the prevalence of delirium in disease states with a higher systemic inflammatory burden, inflammatory biomarkers may be useful for monitoring delirium disease activity and predicting risk of long-term cognitive impairment.

Lower percentages of patients with cognitive impairments were reported in studies using screening tests as compared to studies that utilized extensive neuropsychological testing. A major limitation of most studies is that a baseline assessment of cognitive status before the onset of critical illness is lacking and is oftentimes difficult to determine unless prior premorbid cognitive screening results were available. Ideally, pre-ICU admission cognition should be available because the real interest is not the absolute level of cognitive performance but rather the change in cognitive functioning.

Another limitation is that cognitive testing is seldom standardized from center to center and from cohort to cohort making the comparison between studies difficult. Furthermore, a large number of different tests and combinations have been used making the interpretation and application of the results to critically ill patients challenging. The most widely used tests include the mini-mental status examination (MMSE) for screening patients for cognitive dysfunction and the Cambridge Neuropsychological Test—Automated Battery (developed at the University of Cambridge) as a more in-depth test for cognitive dysfunction in research studies.

PSYCHOLOGICAL AND BEHAVIORAL IMPAIRMENT

The increasing awareness of the PICS has led to the realization that new onset behavioral changes and psychiatric symptoms are the result of the ICU

experience in survivors of critical illness. Akin to the psychological trauma experienced by survivors of natural or man-made catastrophes, the time spent in the ICU can be as harrowing as a near-death experience to many. The reported prevalence of anxiety and depression after ICU discharge varies between 6% and 28% among different studies depending on the “cut-off” scores and methodology used. Levels of anxiety and depression appear to decrease in the first year after ICU discharge; however, it is unclear whether this improvement remains or continues to full resolution of symptoms. On the contrary, in patients with ARDS, levels of depression increased from 16% at 1 year after discharge to 23% at 2 years. It has also been suggested that 14% to 27% of critically ill patients may develop a posttraumatic stress reaction or post-traumatic stress disorder (PTSD). Importantly, post-traumatic stress does not appear to decrease over time after ICU discharge and may endure for a number of years. Criteria for the diagnosis of PTSD are defined in the DSM-IV-TR. Factors associated with an increased likelihood of both anxiety, depression and PTSD after ICU discharge are listed in [Table 86–4](#).

Patients who had neuropsychological impairment after ICU care had statistically significantly higher depression scores than those who did not require ICU-level of care.¹² Increased severity of illness does not seem to predict an increased risk of

developing psychological dysfunction, but rather it is both the subjective and objective aspects of the ICU experience that seem to be associated with it. In addition, these subjective and objective indicators are associated with the severity of anxiety and depression experienced by patients after ICU discharge.

The subjective indicators include the reported unpleasant memories of being in the ICU. Patients often report disturbing recollections and these experiences are often persecutory in nature and are associated with feelings of being elsewhere reliving a previous life event or fighting for survival. The lack of memory for actual events may mean that this is the way in which patients process these delusions or unreal experiences that result in longer term psychological problems. In fact, it has been proposed that the content of the ICU memories was more important than their number, and that delusional memories were more likely to result in distress than factual memories, even if these were unpleasant.¹³ Patients frequently describe these memories as extremely vivid and real. The traumatic memories may also be linked to the recollection of certain persistent physical symptoms. Some patients may make strenuous efforts to block these traumatic memories but, paradoxically, this may only cause them to occur more frequently.

The objective indicators include variables such as length-of-stay (LOS), duration of sedation and/or neuromuscular blockade, mechanical ventilation, and other respiratory supportive therapies. Some studies show that decreased time under sedation or in mechanical ventilation result in decreased post-traumatic stress symptoms and anxiety. It is interesting to note that there has been some inconclusive evidence to support the role of corticosteroid supplementation during acute illness in preventing PTSD during recovery—as PTSD is associated with abnormalities of the hypothalamic–pituitary–adrenal axis and in stress response in general.

Psychological and behavioral outcome after ICU care has been mainly assessed using standardized questionnaires with demonstrated reliability and validity. Tools used to assess anxiety, depression, and PTSD are listed in [Table 86–5](#).

TABLE 86–4 Factors associated with increased likelihood of psychological dysfunction.

Female sex
Younger age
Longer duration of sedation
Pre-existing anxiety or depressive symptoms
Injuries resulting from trauma
Longer ICU stay
Longer mechanical ventilation
Alcohol dependence prior to critical illness

CONSEQUENCES OF THE POST-INTENSIVE CARE SYNDROME

Impact on the Patient

Health-related quality of life (HRQoL) sums up the effects of the ICU stay in survivors of critical illness and is probably the best documented of all non-mortality outcomes after hospital discharge. HRQoL encompasses both the physical and psychological aspects of the individual's overall well-being. HRQoL after ICU discharge may range from normal to reduced in different patient populations and are usually compared to the “normal” population in different studies. Elderly survivors tend to have decreased HRQoL mostly in the physical domains. Survivors of severe trauma tend to have more permanent reductions in their HRQoL due to the fact that their HRQoL probably is already reduced at baseline from alcohol and substance abuse, even though these patients are typically younger and frequently do not suffer from prior chronic organ dysfunctions. Studies that compare pre-ICU HRQoL with post-ICU data indicate that ICU patients in general express a reduced HRQoL prior to ICU admission compared to the matched general population. The burden of preexisting medical conditions is one of the most significant factors associated with a reduction in HRQoL after ICU care. This strongly suggests that in most acutely ill ICU patients, their HRQoL after ICU discharge probably will never equal a matched general population. Working status

or the ability to return to work is also a frequently reported outcome measure and is in general found to be low and reported to range from 23% to 35% in different studies.

Compounding the already burdened survivor, depression has been associated with poorer HRQoL. However, the direction of this relationship is not clear, and it may be that patients with a poorer HRQoL have a more prolonged recovery and thus are more likely to be depressed. This is an important issue because it suggests that if other aspects of HRQoL are better, then perhaps emotional outcome might be improved. Depression may interfere with the speed of recovery, and in some patients may lead to suicidal attempts.

Impact on Caregivers

There is no question that caregivers have a devastating, parallel, but different experience compared with their loved one. For the family and other caregivers, the daily and overwhelming stress experienced while the patient is in the ICU leaves its mark, and they similarly may experience compromised HRQoL and mental health, including PTSD, emotional distress, caregiver burden, depression and anxiety.¹⁴ There is a strong relationship between high levels of PTSD-related symptoms in family members and those in patients. In some cases, family therapy may be needed. As a result returning to the hospital or doctor's office for outpatient appointments can be very stressful but, at the same time, it may be therapeutic and provide needed reassurance of their loved one's recovery. For bereaved families, the incidence of PTSD may be even higher and often goes completely unrecognized. Even when home care is provided by family members, there is still great opportunity cost, as these individuals must sacrifice other endeavors to free up time at home. Caregivers themselves also may face significant cognitive morbidity simply as a consequence of caring for their chronically ill family members.

Impact on the Health Care System

Along with personal costs, there are significant financial costs associated with surviving an episode of critical illness. ICU survivors face long hospital

LOS and post-discharge care that frequently involves expensive skilled nursing and long-term acute care (LTAC) facilities. Compared with the extensive resources devoted to helping the patient survive their ICU stay, far fewer resources are devoted to improving outcomes in the post-ICU period and systems are not in place to facilitate the patient's transition from the acute to the chronic phase of their illness. Transferring patients to LTACs decreases hospital costs, but increases total costs, with no consistent improvement in long-term outcomes. In the era of intensivist physician staffing and hospitalist medicine, it is becoming less common that a single physician provides both hospital care and post-discharge care. Instead, the responsibility for post-discharge care falls on busy general practitioners, who are frequently unaware of events in the ICU, and often lack the time and expertise to diagnose the myriad of sequelae of critical illness.

STRATEGIES TO MINIMIZE OR PREVENT PICS

Physical and Neurocognitive Domains

Controlling the modifiable risk factors known to be associated with the different aspects of PICS is probably the first step in mitigating its effects on ICU survivors. These would include maintaining euglycemia, minimizing use of sedation and neuromuscular blockers, early liberation from mechanical ventilation, judicious use of corticosteroids, and early exercise and mobilization.¹⁵ Early identification of ICU-AW will be the key in initiating early physical and occupational therapy. Early exercise and mobilization has been shown to increase the number of patients being discharged from the hospital with an independent functional status. Studies have also demonstrated a link between exercise and cognition through improved cerebrovascular function. Identifying exercise as a mechanism that reverses or alters the trajectory of cognitive impairment would have an important impact on the HRQoL in survivors of critical illness.¹⁶ Furthermore, combining both cognitive and physical rehabilitation has been shown to result in significantly better executive functioning and fewer disabilities in instrumental activities

of daily living. An ICU sleep-promotion initiative has likewise been shown to reduce incident delirium and cognitive impairment. Better sleep efficiency may contribute to improving HRQoL and reducing fatigue to allow more effective participation in physical rehabilitation.

Psychological Domain

The psychological stress resulting from the ICU experience has been shown to be partly contributed by inaccurate memories during the ICU stay. Therefore, it has been suggested that providing survivors with an ICU diary may improve their understanding of their ICU experience and act as a “debriefing” tool. ICU diaries may be compiled by any of the ICU staff members, particularly nurses, and also by family members. It can be a written account complemented by photographs or videos. It should be viewed as a form of exposure to accurate and potentially corrective information, thereby reducing the anxiety caused by inaccurate and oftentimes frightening memories of the ICU stay. Also, reading or viewing of the ICU diary is entirely voluntary at a time of the patient's choosing and should be followed by a discussion of the contents with a member of the ICU staff. This should be viewed as a first step in learning to modify and control feelings and reduce physiological arousal as a step to recovery. Those patients who have received ICU diaries had lower levels of PTSD-related symptoms than those who did not.¹⁷

A stepped care approach with different degrees of therapeutic intervention depending on patient need may represent a more viable and flexible model for recovering critical illness survivors. This may involve designing or using off the shelf self-help programs to help individuals coping with lower levels of symptoms of anxiety, panic or depression. Those patients not responding to this or who exhibit greater symptom levels may then be referred to specialist psychological services for cognitive behavioral therapy or eye movement desensitization and reprocessing. These are therapies designed to reduce the emotional impact of distressing and traumatic memories and facilitate new ways of thinking. A stepped care approach may offer the appropriate and timely help to the maximum of patients, and may be more cost-effective compared with a more

conventional approach of referring all patients to a counselor or clinical psychologist.

FUTURE DIRECTIONS

As the public is slowly becoming more aware of the PCIS because of increased reporting in mainstream media, efforts to further expand knowledge on this syndrome and to implement interventions to treat or mitigate its effects are more important than ever. With the percentage of the elderly population rising to much higher numbers in the next few decades, coupled with increasing survivorship from the ICU, we may be facing a public health emergency. Future research should be geared towards standardizing the definition of cognitive impairment, defining the spectrum of disability after critical illness, refining the associations of risk factors, detailing specific patient and family-centered outcomes, and improving study designs to address long-term patient-centered functional outcomes. In addition, much more research is needed to evaluate the effectiveness of educational strategies that raise awareness and promote treatment of post-ICU morbidity among general practitioners.

A potentially useful post-intensive care recovery intervention is the concept of the post-ICU clinic. From recent experience from the United Kingdom, it has been shown to increase understanding of the longer term recovery from critical illness.¹⁸ However, the provision of services in different clinics is varied, unspecialized and oftentimes inconsistent, and tend to have funding problems hence restricting the number of patients who can be seen. Currently, it is still unclear whether these clinics should be staffed by intensivists or general practitioners.

Nonetheless, a well-designed care model similar to disease management programs for diabetes, heart failure, and COPD, will facilitate the transition of patients and their families to the outpatient setting, allow for early recognition of post-ICU complications and sequelae, increase access to a variety of health care providers, and improve HRQoL. Likewise, principles of longitudinal care models developed from acute stroke care, cardiac rehabilitation, and post-traumatic brain injury may be applied to survivors of critical illness.

CONCLUSIONS

Recent data shows that PCIS is common and involves the physical, cognitive, and mental health status in survivors of critical illness. These impairments are frequently under recognized and adversely impact the daily functioning and overall QOL. It is critical that interventions to prevent the sequelae of acute critical illness begin during the ICU stay and involve not only the ICU staff but those involved in the care of the patient after the acute care hospitalization.

Outcomes Research and Reporting

Angela K. M. Lipshutz, MD, MPH and
Michael A. Gropper, MD, PhD

KEY POINTS

- 1 Outcomes research evaluates the effects of medical care and the health care process on individual and societal health.
- 2 Outcomes research seeks to understand the effectiveness of an intervention rather than its efficacy. It is this focus, not the methodology employed, that differentiates outcomes research from traditional clinical research.
- 3 Commonly used outcome measures include mortality, health status, cost, and quality measures.
- 4 Although outcomes research is not defined by a specific methodology, outcomes researchers often utilize observational study designs and methods from the social sciences. The use of large administrative datasets is increasingly popular.
- 5 The major limitations of observational studies are bias and confounding.
- 6 Matching, stratification, multivariate analysis, propensity scores, and instrumental variables are tools used to adjust for confounding.
- 7 Outcomes researchers in the intensive care unit face unique challenges due to the breadth of patients, diseases, therapies, providers, and health care delivery models used in critical care.

INTRODUCTION

Since the Institute of Medicine (IOM) published its first report in the quality series, *To Err is Human*, in 1999, there has been increased awareness of the problems that face health care in the United States and an increased emphasis on improving the quality of care our patients receive.¹ Outcomes research, which “studies the end results of medical care—the effect of the health care process on the health and well-being of patients and populations,”² is one type of research used to study, understand, and improve health care quality. Outcomes research differs from more traditional medical research in its focus and endpoints; it seeks to understand the effectiveness of

an intervention rather than its efficacy. Ultimately, the results of outcomes research can be used to benchmark performance, reduce adverse events, formulate clinical practice guidelines, and inform health policy decisions.^{3,4}

In the critical care setting, outcomes research can be particularly impactful for several reasons. First, ICU patients are at a high risk of death and preventable harms due to the acuity of their illnesses and the frequency and complexity of interventions.⁵ Additionally, the costs of ICU care are substantial. ICU patients inhabit only 10% of inpatient beds, but account for almost a quarter of acute care hospital costs.^{6,7} In 2005, critical care costs in the United States

totaled \$81.7 billion per year—4.1% of national health expenditures and 0.66% of the gross national product.⁸ Furthermore, resource utilization varies significantly, but an association between increased expenditure and quality of care has not been clearly elucidated.⁹⁻¹² Therefore, outcomes research in critical care has the potential to make ICU care better, safer, and more cost-effective.

This chapter describes the historical and theoretical basis for outcomes research, methods used by outcomes researchers, endpoints of outcomes research, and common challenges and limitations.

HISTORY AND THEORY

Florence Nightingale and Ernst Codman are often cited as the earliest outcomes researchers—Nightingale for her work studying combat deaths during the Crimean War, and Codman, an early 20th century surgeon at the Massachusetts General Hospital, for advocating hospital reporting of patient outcomes after noting that hospitals routinely reported the number of patients treated, but not the effects of the treatment.¹³⁻¹⁵ However, no framework for outcomes research existed until 1966, when Avedis Donabedian put forth a model for evaluating health services and the quality of medical care.¹⁶ The Donabedian model suggests three dimensions for assessing health care quality: structure, process, and outcome ([Figure 87-1](#)). Structure refers to the characteristics of the setting or environment in which care is delivered, while process focuses on whether appropriate medical practices are utilized. Outcomes range from mortality and length of stay to functional status and quality of life. Although Donabedian recognized the inherent limitations of outcome measures (see the “Limitations” section), he believed that outcomes “remain the ultimate validators of the effectiveness and quality of medical care.”¹⁶

In 1989, the United States Congress acknowledged the importance of outcomes research when it created the Agency for Health Care Policy and Research [later the Agency for Healthcare Research and Quality (AHRQ)] “for the purpose of enhancing the quality, appropriateness, and effectiveness of health care services and access to care.”¹⁷ The Patient-Centered Outcomes Research Institute (PCORI) was established in 2010 as a part of the Patient Protection and Affordable Care Act, further solidifying outcomes research in the American lexicon.

THE FOCUS OF OUTCOMES RESEARCH

Outcomes Research Versus Traditional Clinical Research

Outcomes research “focuses on the effects of medical care on individuals and society.”⁴ It is this research focus, not necessarily the methodology, that distinguishes outcomes research from traditional clinical research.^{4,13,18} [Table 87-1](#) describes the differences between outcomes research and traditional clinical research.⁴ Traditional clinical research is hypothesis-driven, and evaluates efficacy, asking whether an intervention works in an idealized setting. Outcomes research is concerned with effectiveness: Does the intervention help an individual patient in a real-world setting?¹⁹ Additionally, outcomes research is patient-centered, rather than disease-centered, and focuses on “what one ultimately wants health care to achieve,”²⁰ for example, improvements in functional status or quality of life. Furthermore, outcomes research tends to be more inclusive in what it considers an intervention. Traditional clinical research often involves the evaluation of new drugs or devices, while the interventions in outcomes research can range from a new drug to

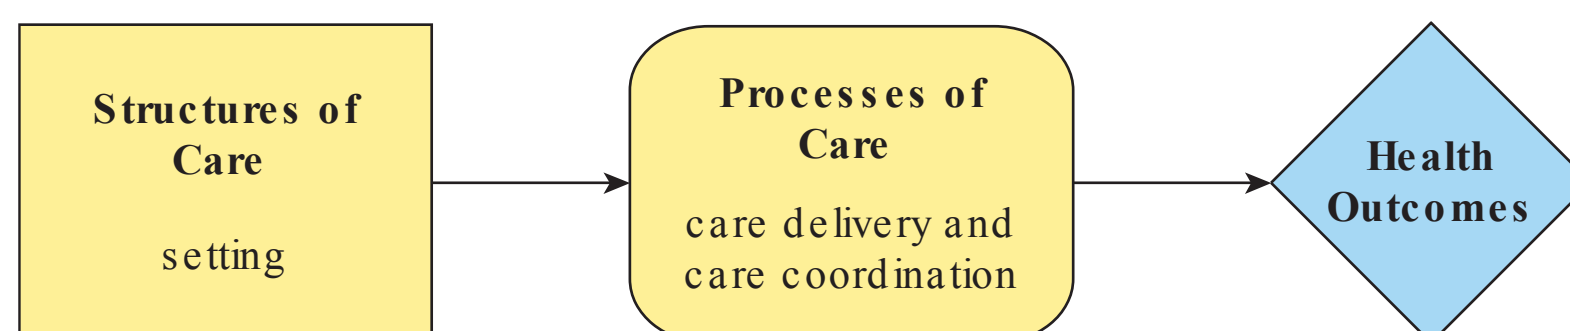

FIGURE 87-1 Donabedian's quality framework. (Reproduced with permission from McDonald KM, Sundaram V, Bravata DM, et al: Closing the Quality Gap: A Critical Analysis of Quality Improvement Strategies (Vol. 7: Care Coordination). 2007 June.)

a new structure for health care delivery. In order to achieve its goals, outcomes research tends to utilize observational study designs and draw methods from the social sciences more frequently than traditional clinical research (see the “Methods” section).

Commonly Used Outcome Measures

Mortality

Mortality is perhaps the most tangible and meaningful endpoint. It is easy to define and almost uniformly recorded. It sounds relatively simple: Did the patient survive the acute illness or insult? However, using mortality as an endpoint is actually not so straightforward. One must first determine the appropriate time at which to assess mortality: ICU or hospital discharge? 30, 60, or 90 days? Years? Selecting a timeframe that is too short may provide an inaccurate assessment of

the impact of an intervention if the natural history of the condition being studied is longer than the study period. A specific intervention might reduce 30-day mortality, but increase 90-day mortality. Conversely, long-term outcomes may reflect the patient’s disease prognosis, age, premorbid conditions,²¹ and preexisting functional status^{22,23} more than the ICU care they received. Therefore, the appropriate mortality endpoint depends on the specific research question, the study design, and the mechanisms of the disease or treatment being studied.⁴

Even when an appropriate mortality endpoint is chosen, outcomes can be artificially affected by patient choice, as well as ICU and hospital practice patterns. For instance, a patient’s decision to transition to comfort care may hasten death; the availability of palliative care suites for transfer of ICU patients receiving comfort measures only alters ICU mortality; and the availability of long-term care facilities for transfer of ventilator-dependent patients could alter hospital mortality. Additionally, comparing mortality rates across different hospitals and ICUs is fraught with problems, largely due to difficulty in adjusting for differences in case-mix.²⁴ Using mortality as an endpoint may not be feasible if the mortality of the condition being studied is relatively low, as the sample size required to generate adequate power to detect a clinically relevant difference will be quite large. And, of course, the use of mortality as an endpoint does not consider morbidities or the quality of life of the survivor.

Health Status

Health status encompasses several measures of patient-assessed outcomes, including functional status and quality of life. Health status is an important endpoint for critical care outcomes research, as recent data has shown that the long-term consequences of critical illness on physical functional status, cognitive function, and quality of life can be profound.²⁵⁻²⁸

Measurement of health status is not standardized, and relies on patient interviews and questionnaires. Physical functional status can be assessed using the 6-minute-walk test, Medical Outcomes Study Short-Form 36 (SF-36),^{25,26} the Karnofsky Performance Status Scale score, the Barthel Index, and the Lawton-Instrumental Activities of Daily Living score.^{29,30} Tools to assess mental health status,

focusing on symptoms of depression, anxiety, and post-traumatic stress disorder, include the Center for Epidemiologic Studies–Depression Scale,³¹ the Hospital Anxiety and Depression Scale,³² and the Impact of Events Scale-Revised.³³ The Informant Questionnaire on Cognitive Decline in the Elderly, the Trail Making Test, and the Repeatable Battery for the Assessment of Neuropsychological Status have been used to determine cognitive function.^{27,28,34} Quality of life can be determined from the results of these various tests, or can be assessed specifically via tools such as the EuroQol-5D³⁰ or SF-36.³⁵ Quality of life data can then be used to calculate quality-adjusted life years (QALYs), which take into account both mortality and quality of life.³⁵

Of note, completion of these instruments by ICU survivors themselves is not always possible, and the use of surrogates to complete them may not be as useful. Additionally, interpretation of these tests requires knowledge of the patient's baseline prior to ICU admission, which may also require a surrogate for determination, and is subject to recall bias. Nonetheless, data is mounting that ICU patients continue to suffer long after their discharge from the hospital: Depression and anxiety may be present in nearly half of ICU survivors,³⁶ and post-traumatic stress disorder in one-third.^{32,33} Decline in cognitive function is common and can persist for up to eight years.²⁷ And physical disability is nearly ubiquitous; in one study, 100% of patients reported experiencing subjective weakness and decreased exercise capacity and almost a quarter of patients were unable to return to work at 5 years after discharge from the ICU.²⁵ Thus, continued work on targeting improvement in health status for ICU survivors is paramount.

Cost

Economic evaluation is “the comparative analysis of alternative health care interventions in their relative costs (resource use) and effectiveness (health effects).”³⁷ With the aging of the US population, and the availability of new and more expensive treatments, the cost of critical care is increasing.^{38,39} As mentioned earlier, ICU care is disproportionately expensive,^{6,7} costing over \$80 billion per year in the United States alone.⁸ Therefore, identifying cost-effective interventions in the ICU is incredibly important. Cost-effectiveness analyses (CEAs)

produce a ratio in which the numerator is the cost of the intervention, and the denominator is the benefit in terms of the clinical outcome.⁴⁰ The clinical outcome is often reported in terms of QALYs, such that the ratio produced is cost per QALY.

Given the increasing importance of CEAs, and the increasing frequency with which they are performed, both the US Public Health Service and the American Thoracic Society convened panels to address methodological issues and provide recommendations for the reporting of CEAs.^{40,41} Their recommendations include describing the model used; identifying model assumptions; describing how estimates of effectiveness, costs, and health states were obtained; and defining the type of costs, year of costs, inflation adjustment methods, and discount rates used. Even when following these recommendations, critical care outcomes researchers face additional challenges that make CEAs more challenging in the ICU setting. These include the complexity of ICU patients, the lack of data on effectiveness of interventions in the ICU, the unavailability of cost data, and the infrequent collection of ideal outcomes measures for CEAs (eg, long-term quality-adjusted survival rates).⁴⁰ The challenge of obtaining accurate cost data can make CEAs difficult to interpret and compare, and limits the generalizability of the results. Charge data (ie, what the patient is billed) are often substituted for cost; however, even when adjusted with cost-per-charge ratios, these data are department and institution specific, and may not reflect actual costs.^{37,42} Therefore, interpretation of CEAs must be undertaken with great caution.

Quality Measures

A common focus of outcomes research is quality improvement. Outcome measures for quality improvement research must be “granular enough to be meaningful to clinicians [and to] adequately drive quality improvement interventions.”³ Since preventability is one of the central tenets of quality improvement, outcome measures must also be viewed as preventable.

A recent study by Martinez et al. utilized a consensus process to identify meaningful outcomes measures for quality improvement in the ICU.³ In the study, 164 ICU providers identified five preventable outcomes: pressure ulcers, central line-associated

bloodstream infection, pulmonary embolism, methicillin-resistant *Staphylococcus aureus* infection, and gastrointestinal bleed. Indeed, data support the preventability of these outcomes. For instance, in a landmark study by Pronovost et al., central-line associated bloodstream infections were eradicated in the state of Michigan.⁴³ However, prior to this study, central-line associated bloodstream infections were not uniformly considered preventable. Therefore, although the development and use of outcomes measures for quality improvement must rely on existing data suggesting preventability, clinicians and researchers must also be creative and innovative, continuing to question our current knowledge base of what is preventable.

Methods

Although the focus of outcomes research differs from that of traditional scientific research, the methods used need not. Outcomes research can take the form of case-control studies, cohort studies, and even randomized controlled trials (RCTs). However, outcomes researchers tend to utilize observational study designs and draw methods from the social sciences more frequently than traditional clinical researchers. The use of large administrative datasets is a growing trend in outcomes research. Additionally, outcomes researchers use qualitative methods to generate hypotheses and describe complex phenomena that do not lend themselves to quantitative methods or traditional hypothesis testing.⁴

Observational Studies

Observational studies can be prospective or retrospective, and include cohort studies, case-control studies, and cross-sectional studies.⁴⁴ Such studies seek to identify associations between an exposure (eg, a medication, intervention, or organization of health care delivery) and outcomes, and can utilize primary or secondary data. Primary data are collected to answer a specific research question, while secondary data are data that already exist but are reemployed to answer a novel research question.⁴⁵

Administrative data are a type of secondary data that were originally collected for reasons other than research. Administrative data include health care encounter data, enrollment data, clinical data, data registries, performance data, survey data, and

national data.⁴ Examples of data sources utilized in critical care outcomes research include Medicare, the University HealthSystem Consortium, the National Inpatient Sample, and the National Hospital Discharge Database.⁴⁶ There are several benefits to using administrative data for outcomes research. First, administrative data may provide answers to research questions that ethically, legally, or practically cannot be answered by RCTs. Second, large registries and administrative data may be broader in scope and thus more generalizable than primary data. Furthermore, large datasets can more efficiently answer questions associated with rare diseases or outcomes. Finally, policymakers may be more interested in outcomes assessed via administrative data. In fact, policy concerns regarding Medicare spending, racial disparities, and unexplained geographic variation in health care are fueled by the results of analysis of administrative data.⁴⁶

However, the use of administrative data is not without its drawbacks. As with all observational studies, studies using administrative data are subject to bias and confounding. Confounding is of particular concern since patients are not randomly assigned to the exposure of interest; thus, any association between the exposure and outcome could be due to a third, unmeasured variable (see the “Limitations” section). However, the primary concern specific to administrative data is data quality. Unlike traditional clinical research, in which the study design is completed before data collection begins, with administrative data, the quality of the data must be assessed before designing the study (but, of course, after the research question is defined).⁴⁵ The Directory of Clinical Databases in the United Kingdom recently developed a framework for assessing the quality of administrative data.⁴⁷ The framework focuses on data coverage and data accuracy (Table 87–2). Coverage is determined by the representativeness of the data, the completeness of recruitment, the variables included, and the extent of missing variables, while accuracy is determined by the collection of raw data, the definitions and rules utilized, the reliability of coding, the independence of observations, and the method of data validation.⁴⁶

Once the quality of the data has been assessed, the process of research can continue (Figure 87–2). Several aspects of this process are unique to secondary data analyses, and deserve mentioning. First, the

TABLE 87–2 Quality domains important in assessing the quality of administrative data.

Quality Domain	Explanation
Coverage	
Representativeness	How well does the data source represent the population that it intends to?
Completeness of recruitment	This feature measures the extent to which all eligible individuals have been included in the data collection scheme
Variables included	What is the extent of the data collected on each individual? Are demographic, exposure, outcome, and confounding variables present?
Completeness of variables	What is the extent of the missing data?
Accuracy	
Collection of raw data	Is the raw data collected are aggregate averages collected?
Explicit definitions	Are the variables explicitly defined?
Explicit rules	Are there explicit rules for deciding how variables are recorded? For example, the timing of physiologic variables
Reliability of coding	Was the reliability of coded conditions and interventions tested?
Independence of observations	Was the data recorder blinded to patient outcome at the time the data were collected?
Data validation	Were data validated using outside sources? Were there consistency checks?

analysis plan must be developed a priori in order to maintain the validity of the study. Since secondary data, by definition, already exists, it can be tempting to perform preliminary analyses before finalizing an analysis plan; this temptation should be avoided as it can bias the results. Similarly, “data-dredging” via post-hoc analyses may result in the identification of erroneous, or at least meaningless, associations, since exploring any 20 associations will, on average, produce one result that is statistically significant to $P < 0.05$.⁴⁵ Thus, the number of statistical tests performed should be minimized. In addition, adjustment for bias and confounding must be performed. However, it is important to remember that even the most sophisticated statistics cannot compensate for poor data quality.

Qualitative Research

Qualitative methods are increasingly being used in outcomes research. Qualitative research uses methods such as interviews, focus groups, field observations, and document review (eg, diaries) in order to “understand complex social processes, organizational change, individual health behaviors, and

nuanced aspects of environmental context that influence quality of care, health care delivery, and health outcomes for individuals and populations.”⁴⁸ Qualitative research differs from quantitative research in that it describes the breadth and complexity of a phenomenon rather than measuring occurrences to determine frequency, incidence, prevalence, or magnitude.⁴⁹ Given the complexity and nuanced aspects of critical care, qualitative research can be particularly useful in this setting.

Qualitative methods should be considered when: (1) the phenomena of interest are difficult to measure quantitatively, (2) a comprehensive understanding of a problem is desired, (3) the goal is to generate insight as to why an intervention has a specific impact, and (4) special populations are being studied.⁴⁹ Once collected, qualitative data can be coded and analyzed. Analysis focuses on identifying taxonomies and themes that can explain and predict outcomes.⁵⁰ Although qualitative methods alone can provide interesting and rich data, mixed methods—which combine quantitative and qualitative methods—are even more impactful as they benefit from the strengths of each approach.⁴⁹

Randomized Controlled Trials

RCTs are traditionally designed as efficacy studies—assessing the impact of an intervention in an ideal setting—and are thus most commonly used in conventional clinical research. RCTs can also be utilized in outcomes research if the study design focuses on effectiveness—the implications of an intervention or exposure in a “real-world” setting. Unlike observational studies, RCTs do not have the problem of confounding since, by definition, the exposure is

allocated randomly. The lack of confounding makes it easier to conclude causality. However, the use of RCTs in outcomes research is relatively rare for several reasons. First, RCTs are expensive and time-consuming. Second, it may not be legal or ethical to randomize patients to certain exposures or interventions. And, finally, some exposures (eg, socioeconomic status or insurance status) may be impossible to randomize.⁴ Nonetheless, RCTs remain the “gold standard,” and should be considered by outcomes researchers when feasible. Recently, two RCTs of early mobilization in the ICU, designed as effectiveness studies, showed improved functional status for patients who received physical therapy during their critical illness.^{51,52}

LIMITATIONS

As with all scientific research, critical care outcomes research faces its own set of challenges and limitations. Some of these limitations are methodological—for instance, due to issues with bias and confounding—and are common to outcomes research across all fields of medicine, while some limitations are unique to critical care medicine.

Methodological

The methodological challenges inherent to outcomes research are, obviously, specific to the study design being employed. Herein, we will consider the limitations of observational studies, since a large portion of outcomes researchers rely on observational methods.

The primary methodological limitations of observational studies are bias and confounding. Bias is a systematic error in the design or conduct of a study. There are several different types of bias that can obscure the results of observational studies. Selection bias exists when the patients in one group are somehow fundamentally different from the patients in the other group. Observational bias exists when there are systematic differences in the way in which the data was obtained. Recall and recording bias are types of observational bias. Recall bias frequently comes into play in studies evaluating ICU patient and family experiences, since the patient’s ultimate outcome may affect how they remember their course of care. Recording bias is especially important when using administrative data, since

data collected for coding and billing may be affected by efforts to increase reimbursement.⁴⁵

A confounding variable is an extraneous variable that is correlated with the independent variable being studied; confounding exists when the exposed and unexposed groups being studied differ in some way that is also related to the outcome. Randomized controlled trials obviate the concern for confounding since randomizing attempts to ensure the exposed and unexposed groups are similar. However, observational studies are subject to confounding, and when confounding occurs, the effect of the exposure on the outcome will be distorted.⁴⁵ Severity of illness is a common confounder in critical care outcomes research. For instance, consider a comparison of two groups of ICU patients with respiratory failure, where one group received a new mode of mechanical ventilation and the primary outcome measure was ventilator-free days. If the group receiving the intervention was younger and had a significantly higher PaO₂-to-FiO₂ ratio at admission, they may have more ventilator-free days simply because they were less sick.

Unlike bias, which is a systematic error and cannot be fixed, there are five commonly used ways

to control for confounding (Table 87–3).^{4,53} Matching attempts to identify confounding variables and matches the exposed and unexposed groups based on these variables. Although this technique is relatively simple, the number of confounding variables upon which groups can be matched is limited since an exact match may not be present, and the analysis is limited since matching variables cannot be evaluated as exposure variables. Additionally, overmatching, which occurs when matching for a variable that is not actually a confounder, can decrease the power of the study. Similar to matching, stratification involves the identification of confounding variables and creation of subclasses based on them. Age is a variable that is commonly stratified, for instance 18 to 65 years old and greater than 65 years old. However, stratification becomes unwieldy when attempting to account for multiple confounders as the number of subgroups increases exponentially.

Multivariable adjustment is perhaps the most commonly used method to adjust for confounding. In multivariable adjustment, the researcher creates a model that includes the exposure and outcome of interest, as well as the confounding variables.

TABLE 87–3 Techniques used to adjust for confounding in observational outcomes research.

Technique	Strengths	Weaknesses
Matching	Simple Balances confounding factors	Difficulty finding matches Possibility of overmatching Requires strong understanding of confounders involved Inability to examine effect of confounders used for matching
Stratification	Simple Ability to see effect modification	Difficult to interpret with many subgroups Requires strong understanding of confounders involved
Multivariable adjustment	Can include many confounders Can examine effects of individual confounders Ability to examine multilevel effects	More complicated analysis Potentially poor fit of model Possibility of missing effect modification
Propensity scores	Single number generated for simpler matching Ability to assess for bias between groups	Potentially matching very different patients with similar scores
Instrumental variables	Only single variable needed Ability to look at questions where other types of adjustment can not be easily accomplished	Difficult to ensure variable is not at all associated with the outcome

Reproduced with permission from Wunsch H, Linde-Zwirble WT, Angus DC: Methods to adjust for bias and confounding in critical care health services research involving observational data, J Crit Care 2006 Mar;21(1):1-7.

The model used depends on the outcome being studied—logistic regression is used when the outcome is binary, linear regression when the outcome is linear, and proportional hazards when the outcome is time to an event. These techniques hold the confounding variables constant while assessing the relationship between the exposure and the outcome. Severity of illness scores, such as the Acute Physiology and Chronic Health Evaluation Score (APACHE),⁵⁴ Simplified Acute Physiology Score (SAPS),⁵⁵ or Mortality Prediction Model Score (MPM),⁵⁶ is commonly included in multivariate analyses in an attempt to account for how sick patients are on admission to the ICU. These scoring systems take into account a large number of variables and provide a single number. However, one must remember that such scores may not capture all pre-existing comorbidities nor pre-existing frailty, which may have a large impact on the patient's clinical trajectory.⁵⁷ Furthermore, multivariate models are not without their pitfalls. Careful attention to which variables are included in the final model, and rigorous testing of model fit are required to avoid erroneous conclusions.

Propensity scores and instrumental variables are two more sophisticated methods of adjusting for confounding. Like severity of illness scores, propensity scores combine multiple variables to create a single value. This value represents a patient's probability of being exposed to the variable of interest.⁵⁸ Patients can then be matched or stratified based on their propensity score, or the propensity score can be included in the multivariate model. The use of propensity scores is increasingly common as they are a powerful tool to decrease the effects of confounding. Instrumental variables, like propensity scores, are associated with the exposure, but are selected because they are independent of outcomes. If an outcome is then analyzed by the instrumental variable, a random distribution of patients is created, which simulates randomization to the exposure. Although enticing, the use of instrumental variables is relatively uncommon, largely because it is difficult to identify variables that do not correlate with the outcome being studied.

Unique to Critical Care

In addition to the methodological limitations associated with observational outcomes research

discussed above, ICU outcomes researchers face a unique set of challenges, largely due to the breadth of patients, diseases, therapies, providers, and health care delivery models associated with critical care medicine. Performing research requires identifying a specific question and defining the disease, treatment, patient population, or provider to study. Defining such variables in the ICU can be complex.⁴ Disease states, such as sepsis or respiratory failure, may be exceedingly broad and lack exact diagnostic criteria or accepted treatment. The patient population is highly variable, including medical, surgical, cardiac, and neurological patients. And the physicians caring for patients range from pulmonologists and cardiologists to anesthesiologists, surgeons, and surgical subspecialists. Therefore, “critical care” does not have an explicit definition in the literature. Although critical care is often defined geographically as patients cared for in an ICU, this is increasingly problematic as the chronically critically ill may be cared for outside the ICU, and some patients in the ICU may not actually be in critical condition.⁴

Furthermore, as mentioned above, critically ill patients may not be able to consent to or participate fully in research due to the severity of their illness, administration of sedative medications, or use of interventions such as mechanical ventilation that decrease their ability to communicate.

CONCLUSION

Outcomes research studies the end result of medical care on patients and society. Outcomes research in critical care is particularly important due to the severity of illness of ICU patients and complexity of the care they receive, as well as the overwhelming cost of ICU care. Critical care outcomes researchers often utilize observational study designs influenced by the social sciences, and focus on patient-centered outcomes such as mortality, functional status, and quality of life. The limitations of observational study designs can be addressed by several statistical methods. Continued emphasis on critical care outcomes research is of paramount importance as we attempt to understand and improve the long-term outcomes of survivors of critical illness.

Critical Care Medicine in the Era of Omics

Samantha Strickler, DO and
John M. Oropello, MD, FACP, FCCP, FCCM

CHAPTER

88

KEY POINTS

- 1 Researchers and physicians are now examining human health and disease in the context of the human genome, epigenome, transcriptome, proteome, and microbiome.
- 2 In critical illness, disease processes are multifaceted, involving numerous interactions between genes and gene products rather than a single locus.
- 3 Network medicine focuses on integrating various omic disciplines to create networks that explain healthy and diseased states.
- 4 Network model analysis of ARDS has revealed redundancy in protein connectivity, with several proteins involved in multiple pathways.
- 5 More basic research needs to be completed, followed by integration of genomic, epigenomic, transcriptomic, proteomic, microbiomic, and other omic data to create more network models of critical illness.

But nature did not deem it her business to make the discovery of her laws easy for us.

-Albert Einstein (1911)

Within the human body there exists an incredible complexity, making the practice of medicine extremely challenging. No two individuals manifest illness identically. In critical care medicine, where illness strains human physiology to the brink of collapse, this becomes even more apparent. With critical illness accounting for nearly 39% of total hospital costs, now more than ever there is a demand to understand the multifaceted pathology that contributes to individual critical illness.¹

For centuries, illness has been studied on a macrolevel with gross anatomy being the epicenter of medicine. However, with the completion of the Human Genome Project (2003), a new paradigm of medicine that focuses on molecular interactions is evolving. Researchers and physicians are now examining human health and disease in the context of the human genome, epigenome, transcriptome, proteome, and microbiome.²⁻⁶ Furthermore, these “omes” are being integrated to create new network models of physiology and pathology ([Figure 88–1](#)).

Since the inception of the omic era, multiple disease states have been examined including Alzheimer’s disease, cancer, and obesity. However, the

FIGURE 88–1 A new paradigm of medicine is developing, which examines illness through the interactions of the human genome, epigenome, transcriptome, proteome, microbiome, and other developing omes.

application of omics and network medicine to critical illness remains vastly unexplored. The intensive care unit is an uncharted frontier. As omics continues to rapidly expand, the molecular derangements of critical illness will become increasingly apparent. Such insight will evolve the practice of critical care medicine—allowing intensivists to augment their understanding of disease, and to more efficiently diagnose and treat the individual with critical illness. (See the “Glossary and Abbreviations” section for key terms.)

FROM MENDEL TO THE HUMAN GENOME PROJECT

For ages mankind has been fascinated by human variability ([Table 88–1](#)). Scientists have extensively hypothesized about the origins and variability of man. One of the earliest recognized publications addressing this query came from Dr. William Harvey, an English physician.⁷ In 1651 he published, *De Generatione Animalium*, which examined the egg and early embryo in different species. In this doctrine, he pronounced, “ex ovo aminum—all things from the egg.” His publication was the first to denounce the

concept of spontaneous generation and propose the theory of epigenesis.

Nearly 200 years later, Austrian monk Gregor Mendel expounded further upon the origins of variability.⁸ In 1865, Mendel published his well-popularized findings examining flower color and texture of the seed of the garden pea. Through his cross breeding of plants he defined the theory of inheritance, demonstrating that each parent contributes an allele to the offspring for a certain characteristic forming a pair. These pairs further segregate independently of one another.

In the mid-1800s researchers further localized hereditary information to a cellular level. In 1869, Swiss physician and researcher, Friedrich Miescher, isolated nuclein (DNA) from leukocytes collected from soiled bandages from a nearby hospital.⁹ In 1882, Walter Flemming, a German physician and professor of anatomy, published the first images of chromosomes in tumor cells ([Figure 88–2](#)). Many decades later in 1944, researchers Oswald Avery, Colin MacLeod, and Maclyn McCarty demonstrated that the elemental blocks of inheritance were contained within DNA through experiments with *Streptococcus pneumoniae*.

2010	<ul style="list-style-type: none">Human Proteome Project is created

Following the Avery, MacLeod, and McCarty findings, interest rapidly grew in the scientific community to characterize DNA further. Utilizing x-ray crystallography, English chemist, Rosalind Franklin, and English physicist, Maurice Wilkins, first described the structure of DNA in 1953.⁷ Together they revealed a repeating helical structure. In the same year, researchers James Watson and Walter Crick published on the structure of DNA (Figure 88–3).¹⁰ They first described DNA as a right-handed double helix, with base pairing of cytosine with guanine and thymine with adenine.

In the next 30 years, interest in deciphering the DNA sequences of various organisms, including

Homo sapiens, quickly expanded. In 1989, international efforts collaborated to form the Human Genome Organization (HUGO), which sought to map the entire human genome. At that time, it was estimated that such a project would cost 200 million dollars per year and take 15 years to complete. In 1989, the National Institutes of Health (NIH) also established the National Human Genome Research Institute to participate in the international Human Genome Project (1989). James Watson led the efforts, which were funded by both the NIH and the Department of Energy.

Simultaneously, simpler organisms were being sequenced. In 1996, yeast, *Saccharomyces cerevisiae*,

FIGURE 88–2 First illustration of human chromosomes from tumor cells in 1882. (Reproduced with permission from Rimoin D, Korf RP: *Emery and Rimoin's Principles and Practice of Medical Genetics*, 6th edition. Oxford: Academic Press; 2013.)

was the first eukaryote deciphered. The roundworm, *Caenorhabditis elegans*, followed in 1989 and was found to contain 19,000 genes.¹¹ By 2000, the genome of the fruit fly, *Drosophila melanogaster*, was sequenced and noted to have 14,000 genes.¹² The mustard plant, *Arabidopsis thaliana*, was sequenced in the same year and contained 26,000 genes.¹³ Comparing the genomes of these different organisms began to reveal remarkable insight into the functionality and complexity of DNA.

After much anticipation, the first draft of the Human Genome Project (HGP) was announced ahead of schedule in 2000, and made publically available in 2001.¹⁴ Surprisingly, the number of protein coding genes identified was much less than anticipated. Due to the complexity and variation displayed in humans, it was predicted that 100,000 protein-coding genes would be identified. However, only approximately 30,000 protein-coding genes were derived in the first publication of the human genome. A second draft completed in 2003 further delineated the number of protein coding genes. Finally, in 2004 the International Human Genome Sequencing Consortium performed an additional revision of the human genome, further refining

FIGURE 88–3 DNA structure as published by Watson and Crick. (Reproduced with permission from Watson JD, Crick FH: *Molecular structure of nucleic acids; a structure for deoxyribose nucleic acid*, *Nature* 1953 Apr 25;171(4356):737-738.)

the number of protein coding genes in the range of 20,000 to 25,000. After this revision, the Human Genome Project was deemed complete.¹⁵

AFTER THE HUMAN GENOME PROJECT: AN ERA OF OMICS

Through the Human Genome Project, a newfound wealth of knowledge was revealed, a blue print for human variability. However, researchers quickly realized that the human genome was a very basic structure, and the protein coding genes could not completely explain the vast differences seen among humans.

Researchers consequently began to search for other parameters that contributed to human variability. In addition to examining the protein-coding regions of DNA, researchers began to analyze the structure, function, and products of the entire human genome. Multiple disciplines quickly developed and flourished, ushering in a new phase of discovery—the era of omics.

Following the completion of the Human Genome Project interest reignited in the already established discipline of epigenetics. Originally termed by British researcher, Conrad Waddington in the early-1940s, epigenetics describes the mechanisms through which undifferentiated cells develop into differentiated cell types such as myocytes, neurons, adipocytes, etc.^{16,17} It is now well established that DNA undergoes reversible, non-encoded modifications, which ultimately influence phenotype.¹⁸ Multiple factors, including developmental stage, age, and environment have

been linked to epigenetic changes. Research has also revealed that these modifications can be maintained and propagated to daughter cells.

Within the past two decades, efforts have focused on examining the epigenomes (epigenetic changes) of the nearly 200 cell types contained within the human body. Researchers have identified several epigenetic modifications affecting transcription, including DNA methylation, histone modification, nucleosome/chromatin packaging, and RNA transcripts (Figure 88–4).¹⁹ DNA methylation describes the addition of a methyl group to cytosine, creating 5-methylcytosine (5 MeC).²⁰ Less commonly, cytosine can also undergo hydroxymethylation. Numerous studies have demonstrated that hyper-methylation represses transcription at promoter regions.²¹ Histones, which are the scaffolding proteins that support DNA packaging, similarly

FIGURE 88–4 Epigenetic modifications. Methyl groups bind to both DNA and histones, altering their structure (methylation). Histones also undergo acetylation, phosphorylation, and ubiquitination, which influences coiling of DNA around histones. These modifications consequently influence gene transcription. (Reproduced with permission from National Human Genome Research Institute.)

undergo methylation, as well as acetylation, phosphorylation, and ubiquitination. These changes alter the structure of the histone tail, which restricts or facilitates the transcription machinery’s access to nucleotides. Nucleosome positioning within the chromatin has also been demonstrated to influence transcription. Akin to histones, the packaging of the nucleosomes exposes certain areas of DNA, which influences binding of transcription factors such as enhancers, silencers, and insulators.

With renewed interest in epigenetics, The National Human Genome Research Institute established two large-scale research projects to examine the human epigenome. In 2003, the ENCyclopedia of DNA Elements (ENCODE) Project was created, with the objective of identifying all functional elements: RNA-transcribed regions, protein-coding regions, transcription-factor-binding sites, chromatin structure, and DNA methylation.^{22,23} At its inception, 35 international research groups examined 30 million bases of human DNA, equivalent to about 1% of the genome. In the second phase of the project, researchers analyzed 1640 genome wide data sets, from 147 cell types.

Through the ENCODE project an intricate regulatory system was revealed.^{24,25} Among the notable findings was pervasive transcription, meaning that the majority of the genome was transcribed. Areas outside of the protein coding regions that were previously thought to be silent were found to undergo transcription. Researchers further revealed that the majority of the human genome (80.4%) participated in a biochemical function. Much of which was thought to be inert DNA, was found to contain regulators of expression, including RNA elements and transcription factor binding sites. Analysis further demonstrated regulatory elements acting both locally (cis) and distally (trans).

In 2008, the National Human Genome Research Institute initiated the Roadmap Epigenomics Program (REP) to more thoroughly characterize the human epigenome (Figure 88–5).²⁶ Specifically, the project sought to examine the temporal changes of the epigenome from stem cells to mature cells in human tissues. The project further aimed to examine the epigenetic changes associated with diseased states. In 2015, the REP published its preliminary integrative analysis of 127 reference human epigenomes.²⁷

FIGURE 88–5 Tissue and cell types utilized to examine the human epigenome in the Roadmap Epigenome Project. (Reproduced with permission from Roadmap Epigenomics Consortium, Kundaje A, Meuleman W, et al: Integrative analysis of 111 reference human epigenomes, Nature 2015 Feb 19;518(7539):317-330.)

REP analysis revealed several epigenetic modifications including histone marks, DNA methylation, DNA accessibility, and RNA expression. As confirmed by previous studies, REP demonstrated that low DNA methylation states were associated with high accessibility for transcription, whereas hypermethylated states were associated with low accessibility. Notably, on average 68% of the reference epigenome was found to be quiescent. Further analysis revealed that embryonic-stem-cell-derived cells and pluripotent cells of en exhibited methylation near regulatory elements,

whereas differentiated cells exhibited methylation loss. Finally, the REP demonstrated specific epigenetic modifications that are associated with diseased states, including enrichment of enhancers, promoters, and open chromatin.

Following the Human Genome Project, international efforts further collaborated to catalog human genomes of various populations, forming the International HapMap Project (2002–2007). This project sought to identify and catalog human genomes to assist with linking genetic variants to disease states.^{28,29} To accomplish this objective the project mapped single nucleotide polymorphisms (SNPs) of 1184 individuals across 11 populations. Similar to fingerprints, representative SNPs (tag SNPs) were recognized as unique identifiers, allowing for identification of areas linked to individual genes (Figure 88–6).

The database created by the HapMap project has subsequently been utilized to conduct genome wide association studies (GWAS) between healthy and diseased populations. GWAS have allowed researchers to grossly sift through entire genomes and identify allele variants associated with diseases. Thus far, GWAS have facilitated the isolation of genes associated with

cancer, diabetes, obesity, and dyslipidemia.^{30–32} Additional GWAS have examined autoimmune diseases such as Crohn disease, ulcerative colitis, and psoriasis. Despite their success, GWAS have demonstrated limitations. Tag SNPs do not precisely localize involved genes; they only serve as general landmarks. Furthermore, disease processes are multifaceted, involving numerous interactions between genes and gene products rather than a single locus.

To better understand human variability and the complexity of disease states, researchers have also examined the human transcriptome. In 2000, the National Human Genome Research Institute initiated the Mammalian Gene Collection (MGC). This project was tasked with creating a database containing at least one complementary DNA (cDNA) per gene for both human and mouse genomes.³³ The MGC later broadened its initial objective, further constructing rat and cow cDNA databases (completed 2009). The MGC and similar international consortiums anticipated that these databases would facilitate functional and comparative genomics. Specifically, transcript analysis would provide insight into the process of gene transcription, protein

FIGURE 88–6 SNPs, haplotypes, and corresponding tag SNPs. Within short segments of chromosomes, single nucleotide polymorphisms (SNPs) have been identified through sequencing. These variations can be utilized as unique identifiers. Within a series of SNPs, specifically designated polymorphisms known as tag SNPs, can be further utilized to serve as surrogate markers for a specific chromosome. (Reproduced with permission from International HapMap Consortium: The International HapMap Project, *Nature*. 2003 Dec 18;426(6968):789-796.)

expression, and the networks of communication occurring at the molecular level.

Within the human transcriptome, approximately 80,000 transcript products have been identified originating from the 20,000 to 25,000 protein coding genes.³⁴ The disproportionate relationship of genes to transcription products, spurred considerable research focusing on transcription initiation and termination.³⁵⁻³⁷ Researchers have since discovered that an individual gene may contain several transcription start sites (TSS), which can then produce various transcript products. Selection of a specific start site has been found to depend on multiple factors, including a cell's developmental phase, cell-cell signaling, and tissue type. Variation in transcription has also been linked to the terminal processing of transcripts through the addition of adenosine monophosphate moieties. This modification, referred to as polyadenylation, influences processing and nuclear transport of transcripts and has been linked to various developmental phases of the cell. After transcription occurs, transcription products undergo additional processing, where certain areas are spliced out to create various alternative spliced products.

Numerous studies have compared the human transcriptomes during healthy and diseased states.³⁸ Transcriptomes of neurodegenerative diseases (eg, Alzheimer's disease), malignancies (eg, breast, prostate cancer), and respiratory diseases (eg, asthma, COPD) are a few of the many disease states that have been analyzed.³⁹ Transcriptome analysis of brain tissue from patients with Alzheimer's disease has revealed alternative promoter regions and transcription start sites.⁴⁰ In various malignancies, transcript studies have also identified abnormal fusion transcripts and alternative splicing (Table 88-2). It is theorized that these alternate transcript products result in cellular dysfunction and disease. Although incredibly informative, transcriptomics has limitations. Specifically, transcript products may be extremely fragile and of such small concentrations that current technologies cannot characterize them. Furthermore, transcriptomics primarily identifies genomic metabolites and has limited capabilities to identify the functional properties of transcript products.

After the completion of the Human Genome Project, researchers also focused efforts towards

examining the protein products of the human genome. In 2009, the Human Proteome Organization (HUPO) announced an international effort to expand upon previous studies examining the human proteome in healthy and diseased states.⁴¹ In September 2010, HUPO officially initiated the Human Proteomic Project (HPP) to construct a comprehensive library of human proteins. The HPP was also tasked with examining protein expression, splice variants, post-translational modifications, and localization of proteins in cells, tissues, and organs. Furthermore, the project planned to analyze proteins during all developmental stages of adult life and under various physiologic and pathologic conditions. Nearly five years after the induction of the HPP, the first draft of the human proteome was published in 2014.⁴² Ongoing efforts continue internationally examining each chromosome to complete a more comprehensive human proteome database.

In the last two decades, research has extended beyond the human chromosome to examine the microorganisms that inhabit the human body, establishing the discipline of microbiomics. One of the first projects examining the human microbiome was the France Human Intestinal Metagenome Initiative (HIMI) established in 2005. The National Institutes of Health (NIH) soon thereafter followed, initiating the Human Microbiome Project (HMP) in 2007.⁴³ At its inception, the project's initial objective was to examine the microbiomes of the mouth, gastrointestinal tract (stool), skin, and vagina. These databases could then be utilized to identify dysfunction, develop treatments, and possibly prevent illnesses linked to dysbiosis. The HMP project also included an initiative to examine ethical, legal, and social implications associated with genomics. Approximately one-year after the establishment of the HMP, the International Human Microbiome Consortium formed in 2008 to further foster collaboration worldwide.

Microbiomes of multiple disease processes have since been analyzed.^{44,45} Most research to date has focused on the microbiomes of the gut and skin.⁴⁶ Numerous studies have repeatedly shown a strong association between diseased states and alterations in the gut microbiome.⁴⁷ For example, in obesity and the Crohn disease, there are associated changes

TABLE 88–2 Transcription derangements identified in cancers.

Cancer Type	Analysis Type	Results
Hodgkin lymphoma	PE WT	Identification of gene fusions, among which fusions CIITA-involving
Non-Hodgkin lymphoma	PEpoly-A ⁺	Detection of 109 genes with multiple somatic mutations, including those involved in histone modifications
MDS	FRsmall RNA	Discovery of novel miRNA dif erentially expressed in tumor
Breast cancer	FRpoly-A ⁺	Alternative splicing and alterations in gene expression (ie, LOX, AIP5L, GALNT3 and MME) have been identified in modulated ERBB2 overexpressing mammary cells
	PEpoly-A ⁺	Identification of 3 known and 24 novel fusion transcripts (including VAPB-IKZF3)
	SE, PEpoly-A ⁺	Discovery of gene fusions in breast cancer transcriptomes with BRCA1 mutations, including novel in-frame WWC1-ADRBK2 fusion in HCC3153 cell line and ADNP-C20orf132 in a primary tumor
	FRpoly-A ⁺	Investigation of EMT-associated alternative splicing events regulated by dif erent classes of splicing factors (RBFOX, MBNL, CELF, hnRNP, or ESRP)
Prostate cancer	SEpoly-A ⁺	Detection of transcription-induced chimeras in prostate adenocarcinoma
	PE WT	Discovery and charcterization of seven novel cancer-specific gene fusions (four involving non-ETS)
	PEpoly-A ⁺	Identification of 121 unannotated prostate cancer-associated ncRNA transcripts, including the characterization of PCAT-1
	FRpoly-A ⁺	25 Previously undescribed alternative splicing events involving known exons, and high-quality singlenucleotide discrepancies, have been detected in prostate cancer cell line LNCaP
Melanoma	PEpoly-A ⁺	Identification of 11 novel gene fusions, 12 readthrough transcripts, somatic mutations and unannotated splice variants
	FRpoly-A ⁺	Somatic CNVs af ecting gene expression and new potential genes and pathways involved in tumorigenesis have been identified in seven human metastatic melanoma cell lines
Ovarian cancer	PEpoly-A ⁺	Discovery of the first gene fusions in ovarian cancer through a novel computational method
Sarcoma	PEpoly-A ⁺	Detection of novel gene fusions in sarcoma through a novel computational method
	FRribodepletion	Evidence of a closer relationship between gene expression levels and protein expression in a human osteosarcoma cell line
Oral carcinoma	MP WT	Association of allelic imbalance with copy number mutations and with dif erential gene expression
Hepatocellular carcinoma	SE WT	Characterization of HBV-related HCCtranscriptome, including identification of exon-level expression changes and novel splicing variants

CNVs, copy number variations; EMT, epithelial-mesenchymal transition; FR, fragment library; HCC, hepatocellular carcinoma; MDS, Myelodys plastic syndrome; PE, paired-end; SE, single-end; WT, whole-transcriptome.

in the diversity and composition of gut flora. Environmental stressors have also been shown to induce virulent behavior of bacteria in the gut. Microbiomic research suggests that there are numerous symbiotic and dysbiotic relationships between the human body and microorganisms which appear to directly influence human health and disease.

As omic research develops, it becomes increasingly apparent that the human genome exists within a highly integrated functional complex. Researchers are only beginning to understand the intricacies of the human genome, epigenome, transcriptome, proteome, and microbiome. Omic research is in its formidable years, and growing exponentially. Each discovery raises new questions and hypotheses, giving rise to an ever-expanding discipline.

NETWORK MEDICINE

Throughout the era of omics, the human genome has revealed itself as a multifaceted structure that exists in a constant state of flux. Genomic studies have repeatedly illustrated that the human genome orchestrates thousands of functional elements and metabolites that interact on multiple levels. In order to comprehend what appears chaotic, a new type of medicine has emerged, network medicine. Specifically, this type of medicine focuses on integrating various omic disciplines to create networks that explain healthy and diseased states (Figure 88–7).^{19,48,49}

Underlying network medicine are several principles utilized to construct network models.⁵⁰ These models assume that biological networks are not random, there is a certain order, and interactions are connected through links or edges. Network medicine designates entities with frequent interactions as nodes. Highly linked nodes are referred to as hubs. Numerous studies have identified hubs as essential functional elements in an organism. Within the nodes there may be subnetworks, or groups of interactions that are referred to as motifs. Networks ultimately create a theoretical model with inherent plasticity amenable to integration of new information.

Various network models have been constructed to explain the functionality of the human genome. Included among them are human disease networks (HDN), where various diseases are linked to the same gene. For example, multiple cancers,

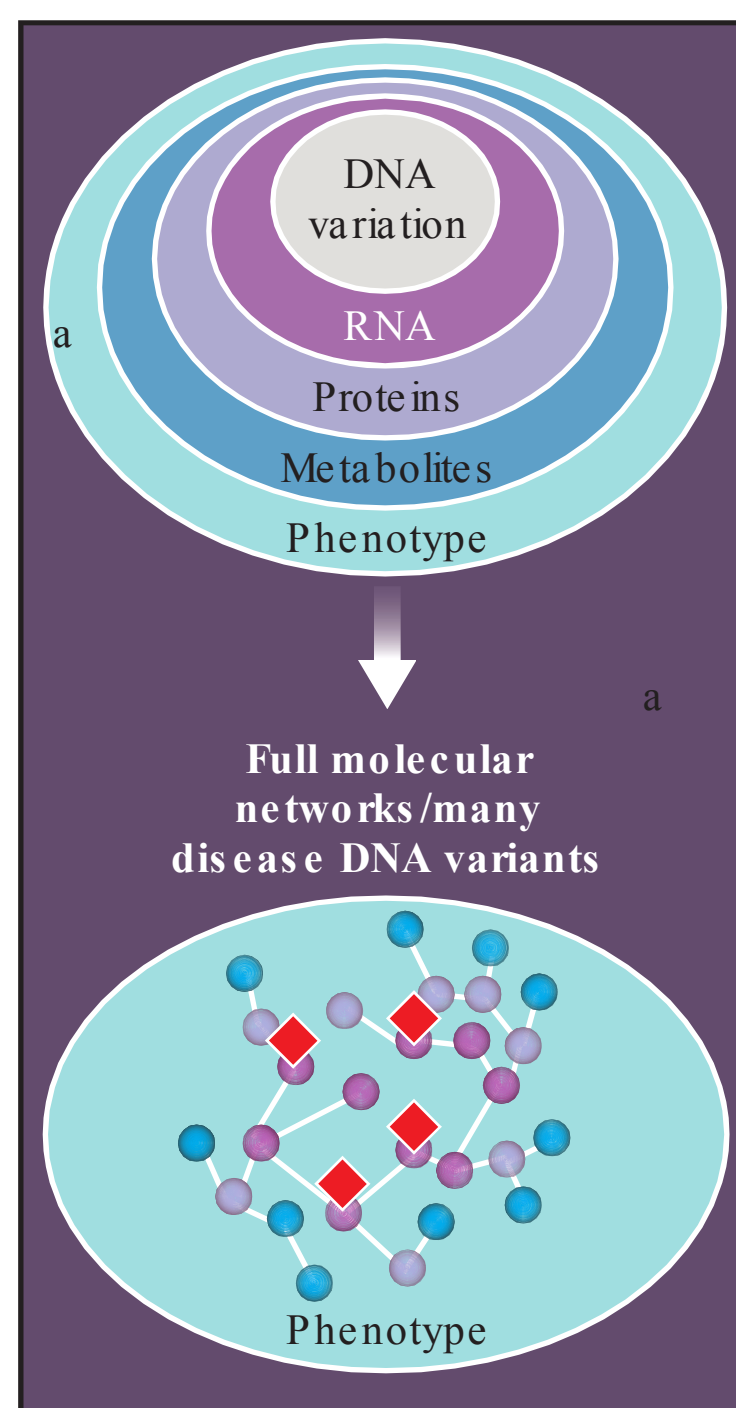

FIGURE 88–7 Network models integrate information from multiple omic technologies to examine relationships between the human genome, its products, and phenotype. (Modified with permission from Schadt EE, Björkegren JL: NEW: network-enabled wisdom in biology, medicine, and health care, *Sci Transl Med*. 2012 Jan 4;4(115):115rv1.)

including breast, head, neck and bladder have been linked to tumor protein 53 gene dysfunction. In another model, referred to as a metabolic disease network (MDN), diseases are linked by a common enzymatic pathway that results in illness. Models have also been constructed based upon phenotype or co-morbidities. Phenotypic disease models (PDM) consider environmental exposures as integral components of variability. These models are relevant to population studies, allowing for analysis in a retrospective manner, from phenotype to genotype.

Newer models have begun to integrate genomic information from multiple platforms to examine common complex diseases utilizing various network algorithms, such as Bayesian models and co-expression gene models.^{49,51} Coined network enabled wisdom (NEW) or systems biology, these models utilize supercomputers and distributed processing to systematically integrate vast amounts of data generated

by omic technology. Through the integration of omic data, network models illustrate the relationships between the human genome and its metabolites. Once fabricated, these networks are validated by comparison to a new human sample population or by knockout mice models. Several network models for common complex diseases are in development including atherosclerosis, diabetes, Alzheimer disease, allergic rhinitis, asthma, obesity, and coronary artery disease (Figure 88–8).^{52,53}

Through the construction and manipulation of network models, the underlying pathology of common complex diseases can be understood. With such information, disease diagnosis and treatment may become infinitely more accurate and personalized. Diseases may also be identified at earlier stages. Network biology can also be utilized to guide development of new pharmaceuticals. By identifying consensual genes or pathways, treatments could be better targeted to address pathologic processes as well as avoid pathways that could result in deleterious side effects. Although in an early phase of

development, network medicine appears to have an incredible potential to expand our understanding of the underlying molecular pathology of illness.

CRITICALOMIC MEDICINE: BRINGING OMICS TO THE INTENSIVE CARE UNIT

The application of omics to critical illness remains vastly unexplored. Most research to date has examined critical illness from a phenotype perspective. Syndromes with multi-organ failure, such as sepsis, trauma, and acute respiratory distress have received the most attention.^{54–57} Genome wide association studies and transcription studies have been the most widely applied to critical illness. The majority of studies have been performed in mice models and in vitro. Few studies have been conducted in the intensive care unit, and of those completed the population size has predominately been small. In this expanding stage, the application of omics to critical care medicine is just starting to reveal the molecular pathology and complex relationships of critical illnesses.

Sepsis has been the most studied phenotype, and justifiably as it constitutes approximately 37% of ICU admissions and carries the highest mortality in general medical and surgical intensive care units.⁵⁸ Efforts have predominately focused on elucidating the molecular pathway of the inflammatory cascade associated with sepsis, with leukocytes being the primary substrate for analysis.^{59,60} In transcription studies, several genes involved in pathogen recognition have displayed up-regulation. Included among them are genes encoding toll-like receptors (TLR) and genes involved in cluster of differentiation 14 (CD14) pathways. Upregulation has also been identified in genes involved in signal transduction pathways that induce immune response elements, including nuclear factor kappa-B (NF- κ B), mitochondrial activated protein kinase, and Janus kinase (JAK).

Several studies have examined transcription during sepsis in attempt to substantiate the hypothesis of a two-phased model, which describes a pro-inflammatory state followed by an anti-inflammatory state. Transcription studies have proposed another potential mechanism involved in early sepsis,

FIGURE 88–8 Arterial wall co-expression gene network constructed from mRNA profiles. In coexpression gene networks, the length of the link between nodes reflects association. Weaker associations have longer links. (Reproduced with permission from Schadt EE, Björkegren JL: NEW: network-enabled wisdom in biology, medicine, and health care, *Sci Transl Med*. 2012 Jan 4;4(115):115rv1.)

adaptive immunity dysfunction. In a small study examining expression profiles of patients with community-acquired pneumonia resulting in severe sepsis or septic shock, genes associated with wounding, inflammatory response, defense response, chemotaxis, and regulation of interleukin-6, exhibited higher expression compared to healthy patients.⁶¹ Notably, this study also found marked variation between gene expression profiles of survivors and non-survivors. In non-survivors, several genes involved in immune response were markedly down-regulated after one week compared to initial response (Table 88–3). The deranged gene expression of the immune response system in non-survivors may be reflective of adaptive immunity dysfunction.

In the setting of sepsis, acute kidney injury (AKI) has been analyzed utilizing GWAS.⁶² In one large study examining 887 patients with sepsis, GWAS identified several SNPs that appeared to be linked to AKI. Three of the polymorphisms rs8094315 (BCL2 gene), rs12457893 (BCL2 gene), and rs2093266 (SERPINA4 gene) were associated with decreased incidence of AKI. Two additional SNPs, rs625145 (SIK3 gene) and rs1955656 (SERPINA5), were also identified; the former being associated with an increased risk of AKI and the latter noted to be in complete disequilibrium with SERPINA4 gene. In previous research, the BCL2 gene has been shown to express

BCL-2, an anti-apoptosis protein. Previous studies have also demonstrated that the SERPINA4 gene encodes kallistatin, which contains vasodilatory, anti-inflammatory, antioxidant, and antiapoptotic properties. The functional role of the SIK3 gene has yet to be delineated in the context of AKI. These findings correspond with previous research, which has identified apoptosis as a key mechanism contributing to the development of AKI in sepsis.⁶³

Omic research has also been utilized to investigate the multi-organ dysfunction that occurs in severe injury. In a multicenter study, examining transcription in severe blunt trauma and burn injuries, lymphocytes displayed remarkably similar patterns of expression as seen in sepsis.⁶⁴ After severe blunt trauma, genes involved in innate immunity, pathogen recognition, and inflammatory response had the greatest increase in expression (Figure 88–9). Conversely, genes involved in T-cell receptor function/proliferation, antigen presentation, apoptosis, and natural killer (NK) cell function were downregulated. Examination of the leukocyte transcriptome in burns (> 20% of total surface area), revealed a nearly identical pattern of transcription to severe blunt trauma. These findings suggest similar mediators (ie, damaged cellular component) or receptors (ie, toll-like receptors) that are instrumental in initiating the inflammatory cascade.

TABLE 88–3 Gene ontology terms and their associated genes that were differentially expressed in sepsis.

Term	Genes
Inflammatory response GO:0006954	IL6, TNF, CCL2, OLR1, ADORA2A, KL, CFB, CCR1, CXCL3, CXCL2, IL1RN, NFKB1, CCL7, CXCL10, TNFAIP6, SIGLEC1, IL23A, CCL23, SAA1, PTX3, IL1A
Defense response GO:0006952	TNF, CCL2, ADORA2A, CXCL3, CCR1, CXCL2, NFKB1, CD74, CCL7, CXCL10, IL23A, CCL23, SAA1, PTX3, IL1A, PLD1, IL6, OLR1, KL, CFB, IL1RN, TNFAIP6, SIGLEC1, IFNB1, CLEC5A
Response to wounding GO:0009611	IL6, TNF, CCL2, OLR1, ADORA2A, KL, CFB, CCR1, CXCL3, CXCL2, IL1RN, NFKB1, CCL7, CXCL10, SIGLEC1, TNFAIP6, IL23A, CCL23, FGA, SAA1, PDGFRA, PTX3, IL1A
Immune response GO:0006955	CSF3, TNF, CCL2, CXCL3, CCR1, CXCL2, OAS3, IFI44L, CCL7, CD74, CXCL10, IL23A, CCL23, PTX3, IL1A, IL6, OLR1, PTGER4, CFB, IL1RN, STXBP2, HLA-DQA2, OASL, TREM1, CLEC5A, GBP1
Chemotaxis GO:0006935	CCRL2, PLD1, IL6, CCL23, CCL2, SAA1, CXCL3, CCR1, CXCL2, ITGA1, CCL7, CXCL10
Cytokine-mediated signaling pathway GO:0019221	CSF3, IL6, TNF, CCL2, CCR1, DUOX1, IL1A

Clinical outcomes after severe blunt trauma and burns have been further examined utilizing transcriptomics. Similar to sepsis models, there also appears to be an exaggerated response of gene expression in complicated recoveries. Furthermore, in the above-described multicenter study, uncomplicated recoveries had a return to baseline expression of upregulated and downregulated pathways within 7 to 14 days after insult. In complicated recoveries, gene expression at 28 days continued to be deranged. These results may be interpreted to suggest that resolution of gene expression derangement is associated with recovery. Alternatively, these findings may suggest that adverse outcomes are associated with exaggerated responses of innate immunity and prolonged derangement of adaptive immunity. Further studies are needed to delineate the mechanisms that contribute to outcomes in both sepsis and trauma.

Critical respiratory illnesses, such as acute respiratory distress syndrome (ARDS) and chronic obstructive pulmonary disease (COPD), have also been examined utilizing omic technology. Several proteomic studies have been performed, examining bronchoalveolar lavage fluids (BALF) in humans to elucidate the molecular pathology of ARDS. In one small study examining the expression of proteins in BALFs of ARDS patients ($n = 8$), 22 proteins exhibited increased expression compared to controls ($n = 9$) over seven days. Utilizing gene ontology analysis, these proteins were linked to inflammation, immunity, response to microbials, response to stress/injury, and enzyme inhibitor activity ([Table 88–4](#)).⁶⁵

Applying network medicine to these findings has revealed connectivity between multiple proteins, including TNF- α , IL1 β , LPS-binding protein, p38 MAPK, β -estradiol, retinoic acid, and the S100 proteins ([Figure 88–10](#)). Analysis has also demonstrated temporal changes in protein expression during the progression of ARDS. On day one, complement proteins, antiproteases, annexin A3, S100 proteins, actin, and extracellular matrix proteins increase, whereas surfactant protein-A, annexin A1, fibrinogen, and fatty acid-binding proteins decrease. On day seven annexin A3 and actin decrease, whereas surfactant protein-A increases; these findings may represent regeneration of damaged lung tissue. Network model analysis of ARDs has also revealed redundancy in protein connectivity, with several proteins involved in multiple pathways. These proteins may also assume various functional roles depending upon the time course of ARDS. Specifically, TNF- α has been found to function as both a pro-inflammatory mediator as well as a mediator of lung repair. Thus far, ARDS has been the only critical illness to be examined utilizing network medicine.

Among critical illnesses, chronic obstructive pulmonary disease (COPD) is the first phenotype to be examined for epigenetic modifications that influence disease progression. Until recently, omic research of COPD had predominately focused on identifying risk loci utilizing GWAS.⁶⁶ However, more and more omic research has begun to focus on epigenetic changes. Comparison of lung samples from healthy controls to those with COPD has demonstrated increased methylation of multiple genes

TABLE 88–4 Gene ontology analysis of proteins found in bronchoalveolar fluid of patients with acute respiratory distress syndrome that were up-regulated.

Reproduced with permission from Chang DW, Hayashi S, Gharib SA, et al: Proteomic and computational analysis of bronchoalveolar proteins during the course of the acute respiratory distress syndrome. *Am J Respir Crit Care Med*. 2008 Oct 1;178(7):701-709.

in COPD (EP300, EPAS1, FOXF1, FOXA2, KDR, LAMA5, SHH, NKX2-1, VEGFA, FZD1, NUMB, and PKDCC).⁶⁷ Hypermethylation has been shown to be associated with down-regulation of cellular communication, multicellular development, and tissue morphogenesis. It has also been associated with up-regulation of co-translational protein targeting to membranes, protein targeting to endoplasmic reticulum, translational initiation, translation termination, and cellular protein complex disassembly. These changes in transcription induced by methylation appear to be associated with the pathogenesis and progression of COPD.

Microbiomics in critical illness has rapidly gained interest, resulting in numerous studies examining the gut microbiome during this time of extreme physiologic stress. Within the gut microbiome, there are five major phyla of bacteria including actinobacteria, bacteroidetes, firmicutes, fusobacteria, and proteobacteria.⁴⁷ During critical illness it has been repeatedly demonstrated that antibiotics, route of nutrition (enteral vs parenteral), vasoactive agents, acid-reducing agents, and opioids induce stress on the gut microbiome altering its phyla composition.

Subsequently, during prolonged critical illness, ultralow diversity communities emerge as well as multidrug-resistant bacteria.⁶⁸ It is hypothesized that these multidrug-resistant bacteria are responsible for the development of late sepsis during critical illness.

Additional studies have demonstrated that bacteria and fungi, specifically *Pseudomonas aeruginosa* and *Candida albicans*, can convert from commensal to virulent during physiologic stress. Administration of opioids, hormones, and steroids has been shown to induce virulence through the bacterial quorum-sensing signaling systems. Analysis of critical illness in animal and in vitro models has demonstrated that virulence can be mitigated with phosphate supplementation. These findings suggest that the gut microbiome plays an influential role in critical illness and preserving its integrity can improve the outcomes of patients.

During this rapidly developing era of omics, criticalomic medicine is just starting to establish its presence in the intensive care unit as a new conceptualized paradigm of medicine. More and more basic research needs to be done, followed by integration of genomic, epigenomic, transcriptomic, proteomic, microbiomic, and other omic data to create more network

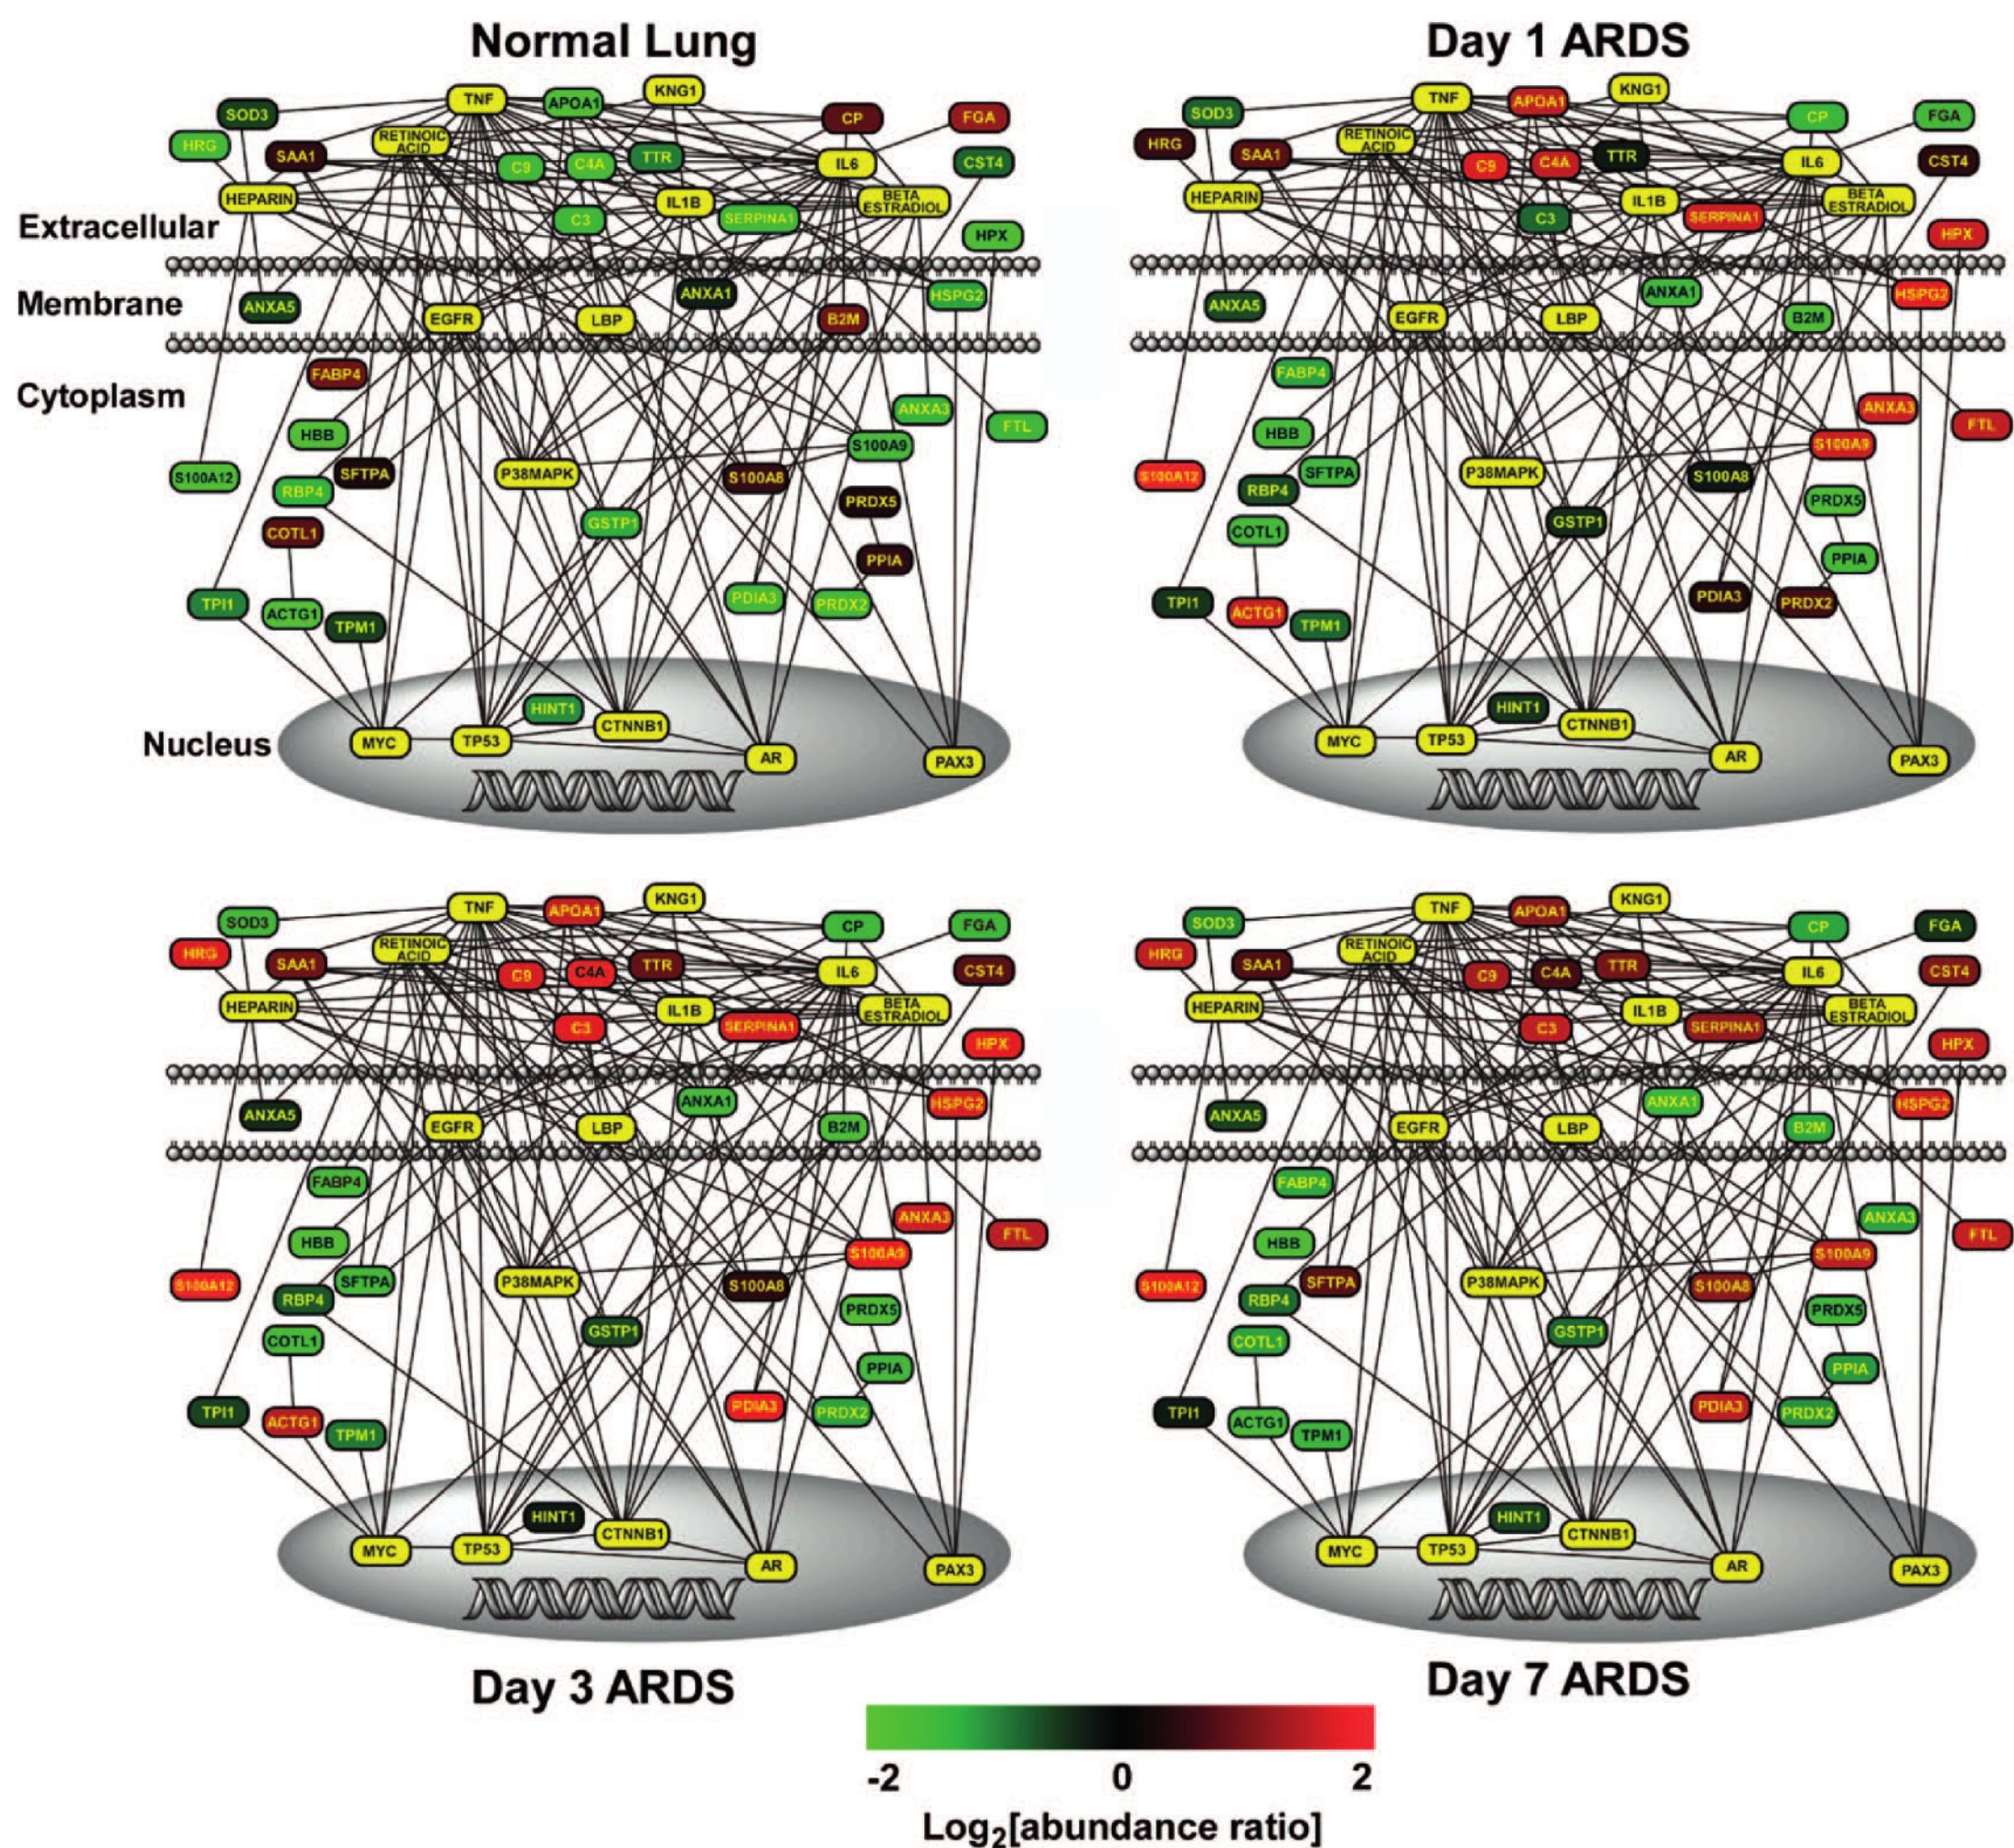

FIGURE 88–10 Network models of proteomes constructed from bronchoalveolar lung fluid from healthy and ARD patients on days 1, 3, and 7. (Reproduced with permission from Chang DW, Hayashi S, Gharib SA, et al: Proteomic and computational analysis of bronchoalveolar proteins during the course of the acute respiratory distress syndrome, *Am J Respir Crit Care Med* 2008 Oct 1;178(7):701-709.)

models of critical illness. Once established, these models can then be manipulated and applied to the bedside through translational medicine. The ethics of omic research and its applications have also yet to be defined, raising many questions about health privacy and determinism. Omic research holds incredible promise to revolutionize the delivery of health care by individualizing prevention, diagnosis, and treatment of illness. However, it must be done thoughtfully and meticulously to augment the full potential of the secrets contained within our nucleotides.

GLOSSARY AND ABBREVIATIONS

- Bayesian network:** a network model that is constructed upon an algorithm that reflects probabilities and conditional dependencies.
- Epistasis:** the effect of one gene being dependent on the presence of one or more modifier genes.

Epigenesis:	development of a plant or animal from an egg or spore through a series of processes.
eSNP:	expressed single nucleotide polymorphism.
Exons:	coding regions of the human genome.
Expression quantitative trait loci (eQTL):	genomic loci that regulate expression levels of mRNAs.
Functional elements:	include genes that encode proteins and non-coding RNAs, transcripts, protein–nucleic-acid interaction sites, and epigenomic modifications.
Haplotype:	contraction for haploid genotypes; specific set of alleles observed on a single chromosome, or part of a chromosome.
Intergenic:	between genes.
Introns:	any nucleotide sequence within a gene that is removed by RNA splicing while the final mature RNA product is generated.
Microarrays:	sometimes called a DNA chip, a small glass slide with short DNA probes attached to it in a specific pattern. When a sample of fragmented DNA is washed over the microarray, pieces of this DNA hybridize to the chip and can then be detected by scanning software. ⁶⁹
Nucleosome:	a unit containing eight histones wrapped with DNA, which packages into chromatin.
Online Mendelian Inheritance in Man (OMIM):	database that contains all of known human diseases linked to genetic component. Funded by NCBI (National Center for Biotechnology Information), established in 1960.

Pseudogenes:	genes that have lost their protein-coding ability or are otherwise no longer expressed in the a cell.
Quantitative gene loci:	DNA that is linked to or is contained within genes that underlie a quantitative trait.
Single nucleotide polymorphism (SNP or snips):	variation in one DNA base, estimated to be about 1 in 10 million bases.
Transcription:	first step of gene expression, in which a particular segment of DNA is copied into RNA by the enzyme RNA polymerase.
Translation:	process in which mRNA, tRNA and ribosomes coordinate to organize amino acids into proteins.

Arterial Line Monitoring and Placement

Richard Weiner, MSN, RN, ANP-BC; Erin Ryan, RN, NP and Joanna Yohannes-Tomicich, MSN, RN, NP-C

CHAPTER

89

INTRODUCTION

Arterial catheterization is one of the most frequently performed invasive procedures performed on critically ill patients. It is generally considered to be a safe procedure with few serious complications and a major complication rate ranging between 1% and 5%.^{1,2,3,4} Although arterial catheterization was traditionally performed by physicians, contemporary practice in many organizations allows credentialing for this procedure to be performed routinely by non-physician providers including nurse practitioners, certified registered nurse anesthetists, and physician assistants. Arterial line placement remains a readily acceptable intervention for unstable patients requiring continuous monitoring of blood pressure, frequent blood sampling, and blood gas analysis.^{1,3,4,5} Newer technologies for hemodynamic monitoring such as measurement of stroke volume variation and cardiac output are also facilitated by the presence of an arterial line. This chapter will review general principles of arterial line placement, monitoring, and care.

INDICATIONS FOR ARTERIAL CANNULATION

In the majority of hospitalized patients, non-invasive indirect monitoring of blood pressure by auscultation of Korotkoff sounds is sufficient. However, in critically ill and hemodynamically unstable patients indirect techniques may underestimate blood pressure¹; thus the need for more intensive blood

pressure monitoring via arterial catheterization may be beneficial. Historically, the indications for placement of arterial lines included: (1) continuous beat-to-beat monitoring of blood pressure; (2) frequent sampling of blood for laboratory analysis and monitoring of ventilatory impairment; (3) arterial administration of drugs such as thrombolytics; and (4) use of an intra-aortic balloon pump.^{1,3} These remain compelling indications for placement of arterial catheters, however technological advances in contemporary design of catheter and monitoring systems now allow arterial lines to be used for more advanced hemodynamic monitoring, including real-time calculation of cardiac output, stroke volume, and evaluation of fluid responsiveness in suspected hypovolemic states.¹ The modern practitioner requires adequate knowledge of new technologies and data interpretation in order to effectively use these new modalities to enhance patient care and delivery.

ARTERIAL WAVEFORM ANALYSIS

The waveform seen on bedside monitors is a visual representation of intravascular fluid dynamics as a result of rhythmic pulsation of blood generated by cardiac systole. Changes in intravascular pressure are transmitted through rigid, fluid-filled tubing that propagates the pressure wave to a transducer. This transducer converts the pressure wave from a mechanical process (displacement of fluid) into an electrical signal that is, in turn, amplified, processed,

FIGURE 89-1 Normal Arterial Line Waveforms (Used with permission from Deranged Physiology. <http://www.derangedphysiology.com/php/Art-Line/Intensive-Care—Normal-arterial-line-waveforms.php>).

and represented on the monitor as a readily recognizable and characteristic wave. As a result of different pressures through arteries of varying circumference and distance from the heart, the visual representation of the waveform on the monitor will be different based on which artery the catheter has been placed (see [Figure 89-1](#)).

EQUIPMENT FOR ARTERIAL LINE PLACEMENT

The basic equipment needed for the placement of an arterial catheter includes (1) a flexible catheter, which selection (long vs short) will depend on site selection (femoral vs radial vs axillary); (2) sterile gown and gloves, hair cap, mask, and drape; (3) sterile connector tubing to attach to the monitoring system; (4) a 2.0 silk suture or tape; (5) a clear bioocclusive dressing; and (6) a monitoring system with pressure transduction tubing. A bedside ultrasound device may be used to identify vessels prior and during insertion of the arterial

catheter. Ultrasound guidance may be beneficial in technically challenging procedures, or if there is known or suspected anatomic deviation.

Commercially available arterial catheter kits are present in most organizations. These kits are customizable and contain the equipment routinely used in arterial catheter insertion. The advantages of using customized kits include efficient storing of supplies used for arterial cannulation and avoidance of the need for the operator to gather all the supplies independently. These commercially available kits usually offer supplies needed for placement via in-line guidewire/catheter systems, as well as via the modified Seldinger technique described below.

MONITORING TECHNIQUES AND SOURCES OF ERROR

Proper monitoring of arterial waveforms requires positioning, calibration, and zeroing of the transducer system in order to prevent false elevations in blood pressure measurement or artificial dampening of the waveform. Zeroing of the transducer is accomplished by opening a stopcock located proximal to the transducer to ambient air, followed by pressing the “zero” button on the bedside monitor. This provides the transducer with a pressure reference value (atmospheric pressure) against which intravascular pressure can be measured. Once this is done, the pressure tracing should rest on the zero line of the monitor and a pressure value of zero should be demonstrated. Errors in zeroing the transducer will not result in the desired pressure equilibration; this may occur from technical difficulty related to user error or from electronic difficulty due to the phenomenon of “zero drift.” Zero drift is, literally, electronic malfunction of the transducer, transduction cable attached to the monitor, or of the monitor itself, which results in artificial offset of the arterial waveform from the zero line. Sequential manual replacement of each element is indicated to systematically troubleshoot the electronic components.

The arterial transducer system must be calibrated to a point where the monitor accurately reflects the mechanical displacement of blood through the artery. If the system is over- or under-responsive to the amplitude of the pulse wave, it will give a falsely elevated or damped waveform.¹ The test

FIGURE 89–2 Arterial Line Dynamic Response testing (Used with permission from Deranged Physiology. <http://www.derangedphysiology.com/php/Art-Line/Intensive-Care—Arterial-line-dynamic-response-testing.php>).

most commonly used to determine the accuracy of the damping coefficient and resonant frequency of the tubing-transducer-monitor system is the fast-flush test.¹ This is performed by briefly flushing the system using the manual flush device and observing a square wave while the flush is in progress, followed by a return to the arterial waveform with one or two discrepant waveforms that may vary in amplitude.¹ A larger number of irregular waveforms corresponds to an underdamped or overdamped system that will provide inaccurate arterial pressure monitoring (Figure 89–2).

The transducer system must be leveled to a point parallel with the midaxillary line of the patient. This is easily estimated by visual inspection, limits

technical challenge, and is approximate to the level of the patient's heart.¹ This plane allows for accurate measurement of hydrostatic pressure within the heart. Additionally, this allows for correlation with other measurements of cardiac filling pressures obtained from devices with catheter tips in the great vessels or intracardiac chambers,¹ such as central venous pressure measurement and hemodynamic measurements obtained from a pulmonary artery catheter. Failure to level the catheter to the desired plane being monitored may generate spuriously low or high pressure readings based on whether the transducer is lower or higher than the desired position, with a degree of inaccuracy proportional to the height offset (Figure 89–3).

FIGURE 89–3 Arterial Line Mechanics (Used with permission from Deranged Physiology. <http://www.derangedphysiology.com/php/Art-Line/Intensive-Care—Arterial-line-mechanics.php>).

TECHNIQUES OF ARTERIAL CANNULATION

Site selection is the first consideration for arterial cannulation. Common sites for placement include the radial, brachial, axillary, pedal, and femoral arteries; the radial, femoral, and axillary sites are the most frequently cannulated.^{3,4} All of these arteries, in the absence of specific patient complications, are of suitable circumference to hold the arterial catheter. However, each of these sites has advantages and disadvantages related to patient comfort during the insertion and once the catheter is in place. For instance, radial catheterization requires little in the way of positioning for insertion, but may leave the affected hand with limited mobility due to the presence of the catheter and tubing. Axillary cannulation is comfortable for the patient, but requires the arm to be immobilized in an unnatural position throughout the procedure. The femoral artery site is arguably the easiest to cannulate and provides an easy access in an emergent situation, but carries the highest risk for infection. Additionally, femoral catheterization severely limits mobility and may prevent ambulation in the alert patient.

MODIFIED SELDINGER TECHNIQUE

The cannulation of deep arteries is frequently achieved using the modified Seldinger technique. This involves the use of a large, hollow introducer needle that is inserted into the artery. The angle, depth, and technique of insertion vary depending on the specific location. A 3-milliliter syringe is attached to the needle prior to insertion. Once the needle penetrates the skin, the syringe is aspirated while the needle is slowly advanced. The operator will recognize that the needle has entered the artery when brisk, pulsatile flow of bright red blood has been obtained. The syringe is then unscrewed while the needle is stabilized with the nondominant hand, and pulsatile flow is seen from the needle. A guidewire is then inserted through the needle, after which the needle is removed. The catheter is then passed over the guidewire, which is then subsequently removed.

Regardless of location, it is vital to maintain visualization of the guidewire while it remains in the

patient in order to prevent inadvertent loss within the vessel. Once the catheter is successfully placed in the artery, it should be attached to the tubing–transducer system. Confirmation of an arterial waveform should be noted on the bedside monitor. The catheter should be secured with a suture or tape and an occlusive dressing with antimicrobial properties should be placed over the insertion site.

RADIAL ARTERY CANNULATION

A flexible board or roll of gauze is placed under the wrist in order to obtain dorsiflexion before the arm is abducted and the hand is secured to a flat surface for stability and immobilization with tape. Local anesthesia is achieved with 1% lidocaine infiltrated laterally and medially to the pulsation of the artery. Administration of lidocaine directly into the artery will result in vasospasm, which may preclude placement. Following topical anesthesia, the radial pulse is palpated with either the index or middle finger of the non-dominant hand until the maximal pulsation is felt. The needle is then inserted at a 15° to 30° angle and advanced slowly until return of bright red, pulsatile blood is noted. If using a commercially prepared needle with in-line guidewire and catheter, the guidewire is then advanced into the artery, and the catheter advanced over the wire. The needle–wire device is then removed and the catheter is attached to the tubing and transducer. Alternatively, the modified Seldinger technique can be used in a similar fashion.

FEMORAL ARTERY CANNULATION

The femoral artery is the preferential site for emergent arterial access due to both its large size and central location relative to other potential cannulation sites. These same attributes make the femoral artery the preferred choice for vascular access for surgical and interventional procedures. Thus, the patient's procedural history should be reviewed, and caution must be taken if the femoral vascular system has been previously manipulated. The leg should be placed in a fully extended and abducted position,

which can be achieved by laying the patient supine and dangling the lower leg off the edge of the bed. The introducer needle should be inserted at a 45° angle to the skin, bevel up and facing the umbilicus, and distal to the crease of the hip. Subsequent steps for cannulation follow the modified Seldinger technique, as described above.

AXILLARY ARTERY CANNULATION

Similar to the femoral site, the axillary artery is cannulated using the modified Seldinger technique. The arm is properly positioned in a position of abduction, external rotation, flexed at the elbow, and raised; commonly it is suspended above the head by use of a makeshift sling affixed to the head of the bed or IV pole. Successful cannulation is achieved by palpating the artery at the top of a neck near to the concavity of the axilla. The introducer needle is inserted at a 15° to 30° angle to the skin, aiming for the point where the pulse is most strongly palpable. Once pulsatile blood is obtained, the procedure follows that as described in the Seldinger technique above.

BRACHIAL ARTERY CANNULATION

The brachial artery can be cannulated using either the Seldinger technique as described for the femoral or axillary approach, or by the use of a catheter-over-wire apparatus as described for radial artery catheterization. The artery is accessed by extending the arm completely and palpating the pulse within the antecubital fossa. Potential disadvantages of this site include distal ischemia and patient discomfort from maintaining the arm in the extended position. Flexing the arm will kink the catheter within the antecubital fossa and preclude proper catheter function.

USE OF ULTRASOUND FOR ARTERIAL CANNULATION

Several studies have shown a reduction in complications and failure rate, as well as an increase in first-pass success with the use of ultrasound guidance during central venous catheter placement compared

to traditional landmark technique.^{2,4,5,6,7} As a result more ICUs are now equipped with various bedside ultrasound machines and practitioners are becoming more comfortable with its use, especially for insertion of invasive catheters. The use of ultrasound for arterial line placement was initially used as salvage therapy when conventional methods had failed. However, in recent years, the use of ultrasound guidance for radial catheter placement has increased.

Initial ultrasound methodology was based on Doppler techniques, whereas current ultrasound systems use more advanced modes such as B-mode which creates a two-dimensional cross-section of the tissue being imaged.^{2,6,7} Other types of images can be displayed to assist the clinician including blood flow. Clinicians use a hand-held probe, typically called a transducer which is placed directly over the area to be imaged. Specific application of ultrasound to arterial cannulation includes differentiating between artery (pulsatile) and vein (nonpulsatile), as well as between blood vessels which appear dark (hypoechoic) in contrast to soft tissue which appears gray (isoechoic). In patients with small arteries or who may be hypotensive, direct visualization of the artery can at times be difficult. In this instance, practitioners can use color flow Doppler to confirm the presence of pulsatile flow within the artery.

Probe selection is also a key component to the proper use of an ultrasound machine. Higher frequency probes (7.5-15 MHz) are used most often for vascular procedures; however, lower frequency probes (5 MHz) may be necessary for deep vessels or obese patients. The ultrasound machine should ideally be positioned on the contralateral side of the patient with the operator on the ipsilateral side. The transducer should be held in the operator non-dominant hand and held low on the probe. Various views can also be used during catheter insertion. While direct visualization of the needle at all times can only be accomplished using the longitudinal (long access) view, the transverse (short access) view allows for visualization of smaller and/or more tortuous arteries and remains the preferred method for radial artery catheterization.⁷

A meta-analysis of four trials (n = 311) by Shiloh et al compared radial artery catheterization using the conventional palpation method (152 patients) versus ultrasound guidance (159 patients). A 71%

improvement (relative risk, 1.71; 95% CI, 1.25-2.32) in the likelihood of first attempt success was noted in the group using ultrasound guidance during radial artery catheterization.² In a separate study by Levin et al, 69 patients undergoing elective surgery and requiring arterial catheter placement were randomized into two groups: ultrasound guidance versus palpation alone. There was a significantly higher first pass success rate using ultrasound guidance (62%) versus palpation alone (34%).⁸ Several other studies have also shown increased first attempt success rates when comparing conventional palpation methods to ultrasound-guided insertion techniques.^{2,4-8}

COMPLICATIONS ASSOCIATED WITH ARTERIAL CANNULATION

Although arterial cannulation is a generally safe procedure, complications can occur. The total complication rate is estimated to range from 15% to 40% of procedures, although clinically significant occurrences are limited to < 5%.^{1-4,7,9} Of these, some of the more common incidents include thrombosis and arterial occlusion, embolization and organ ischemia, infection, bleeding, and/or hematoma formation. Less severe but still common complications include vasospasm, diagnostic blood loss, and pain. Heparin-induced thrombocytopenia is also a problem as a result of the heparinized solution sometimes used in continuous flush systems.

Thrombosis

Thrombosis is the most common complication associated with catheter placement.^{3,9} It is far more common in the narrow vessels of the distal circulation than in the larger central arteries. In addition to site selection, the incidence of thrombosis increases with duration of indwelling catheter use, length and gauge of arterial catheter selected, and predisposing hypercoagulable state.⁹ It is mitigated by use of a continuous flush system, which works to limit stagnation or turbulence of blood flow through the catheter. Although thrombosis may occur, it is usually not a serious complication in that it rarely results in clinically significant ischemia. Furthermore, ischemia usually resolves with catheter

removal, and the thrombus is resorbed within several weeks of catheter removal. Clinically significant ischemia is rare, occurring in < 1% of arterial catheter placements, and usually develops in the setting of preexisting or concurrent circulatory alterations. However, when surgical intervention for ischemia is required, partial to total amputation of the affected extremity is frequently necessary.

Embolization

Cerebral embolization occurs as a result of either air being externally introduced into the systemic circulation, or via dislodgment of a thrombus at the catheter site. It is frequently associated with peripheral cannulation at radial and brachial sites, although has the potential to occur with any catheter. Since gas travels up a fluid-filled system, air will travel up to the cerebral circulation in a sitting or nonrecumbent patient. The rate of instillation of air into the circulation will also predispose to higher rates of embolization. Manual flushing of the arterial catheter with a syringe as opposed to use of the flush valve can cause higher volumes of air to be introduced. Clinical relevance, if any, depends on the site of embolization, the volume of air involved, and the extent of vessel occlusion.

Infection

As with any percutaneous procedure, there is a risk of infection associated with arterial catheterization. The most common routes of arterial infection include contamination with skin flora during catheter insertion, contaminated sterile flush/infusate system, and introduction of bacteria during blood drawing or opening of the tubing–stopcock system to the ambient environment. Common practices to mitigate infection include the use of chlorhexidine solution prior to catheter insertion, use of sterile technique during insertion (including mask, sterile gown and gloves, and hair cap if necessary), and covering stopcocks with diaphragms instead of caps.¹ Routine changing of the tubing/transducer system varies across institutions; 96 hours is a common practice. Routine changing of the arterial catheter itself is infrequently performed as arterial catheterization results in a very low rate of bacteremia (0%-5%),¹ and is rarely the cause of fever. However, repeat cannulation at a new site may be indicated if

all other sources of sepsis are ruled out. The most common bacterial isolate from arterial catheters sent for microbial analysis is *Staphylococcus epidermidis*. If bacteremia from the arterial catheter is confirmed, treatment with appropriate antimicrobial agents is indicated.

Hemodynamically Significant Retroperitoneal Bleeding

The femoral artery is a large vessel that is frequently selected in emergent situations due to ease of cannulation. However, improper technique can result in transection of the artery and resultant bleeding into the retroperitoneal space. Large amounts of occult bleeding into the retroperitoneum can occur. Unexplained hemodynamic instability and pallor after femoral arterial catheterization should be promptly evaluated radiographically if hematoma or bleeding is suspected.

Hematoma

Percutaneous puncture of smaller, superficial arteries may result in smaller, visible hematomas; these are more frequently seen at the radial, brachial, and dorsalis pedis sites, but can be seen with axillary puncture. If superficial hematoma develops, direct manual pressure should be held until the hematoma is reduced and the area is soft. The procedure should be aborted, and a new site selected.

Vasospasm

Vasospasm may occur under similar conditions to local hematoma formation. The small, superficial radial, brachial, and dorsalis pedis arteries may become vasospastic after cannulated. If the catheter is unable to be placed due to obstruction or inability to advance the guidewire, the operator may notice diminution of a palpable pulse. In such circumstance, the procedure should be aborted and a new site selected, as further attempts at cannulation of the artery are less likely to be successful and may result in unnecessary patient discomfort.

Diagnostic Blood Loss

Significant blood loss can occur from frequent arterial blood sampling as a result of the need to draw intraarterial blood that is not contaminated by saline diluent

or heparinized flush from the transducer system. In order to assure that pure blood is taken, 3 to 5 ml of blood is extracted prior to obtaining the sample for analysis. This can aggregately lead to an increased need for transfusion (with associated morbidity risks). Mitigation of blood loss can be achieved through use of pediatric tubing (smaller volumes), utilization of tubing systems that incorporate a reservoir, and point of care rather than traditional chemical analysis.

Heparin-Induced Thrombocytopenia (HIT)

Some institutions use small amounts of heparin in the arterial flush solution. In critically ill patients with new thrombocytopenia (platelet count decrease of 50% of preheparin levels or absolute platelet count of $< 100,000/\text{ml}$) but no clear etiology, HIT should be considered. If heparin is considered to be a likely cause of thrombocytopenia, all use of heparin in the flush solution should be discontinued. Alternatives include sodium citrate, lactated Ringer's, or 0.9% saline solution.

SUMMARY

Arterial line placement has become a commonly accepted procedure for continuous monitoring of blood pressure and as a reliable access for frequent blood samplings in critical care settings. Although generally considered a safe procedure with few serious complications, consideration of appropriate site selection, contraindications, and potential complications are important prior to insertion of an arterial line.¹⁰ Once the site is selected, use of ultrasound evaluation of the vessel should be considered. Complications associated with arterial catheterization include arterial spasm, thrombosis, embolization and distal ischemia, infection, bleeding and/or hematoma formation. Once accurately placed, continued necessity of the arterial catheter should be evaluated on an ongoing basis, and the catheter should be discontinued as early as possible once the patient is stabilized.

Bronchoscopy

Preethi Rajan, MD and
Sanjay Chawla, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 Bronchoscopy is an important and useful tool in the management and care of critically patients.
- 2 Bronchoscopy can aid in diagnosing pulmonary pathology by direct visualization of the tracheobronchial tree as well as acquisition of deep sampling for culture or in select cases, tissue biopsy.
- 3 Clinicians need to be aware of the physiologic effects, indications, contraindications and complications of bronchoscopy so that patients can be properly selected and derive benefit from the procedure.

INTRODUCTION

In 1897, Gustav Killian first viewed the trachea and mainstem bronchi via a rigid tube, the prototype for the rigid bronchoscope. Later that year, he removed a bone from the right mainstem of one of his patients, the first known therapeutic use of the bronchoscope. In the early 1900s, Chevalier Jackson added an electrical light source to the distal end of the bronchoscope as well as a suction channel. The flexible bronchoscope was first used in clinical practice in 1967 by Shigeto Ikeda in Japan and by the late 1980s, the videobronchoscope was introduced by Asahi Pentax. For the first time this allowed for visualization of the airways on a screen rather than through the eyepiece of the scope.

Flexible fiberoptic bronchoscopy is an integral and vital skill and has become a common procedure in the intensive care unit (ICU). It allows for real-time imaging of the airways from the vocal cords to the subsegmental bronchi. It can be diagnostic and/or therapeutic such as for airway inspection, foreign body removal, suctioning of secretions, collection of

samples and placement of devices or drugs within the airway.

PHYSIOLOGIC EFFECTS OF BRONCHOSCOPY

Bronchoscopy is not a physiologically neutral procedure and continuous monitoring of heart rate, blood pressure and oxygenation must be done during and after the procedure. In ICU patients, ventilator parameters are also monitored to ensure that adequate tidal volumes are delivered and airway pressures are not excessively elevated. The following changes must be taken into account and anticipated during bronchoscopy.

Increased airway resistance. Partial occlusion of the airway by a bronchoscope can increase airway resistance, which can effect peak inspiratory pressure (PIP) and positive end-expiratory pressure (PEEP) as well as delivered tidal volume. These changes can have hemodynamic consequences in patients who may already have cardiovascular instability.

Decreased lung compliance. Bronchoscopy can decrease lung compliance by alveolar collapse from suctioning or surfactant loss after bronchoalveolar lavage (BAL). These effects can be especially significant in patients with decreased compliance, such as acute respiratory distress syndrome (ARDS), pneumonia, atelectasis, and chronic obstructive pulmonary disease (COPD).

Gas exchange. The most common gas exchange abnormality is transient hypoxemia from airway obstruction, alveolar collapse, fluid within the alveoli during BAL or bronchospasm. Oxygenation is likely to worsen in a critically ill patient because of the bronchoscope in the airways or endotracheal tube (ETT) blocking airflow. In patients who are not mechanically ventilated, continuous positive airway pressure (CPAP) applied via full-face mask has been effective in recruiting alveoli and increasing the efficiency of gas exchange in hypoxemic patients.¹ Sedation given to a spontaneously breathing patient can also suppress ventilation and gas exchange. Additionally, small increases in PaCO_2 can occur and may need to be monitored in severely hypercapnic patients. Changes in both PaCO_2 and PaO_2 may be more dramatic during suctioning.² Patients should be preoxygenated with 100% oxygen prior to and during bronchoscopy.

Cardiovascular effects. Changes in intrathoracic pressure especially during coughing may affect venous return and afterload of the left ventricle. Changes in vascular tone from hypoxemia can also result in significant hemodynamic changes. In a small proportion of patients major arrhythmias may develop.²

INDICATIONS

The reasons for bronchoscopy in the ICU are generally similar to those in the non-ICU setting but are usually focused to a few specific indications and may be either diagnostic, therapeutic or both. The majority of ICU patients who undergo bronchoscopy are mechanically ventilated.³ The most common reason for diagnostic bronchoscopy is collection of lower respiratory tract samples for culture while the most common therapeutic indication is removal of mucus plugs or bronchial secretions.⁴

DIAGNOSTIC INDICATIONS

While bronchoscopy can be helpful for many diagnostic purposes, we will focus on the key indications in most ICUs including evaluation for infection, hemoptysis, airway inspection, and inhalation injury.

Evaluation of Parenchymal Infiltrates

Bronchoscopy with collection of samples by BAL or bronchial washings may be helpful to identify infectious pathogens in the lower airways when cultures of tracheobronchial secretions or nasal swab for viral polymerase chain reaction (PCR) are unrevealing. It allows for directed sampling of the lower respiratory tract.⁵ Thus, it is more specific than blind methods of obtaining tracheobronchial samples and may help distinguish between infection and colonization. However, this may not be useful in cases of uncomplicated community acquired pneumonia although it may be valuable in cases of poor response to empiric antimicrobial therapy, clinical progression of infection, and in immunocompromised patients in whom the differential diagnosis includes opportunistic pathogens.⁶

In addition to BAL, sterile samples using a protected specimen brush (PSB) can also be obtained by flexible bronchoscopy. Transbronchial lung biopsy remains a controversial procedure when evaluating for infection. It carries a high risk for pneumothorax as well as hemorrhage in mechanically ventilated patients and should be considered only in selected cases.⁷ With experienced personnel, transbronchial biopsy while on mechanical ventilation may be preferred over surgical lung biopsy and can provide useful information to impact a change in therapy.⁸

Evaluation of Hemoptysis

Bronchoscopy can rapidly identify the location and extent of bleeding within the airways. If the source of bleeding is not readily discernible, segmental lavages can be performed to locate the area where fresh blood is recovered. In cases of mild to moderate hemoptysis, flexible bronchoscopy has a diagnostic and therapeutic role but rigid bronchoscopy is preferred in massive hemoptysis.

For mild to moderate hemoptysis, cold saline, diluted epinephrine, and fibrin precursors can be instilled into the site of bleeding.⁹ In massive hemoptysis, a rigid bronchoscope provides better control of the airway, ventilation during the procedure, visualization and more effective aspiration of blood and clots.⁹ Flexible bronchoscopy permits visualization of more distal airways but has limited suctioning capabilities. It does, however, allow for some basic procedures for airway maintenance and immediate control of bleeding, while awaiting more definitive procedures. For example, an endobronchial blocker (a Fogarty balloon-tipped catheter) can be introduced through the flexible bronchoscope in order to tamponade a bleeding bronchial subsegment. In cases where a bleeding endobronchial lesion is identified, electrocautery, cryosurgery and laser photocoagulation can be used.¹⁰

Airway Inspection

Airway inspection is frequently used in the positioning of an ETT or endobronchial tube, especially when airway management is difficult due to anatomical reasons. It can be performed prior to intubation if a difficult airway is anticipated and can also be used to guide ETT placement when direct laryngoscopy is not possible, such as in cases of head and neck anatomical anomalies due to congenital conditions or as a result of surgery or cancer. It is used in cases where intubation needs to be performed without sedation. Airway inspection can also reveal airway lesions. Finally, flexible bronchoscopy may be used in patients who have undergone lung transplantations to monitor the integrity of anastomotic sites.¹¹

Inhalation Injury

Inhalation of large amounts of smoke and particulate matter can result in significant inflammation and irritation of the airways.¹² This in turn can cause pulmonary edema, cast formation, airway obstruction, ventilation/perfusion (V/Q) mismatch and the loss of pulmonary vasoconstriction. Bronchoscopic evaluation helps identify patients with airway obstruction and those with severe airway injury who might require more aggressive airway management.¹³ Some patients may benefit from early intubation and mechanical ventilation in anticipation of

possible complications as a result of the injury and clinicians should therefore have a low threshold to perform flexible bronchoscopy in these patients.

THERAPEUTIC

Therapeutic uses of flexible bronchoscopy in the ICU sometimes overlap with diagnostic indications and can include treatment of atelectasis, removal of foreign bodies, removal of bronchial secretions and placements of drugs or devices.

Persistent and/or Recurrent Atelectasis

Atelectasis is a common complication in ICU patients and a major cause for delayed recovery due to shunting and worsened hypoxemia. When atelectasis is caused by mucous plugging, flexible bronchoscopy can suction retained secretions, especially those that are thick and tenacious. In this scenario, a bronchial wash or lavage with normal saline can help loosen and access secretions by suctioning. Adjunctive measures such as chest physiotherapy and nebulizers are then instituted to maintain airway patency.^{3,11}

Foreign Body Removal

Flexible bronchoscopy can locate foreign bodies within the airways. Removal can be accomplished with small forceps, baskets, and Fogarty balloon catheters that are inserted through the working channel. However, a flexible bronchoscope has limited capacity to grasp and remove objects and a rigid bronchoscope may be necessary if the object is large or if airway protection is necessary during the procedure.

Removal of Bronchial Secretions

Bronchoscopy can also be used to remove secretions that are thick, tenacious, impacted or present distally within the airways, which may not be accessible by in-line suctioning. Clearing of the airways in this manner can improve ventilator parameters and hasten recovery and ventilator weaning.

Placement of Drugs or Devices

Devices including stents, endobronchial blockers, double-lumen ETTs as well as therapeutic coagulants

for hemoptysis can be delivered or placed with a flexible bronchoscope. Additionally, while seldom used (< 1%), flexible bronchoscopy may be helpful to better visualize the laryngeal opening and vocal cords during a difficult intubation.^{2,4} However, this should be done by an experienced bronchoscopist and preferably in the earlier stages of intubation rather than a rescue maneuver after multiple attempts at direct laryngoscopy.²

PROCEDURE IN MECHANICALLY VENTILATED PATIENTS

In mechanically ventilated patients, bronchoscopy is usually performed through the ETT or tracheostomy tube. While the bronchoscope may occupy ~10% of the tracheal lumen it will typically occlude ~50% of the ETT.¹⁴ The bronchoscope is introduced into the airway without disconnection from the mechanical ventilator via an adapted valve, which allows for continued ventilation and maintenance of PEEP during the procedure.

Prior to the procedure, many patients will require increased sedation and analgesia to help minimize coughing, dyspnea and discomfort during the procedure. Clinicians should be skilled and credentialed in delivering conscious sedation. Continuous vital sign monitoring is required to detect physiologic changes as previously described. Additionally, nebulized or instilled 1% lidocaine may help to locally anesthetize the airway as well as reduce the overall dose sedation required during the procedure.¹⁵

In order to obtain respiratory secretions through BAL, the tip of the flexible bronchoscope is first wedged into the lumen of a target airway, thereby isolating a particular segment from the rest of the tracheobronchial tree. Isotonic saline is then instilled by syringe through the working channel of the bronchoscope and then aspirated back into the same syringe. Several aliquots (3-6) are instilled sequentially and range from 50 to 100 mL each. Each aliquot should have an expected return of 40% to 70% of the initial volume depending on the segment being evaluated.³ The aliquots from a single lavage can be mixed together and sent for microbiological analysis, including differential cell counts and quantitative cultures and cytopathology.

A PSB is a double lumen catheter brush with an occluding plug to prevent contamination from

<ul style="list-style-type: none">• Obtain consent and perform a time out prior to starting the procedure• Hold enteral feedings prior to and during the procedure• Check that the internal diameter of ETT is at least 2 mm larger than the bronchoscope diameter• Raise FiO₂ to 100%, 10-15 minutes prior to and during the procedure• Provide continuous monitoring of heart rate, blood pressure, respiratory rate, and oxygenation by noninvasive pulse oximetry• Assess expired tidal volume and peak airway pressures prior to and during the procedure• Assess the need for additional sedation, analgesia and possibly muscle relaxation• Lubricate the bronchoscope prior to use
--

airway secretions when the catheter is passed through the flexible bronchoscope channel. Samples from a PSB are felt to be more representative of infection since contamination is minimized.

SAFETY

In general, flexible bronchoscopy is a safe and well tolerated procedure. Table 90–1 shows a quick checklist to review prior to the procedure to help minimize complications. Table 90–2 lists general contraindications.

Bronchoscopy should be delayed if a pneumothorax is present and can be reconsidered once it has resolved or addressed by chest tube drainage. Increased intracranial pressure is considered a relative contraindication to bronchoscopy. However, deep sedation with paralysis while monitoring cerebral hemodynamics may minimize complications if the procedure is considered necessary.

--

COMPLICATIONS

The complication rate from bronchoscopy is low and reported to range from 0.08% to 1.08%. Most complications are from biopsies especially bleeding and pneumothorax. The risk of pneumothorax related to transbronchial biopsy is somewhat higher in the ICU given the lack of fluoroscopy and positive airway pressure.¹⁶ A chest X-ray is generally recommended for patients undergoing transbronchial biopsy to assess for pneumothorax but is not routinely ordered following flexible bronchoscopy.

Other complications include increased airway resistance related to blockage of airways by the bronchoscope. Bronchospasm/laryngospasm may occur due to airway irritation, especially in

patients with known COPD. This, in turn, can result in increased airway resistance with elevated peak airway pressures. Patients may experience hypotension secondary to sedation given for the procedure. Hypoxemia can result from bronchospasm and increased airway resistance. Cardiac arrhythmias are also a known complication and highlight the importance of continuous monitoring of vital signs.

Following the procedure, patients can experience persistent hypoxemia from (V/Q) mismatch due to lavage fluid installation or persistent bronchospasm. Patients may also experience fever, which is usually self-limited and has been reported in 9% to 16% of patients undergoing the procedure.¹⁶

Cardiac Output Measurement

Paul E. Marik, MD, FCCM, FCCP

KEY POINTS

- 1 Measurement of stroke volume and cardiac output is fundamental to the hemodynamic management of critically ill patients in the ICU and unstable patients in the operating room.
- 2 Common methods of measuring cardiac output include the pulmonary artery catheter, transpulmonary thermodilution, pulse contour analysis, esophageal Doppler and bioreactance technology.
- 3 Perioperative optimization of cardiac output with targeted fluid challenges reduces postoperative complications and mortality.
- 4 Targeting supranormal hemodynamic targets in patients with traumatic injuries and those with sepsis does not improve outcome and may be harmful.

INTRODUCTION

The management of hemodynamically unstable patients requires an assessment of the cardiac output (CO) and the patients' intravascular volume status (cardiac preload). In most instances the absolute value of the CO is less important than the response of the CO to a therapeutic intervention. In limited circumstances, most notably in the perioperative setting, optimization of CO has been associated with improved patient outcomes. This chapter will review the role of CO monitoring in the ICU and operating room. The most common methods of monitoring CO will be reviewed followed by the utility of CO monitoring.

METHODS OF MEASURING CARDIAC OUTPUT

Pulmonary Artery Catheter

Adolph Fick described the first method of CO estimation in 1870.¹ Fick described how to compute an animal's CO from arterial and venous blood oxygen

measurements. Fick's original principle was later adapted in the development of Stewart's indicator-dilution method in 1897,² and Fegler's thermodilution method in 1954.³ The introduction of the PAC in 1970 and its subsequent use in performing thermodilution measurements in humans translated the ability to measure CO from the experimental physiology laboratory to multiple clinical settings.⁴ The direct Fick method was the reference standard by which all other methods of determining CO were evaluated until the introduction of the PAC. Currently the PAC is considered the "gold standard" against which other devices are compared. Remarkably, the accuracy of the CO measurements as determined by the PAC has never been established. Furthermore, electromagnetometry and ultrasound using aortic flowprobes most closely represent a true "gold standard" for determination of CO but can only be performed in instrumented animals.⁵⁻⁷ Despite the ubiquitous use of the PAC remarkably few studies have investigated the accuracy of the CO measurements as determined by thermodilution.

A number of studies have compared the thermodilution CO with that measured by the Fick technique. These studies have reported a percentage error of between 56% and 83% (with < 30% being clinically acceptable).⁸⁻¹⁰ Philips et al compared thermodilution CO with surgically implanted ultrasonic flow probes in an ovine model.⁵ The percentage bias and precision was -17% and 47%, respectively; the PAC under-measured dobutamine-induced CO changes by 20% (relative 66%) compared with the flow probe. This study found that the PAC was an inaccurate measure of CO and was unreliable for detection of CO changes less than 30%. Critchely et al¹¹ using a similar methodology in pigs reported a precision of 26%. These studies suggest that the true CO has to change by at least 25% to be detected by the PAC. Furthermore, the required change may be as high as 100% depending on the monitor being used.¹² It is likely that multiple factors interact to affect the accuracy of the thermodilution CO calculation.¹³ Occult warming of cold indicator before injection can produce indicator losses leading to overestimation of CO. Several physical variables additionally influence the extent of indicator loss through the catheter.¹⁴ In addition, cold indicator losses to surrounding tissue occur during intravascular transit, particularly during low flow states.¹⁵ For thermodilution CO measurements to be “accurate,” complete mixing of the thermal indicator must occur in the setting of unidirectional flow within the right ventricle. Incomplete mixing of cold injectate due to tricuspid regurgitation will lead to recirculation of indicator, increased total area under the thermodilution curve and underestimation of CO.^{7,16,17} This finding is important as the incidence of tricuspid regurgitation is about 15% in the general population increasing to greater than 70% in elderly patients.¹⁸⁻²⁰

Transpulmonary Thermodilution

Transpulmonary thermodilution (TPTD) similar to the PAC calculates the CO by the indicator dilution method using the modified Stewart–Hamilton equation. With this method a known quantity of cold injectate is delivered via a central venous catheter and mixing of the thermal indicator occurs as it passes through the right atrium and ventricle, pulmonary circulation, left atrium, ventricle and aorta. A thermistor-tipped arterial line quantifies the change

in temperature over time in a large proximal artery (femoral artery). A monoexponential transformation of the curve with extrapolation of a truncated descending limb back to baseline allows calculation of area under the curve for CO measurement. TPTD suffers from many of the errors and limitations associated with CO determined by the PAC. Compared with PAC thermodilution, the greater transit time and distance between injectate delivery and measurement with TPTD will tend to increase the error associated with conductive loss and recirculation while reducing the potential for the measured CO to be unrepresentative of its true value over the entire respiratory cycle. Nevertheless, several studies have validated the CO measurements obtained by TPTD with the Fick method.^{21,22} In addition, the reproducibility of the CO measurements by TPTD appears significantly better than that of the PAC with a precision of about 7% (compared to 25% for the PAC).²³

Pulse Contour Analysis

The concept of pulse contour analysis is based on the relation between blood pressure, stroke volume (SV), arterial compliance, and systemic vascular resistance (SVR).²⁴ If arterial compliance remains unchanged the area under the systolic portion of the arterial waveform is proportional to the stroke volume. The SV or CO can be calculated from the arterial pressure waveform if the arterial compliance and SVR is known. Although the pulse contour systems which are commercially available use different pressure–volume conversion algorithms, they are based on this basic principle. These systems can be divided into 3 categories:

1. pulse contour analysis requiring an indicator dilution CO measurement to calibrate the pulse contour, that is, the LiDCO system (LiDCO, Cambridge, UK) and the PiCCO system (Pulsion, Munich, Germany)
2. pulse contour analysis requiring patient demographic and physical characteristics for arterial impedance estimation, that is, the FloTrac system (Edwards Lifesciences, Irvine, California, USA)
3. pulse contour analysis that does not require calibration or preloaded data, that is, the MostCare system (Vytech Health, Padua, Italy).

Clinical data suggests that only those pulse contour devices that are calibrated to an external method have acceptable clinical accuracy (vascular compliance is measured rather than calculated using predictive algorithms). Furthermore, these devices should be recalibrated when vascular tone changes (eg, use of a vasoconstrictor or vasodilator). The FloTrac™ system has found popular appeal as the system is operator independent, easy to use, needs no external calibration, and only requires a peripheral arterial line (usually radial artery). The accuracy of the first, second, and third generations of this device have been evaluated in over 45 studies; these studies have determined the accuracy of this device to be “clinically unacceptable.”²⁵ This device is particularly inaccurate in patients with a low SVR (eg, sepsis or liver failure). More problematic is the fact that the system does not accurately track changes in SV following a volume challenge or following the use of vasopressors. These limitations significantly restrict the clinical utility of this device.²⁵

Esophageal Doppler

The esophageal Doppler technique measures blood flow velocity in the descending aorta by means of a Doppler transducer placed at the tip of a flexible probe. The probe is introduced into the esophagus of sedated, mechanically ventilated patients and then rotated so that the transducer faces the descending aorta and a characteristic aortic velocity signal is obtained. The CO is calculated based on the diameter of the aorta (measured or estimated), the distribution of the CO to the descending aorta and the measured flow velocity of blood in the aorta. As esophageal Doppler probes are inserted blindly, the resulting waveform is highly dependent on correct positioning. The clinician must adjust the depth, rotate the probe and adjust the gain to obtain an optimal signal.²⁶ Poor positioning of the esophageal probe tends to underestimate the true CO. There is a significant learning curve in obtaining adequate Doppler signals and the correlations are better in studies where the investigator is not blinded to the results of the CO obtained with a PAC.²⁷

Bioreactance

Due to the limitations of bioimpedance devices newer methods of processing the impedance signal

have been developed. The most promising technology to reach the marketplace is the NICOM device (Cheetah Medical, Portland, OR), which measures the bioreactance or the phase shift in voltage across the thorax. Phase Shifts occur only as a result of pulsatile flow; therefore, the NICOM signal is correlated almost wholly with aortic flow. Furthermore, as the underlying level of thoracic fluid is relatively static, neither the underlying levels of thoracic fluid, nor their change induce any phase shift and do not contribute to the NICOM signal. NICOM is totally noninvasive; the system consists of a high-frequency (75 kHz) sine wave generator and four dual electrode “stickers” that are used to establish electrical contact with the body.²⁸ Within each sticker, one electrode is used by the high-frequency current generator to inject the high-frequency sine wave into the body, while the other electrode is used by the voltage input amplifier. The system’s signal processing unit determines the relative phase shift ($\Delta\Phi$) between the input and output signals. Unlike bioimpedance, bioreactance-based CO measurements do not use the static impedance and do not depend on the distance between the electrodes for the calculations of SV, both factors reducing the reliability of the result.²⁸ NICOM averages the signal over one minute therefore allowing “accurate” determination of CO in patients with arrhythmias. The CO as measured by bioreactance has been shown to be correlated with flow on cardiac bypass²⁸ as well as that measured by the Direct Fick method, thermodilution, pulse contour analysis, and carotid Doppler.^{10,29-33} Importantly, the device tracks changes in CO closely.^{10,29-33}

UTILITY OF CARDIAC OUTPUT MONITORING

Determining Fluid and Inotrope Responsiveness

The measurement of SV and CO is fundamental to the hemodynamic management of critically ill patients in the ICU and unstable patients in the operating room. Fluid resuscitation is generally regarded as the first step in the resuscitation of hemodynamically unstable patients. Fundamentally, the only reason to give a patient a fluid challenge is to increase stroke volume (volume responsiveness).

If the fluid challenge does not increase stroke volume, volume loading serves the patient no useful benefit (may be harmful). Clinical studies, however, have demonstrated that only about 50% of hemodynamically unstable patients are volume responsive.³⁴ According to the Frank–Starling principle as the preload increases left ventricular (LV) stroke volume increases until the optimal preload is achieved at which point the stroke volume remains relatively constant. Once the left ventricle is functioning near the “flat” part of the Frank–Starling curve fluid loading has little effect on the stroke volume. This implies that the measurement of SV and its change with a preload challenge is essential in all patients undergoing fluid resuscitation. Similarly, the use of an inotropic agent is based on the assumption that these agents will increase CO. CO monitoring is therefore essential when inotropic agents are being used to allow titration of the drug to the desired effect. Previously static pressure measurements, namely the pulmonary capillary wedge pressure (PCWP) and the central venous pressure (CVP), have been used to guide fluid therapy. However, studies performed over the last 2 decades demonstrate that these techniques are unable to accurately assess volume status or fluid responsiveness.³⁵ Therefore, both fluid challenges and the use of inotropic agent should be based on the response of the SV to either of these challenges.

While a number of definitions exist, an increase in stroke volume (or cardiac output) $> 10\%$ to 15% has been used to define volume responsiveness. Interestingly, this rather arbitrary definition was based on the precision of the PAC from studies performed in the 1980s (which we now know are incorrect).³⁶ Furthermore, although the volume of the fluid bolus has not been well standardized, a volume of between 500 and 1000 mL (or 10 mL/kg) of crystalloid solution has been most studied.³⁴ As an operational definition we use a $> 10\%$ increase in stroke volume following a 500 mL crystalloid bolus (over 10 minutes) as an indicator of fluid responsiveness. Fluid boluses of greater than 500 mL should be avoided as this may lead to volume overload. More importantly, large fluid boluses may acutely increase cardiac filling pressures. Increased cardiac filling pressures trigger the release of natriuretic peptides. Natriuretic peptides cleave membrane-bound

proteoglycans and glycoproteins (most notably syndecan-1 and hyaluronic acid) off the endothelial glycocalyx.^{37,38} The endothelial glycocalyx plays a major role in regulating endothelial permeability.³⁹ Therefore, excessive volume expansion increases the release of natriuretic peptides which in turn damages the endothelial glycocalyx and this is followed by a rapid shift of intravascular fluid into the interstitial space leading to a marked increase in lung water and tissue edema.^{37,38} In most circumstances, it would therefore be desirable to determine whether the patient will be fluid responsive without actually administering a fluid bolus. In this regard, the passive leg raising maneuver has received the most attention. Lifting the legs passively from the horizontal position induces a gravitational transfer of blood from the lower limbs toward the intrathoracic compartment. Beyond its ease of use, this method has the advantage of reversing its effects once the legs are tilted down (reversal of the effects on cardiac filling pressures). Therefore, PLR may be considered a reversible “autotransfusion.” A recent meta-analysis, which pooled the results of eight studies, confirmed the excellent value of PLR to predict fluid responsiveness in critically ill patients with a global area under the ROC curve of 0.95.⁴⁰ It should, however, be noted that intra-abdominal hypertension (an intra-abdominal pressure of > 16 mm Hg) impairs venous return and reduces the ability of PLR to detect fluid responsiveness.⁴¹ Similarly, it is likely (although it has not been studied) that patient’s with very thin legs from loss of muscle mass may have a limited “autotransfusion” following a PLR maneuver (and a false negative test). When performing the PLR maneuver, it is important that the method be standardized. The lower limbs should be elevated to 45° (automatic bed elevation or wedge pillow) while at the same time placing the patient in the supine from a 45° semirecumbent position. Starting the PLR maneuver from a total horizontal position may induce an insufficient venous blood shift to significantly elevate cardiac preload.⁴² By contrast, starting PLR from a semirecumbent position induces a larger increase in cardiac preload as it induces the shift of venous blood not only from both the legs but also from the abdominal compartment.⁴³ Since the maximal hemodynamic effects of PLR occur within the first minute of leg elevation,⁴⁴ it is important

to assess these effects with a method able to track changes in cardiac output or stroke volume on a real-time basis, that is, pulse contour analysis (calibrated), esophageal Doppler, or bioreactance. While the change in SV may be detected within the first minute of the PLR maneuver with pulse contour analysis it may take up to 3 minutes for this change to be detected by bioreactance.

Optimizing Cardiac Output in Elective Surgical Patients

A seminal paper published by Shoemaker et al. in 1982 demonstrated that postoperative patients with an oxygen delivery (DO_2) $< 550 \text{ mL/min/m}^2$ and a cardiac index (CI) $< 4.5 \text{ L/min/m}^2$ were at a significantly greater risk of dying than patients whose DO_2 and CI were above these thresholds.⁴⁵ These authors hypothesized that optimizing postoperative DO_2 using the cardiorespiratory pattern of those who survived ($\text{DO}_2 > 550 \text{ mL/min/m}^2$ and cardiac index $> 4.5 \text{ L/min/m}^2$) would improve the outcome of patients undergoing high-risk surgery.⁴⁶ This study was followed by a pseudorandomized control trial in which 100 patients were “randomized” to achieve these postoperative DO_2 and VO_2 targets (supranormal) or a control group with standard postoperative hemodynamic goals.⁴⁶ The mortality of the control group was 48% compared to 13% in the supranormal group ($P < 0.03$). In 1988 these authors published a now landmark study in which they measured DO_2 and VO_2 in 100 consecutive patients undergoing high-risk surgical operations.⁴⁷ They calculated the intraoperative and postoperative oxygen debt (VO_2 debt) by subtracting the measured VO_2 from the estimated VO_2 requirements corrected for temperature and anesthesia. The estimated VO_2 during anesthesia was calculated using the following formula: $\text{VO}_2 (\text{anesthesia}) = 10 \times \text{kg}^{0.72}$.⁴⁷ This unvalidated equation was published in a textbook by Lowe and Ernst.⁴⁸ Shoemaker and colleagues then correlated the calculated VO_2 deficit with the subsequent development of lethal and nonlethal organ failure. In this study the cumulative VO_2 deficit averaged $33.5 \pm 36.9 \text{ L/m}^2$ in nonsurvivors, $26.8 \pm 32.1 \text{ L/m}^2$ in survivors with organ failure, and $8.0 \pm 10.9 \text{ L/m}^2$ in survivors without organ failure ($P < 0.05$). Shoemaker and colleagues noted that the

oxygen debt was incurred almost exclusively during the intraoperative period. Based on these findings, the authors proposed that the greater the oxygen debt incurred (during surgery), the greater the risk of organ failure and death.⁴⁷ This observation was supported by experimental models of hemorrhagic shock in which the magnitude of VO_2 deficit was related to the risk of death of the study animals.⁴⁹ The same year (1988) these authors published the results of two series of patients.⁵⁰ The first series was again a pseudo-randomized study in which a $\text{DO}_2 > 600 \text{ mL/min/m}^2$ and $\text{CI} > 4.5 \text{ L/min/m}^2$ were targeted in the postoperative period as compared to standard postoperative hemodynamic targets. The reported mortality was 38% in the control group compared to 21% in the protocol group ($P < 0.05$). In the second series, patients were randomized preoperatively into one of three treatment groups, namely: (i) a central venous pressure (CVP)-control group, (ii) a pulmonary artery (PAC) control group, and (iii) a PAC protocol group in which “supranormal” hemodynamic and oxygen transport values were used as the goals of care ($\text{DO}_2 > 600 \text{ mL/min/m}^2$ and $\text{CI} > 4.5 \text{ L/min/m}^2$). The reported mortality was 23% in the CVP control group, 33% in the PA-control group, and 4% in the PA-protocol group ($P < 0.01$). Complications were observed less frequently in patients treated by the protocol in both series. Based on the VO_2 debt incurred intraoperatively and the summation of their outcome data, Shoemaker and colleagues recommended that “in the high-risk patient, PA catheterization should be instituted preoperatively and that the important cardiorespiratory values be prophylactically augmented beginning in the preoperative and continued into the intraoperative and immediate postoperative periods.”⁵¹

The concept of deliberate perioperative supranormal oxygen delivery was subsequently tested in a true randomized controlled clinical trial by Boyd and colleagues published in 1993.⁵² In this study 107 high-risk surgical patients were randomized to a control group or a protocol group in which DO_2 was increased to greater than 600 mL/min/m^2 by the use of a dopexamine hydrochloride infusion. The mortality was 5.7% in the protocol group compared to 22.2% ($P = 0.01$) in the control group with half the number of complication in the protocol group as compared to the control group ($P = 0.008$). Patients

enrolled in this RCT were followed for 15 years following randomization to ascertain their length of survival after surgery.⁵³ Remarkably 20.7% of the goal directed therapy patients versus 7.5% of the control group were alive at 15 years. The authors concluded that short-term goal directed therapy in the perioperative period may improve long-term outcome, in part due to its ability to reduce the number of perioperative complications. The study of Boyd and colleagues has been followed by at least 30 RCTs which have studied perioperative hemodynamic optimization in a variety of settings using various goals and techniques of hemodynamic optimization.⁵⁴⁻⁵⁶ The initial preemptive hemodynamic studies used the PAC and targeted the Shoemaker “supranormal” goals while more recent studies have “optimized” CO using esophageal Doppler or dynamic indices of fluid responsiveness. Meta-analyses of these studies have demonstrated that both approaches reduce surgical mortality and morbidity.⁵⁴⁻⁵⁶ Furthermore, while mortality was reduced only in the high-risk patients’ morbidity was reduced across all risk groups. In addition, these meta-analyses have demonstrated that the PAC has been largely replaced by less invasive hemodynamic monitoring techniques.

The original goal directed therapy (GDT) study by Shoemaker et al published in 1982 demonstrated the benefit of achieving postoperative supranormal hemodynamic targets.⁴⁶ Following their 1988 study in which they demonstrated that the oxygen debt was incurred intraoperatively,⁴⁷ they recommended preemptive perioperative (preoperative or intraoperative) hemodynamic optimization.⁵⁰ The studies that followed demonstrated that this approach reduced surgical morbidity and mortality.⁵⁴⁻⁵⁶ In their 1988 paper Shoemaker and colleagues were unable to determine “which of these influences are operative” to explain the intraoperative oxygen debt.⁴⁷ Furthermore, as already mentioned the VO_2 deficit was calculated using a formula that had not been validated.⁴⁸ At face value it would appear to be counter-intuitive that anesthesia would result in an oxygen debt. General anesthesia and neuromuscular blockade reduce metabolic rate and oxygen consumption while DO_2 remains largely unchanged.^{57,58} Hypothermia occurs frequently during anesthesia which further reduces metabolic oxygen requirements.^{59,60} Indeed, in Shoemaker’s pivotal paper VO_2 fell during

the intra-operative period reaching a nadir and the end of surgery.⁴⁷ In this study VO_2 increased sharply after surgery reaching the pre-operative VO_2 at 1 hour with the VO_2 peaking at 4 hours. It is therefore difficult to understand how anesthesia induces an oxygen debt. This apparent contradiction is best resolved by an analysis of the time course of the mixed venous oxygen saturation (SmvO_2) or central venous oxygen saturation (ScvO_2) during the perioperative period. SmvO_2 (or ScvO_2) is a reflection of the balance between DO_2 and VO_2 ; in patients who incur an oxygen debt the SmvO_2 should fall. A number of studies have monitored the $\text{SmvO}_2/\text{ScvO}_2$ in the perioperative period.⁶¹⁻⁶⁴ These studies have reproducibly demonstrate that the $\text{SmvO}_2/\text{ScvO}_2$ remains stable or increases slightly during anesthesia and surgery but falls sharply in the immediate post-anesthesia period. This data suggests that the oxygen debt is incurred postoperatively with the withdrawal of anesthesia (and NMB) and with the development of postoperative pain, agitation, shivering, and increased sympathetic tone. Furthermore, those patients with limited cardiac reserve and most likely to have the largest postoperative fall in $\text{SmvO}_2/\text{ScvO}_2$ and incur the largest oxygen debt. Indeed, these are the patients that have been demonstrated to be at the greatest risk of death and postoperative morbidity.^{62,64} This would suggest that optimization of CO and DO_2 in the immediate postoperative period should be as effective as initiating hemodynamic optimization preoperatively or during the intraoperative period. Meta-analyses have confirmed the benefit of hemodynamic optimization whether initiated pre, intra, or postoperatively.^{54,55}

Optimizing Cardiac Output in Trauma Patients

Patients who suffer severe traumatic injuries with blood loss incur an oxygen debt. The early increases in CO and DO_2 following resuscitation of trauma patients is considered compensation in order to replenish the oxygen debt. It has therefore been postulated that hemodynamic optimization following trauma targeting supranormal goals would decrease the incidence of multiple organ failure and death.^{65,66} Bishop and coworkers pseudo-randomized 115 patients who had suffered from

severe traumatic injuries to normal or supranormal hemodynamic goals (using a PAC) on admission to the SICU.⁶⁷ In this study patients in the supranormal group had significantly fewer organ failures and a lower risk of death. Furthermore, the CI and DO_2 of the survivors were significantly higher than those of the patients who died. McKinley and colleagues randomized 36 patients following traumatic shock to a protocol that aimed to achieve a $\text{DO}_2 > 600 \text{ mL/min/m}^2$ or a protocol that aimed for a DO_2 of about 500 mL/min/m^2 .⁶⁸ The patients in the 500 mL/min/m^2 group received less fluid and blood; however, there was no difference in outcomes between the groups. Velmahos et al randomized 75 severely injured patients to normal or supranormal hemodynamic goals in the pre-ICU period.⁶⁹ Survival rates were identical between the normal and supranormal groups. However, patients from either group who achieved supranormal values had improved survival rates compared with patients who did not. In this study patients in the supranormal group who could not achieve supranormal values had a higher death rate than similar patients in the control group. These findings support the argument that achieving supranormal values is an indicator of physiologic reserve rather than being a useful endpoint of resuscitation. Patients who have the inherent ability to respond to trauma by increasing their CO and oxygen transport capacity beyond normal levels are more likely to eliminate the existing oxygen deficit, avoid organ failure, and survive. Furthermore, attempts to optimize patients who do not have the necessary physiologic reserve may be detrimental. Based on the assimilation of these studies it would appear that targeting supranormal DO_2 does not improve the outcome of patients who have suffered traumatic injuries and that the most appropriate hemodynamic goals would be a $\text{MAP} > 65 \text{ mm Hg}$ with a normal cardiac index ($> 2.5 \text{ L/min/m}^2$).

Optimizing Cardiac Output in Medical Patients

It is widely believed that patients with sepsis, particularly those with an increased lactate concentration, have an oxygen debt (due to increased oxygen demand) and that increasing oxygen delivery will increase oxygen consumption and improve patient

outcome.⁷⁰ This concept was popularized by Edwards et al⁷¹ and Astiz et al⁷² in the late 1980s. There is, however, scant evidence that in patients with sepsis tissue hypoxia occurs. Hotchkiss and Karl in a seminal review published by over 20 years ago demonstrated that cellular hypoxia and bioenergetic failure do not occur in sepsis.⁷³ Using phosphorus 31 NMR spectroscopy to monitor concentrations of high-energy phosphates, Song et al, demonstrated normal concentrations of ATP in the leg muscle of septic rats.⁷⁴ Jepson et al confirmed these findings.⁷⁵ Similarly, Solomon et al demonstrated that sepsis-induced myocardial depression was not due to bioenergetic failure.⁷⁶ Using the hypoxic marker [^{18}F] Fluoromisonidazole, Hotchkiss et al were unable to demonstrate evidence of cellular hypoxia in the muscle, heart, lung, and diaphragm of septic rats.⁷⁷ Additional studies support these findings. In a porcine peritonitis model, Regueira et al demonstrated a significant increase in arterial lactate concentration yet there was no significant change in hepatic and muscle mitochondrial oxidative function.⁷⁸

While sepsis is considered to be hypermetabolic condition oxygen consumption and energy expenditure are broadly comparable to that of normal people, with energy expenditure decreasing with increasing sepsis severity.⁷⁹⁻⁸¹ Therefore, there is no requirement that oxygen delivery increase with sepsis. Ronco and colleagues determined the critical oxygen delivery threshold for anaerobic metabolism in septic and nonseptic critically ill humans while life support was being discontinued.⁸² In this study there was no difference in the critical oxygen delivery threshold between septic and nonseptic patients. The critical oxygen delivery threshold was $3.8 \pm 1.5 \text{ mL/min/kg}$ (266 mL/min in a 70 kg patient); assuming a hemoglobin concentration of 10 g/L translates into a cardiac output of approximately 2 L/min . It is likely that only preterminal moribund patients with septic shock would have such a low cardiac output.

Several studies performed over four decades ago provide strong evidence that hyperlactacidemia noted during shock states was unlikely to be caused by tissue hypoxia.^{83,84} It has now been well established that epinephrine released as part of the stress response in patients with shock stimulates $\text{Na}^+ \text{K}^+$ ATPase activity. Increased activity of $\text{Na}^+ \text{K}^+$ ATPase leads to increased

lactate production under well-oxygenated conditions in various cells, including erythrocytes, vascular smooth muscle, neurons, glia, and skeletal muscle.^{85,86} This concept was confirmed by Levy and colleagues, who in patients with septic shock demonstrated that skeletal muscle was the leading source of lactate formation as a result of exaggerated aerobic glycolysis through $\text{Na}^+ \text{K}^+$ ATPase stimulation.⁸⁷ Selective inhibition of $\text{Na}^+ \text{K}^+$ ATPase with ouabain infusion stopped over-production of muscle lactate and pyruvate. In summary, these data suggest that oxygen requirements are not increased in patients with sepsis, that an oxygen debt does not exist in patients with sepsis, and that lactate is produced aerobically as part of the stress response. This would suggest that increasing oxygen delivery would not be a useful exercise. In a pivotal study published in 1994, Hayes and colleagues randomized 109 fluid resuscitated critically ill patients to receive dobutamine titrated to achieve a $\text{DO}_2 > 600 \text{ mL/min/m}^2$ or a control group who received dobutamine only if the $\text{CI} < 2.8 \text{ L/m}^2$.⁸⁸ During treatment there was no difference between groups in the MAP or VO_2 , despite a significantly higher CI and DO_2 in the treatment group. The in-hospital mortality was significantly higher in the treatment group (34% vs 54%, $P = 0.04$). In a follow-up publication limited to those patients with sepsis, these authors demonstrated that those patients with normal hemodynamics and those who reached the supranormal DO_2 goal spontaneously (fluid alone) had a significantly lower mortality than those in whom the DO_2 goals were achieved with dobutamine.⁸⁹ The findings of this study are in keeping with the studies in trauma patients which suggest that attempts at driving up oxygen delivery in patients with limited cardiac reserve is not beneficial and maybe potentially harmful. This concept is supported by the study by Gattinoni and colleagues.⁹⁰ These authors randomized 762 critically ill patients to three groups, namely (i) a control group, (ii) a group with a target cardiac index $> 4.5 \text{ L/min/m}^2$ (supranormal group), and (iii) a group with a target $\text{SmvO}_2 > 70\%$. In this study there was no difference in outcome between any of the groups.

In conclusion, fluid challenges and the use of inotropic agents should be guided by the change in cardiac output following these interventions. Perioperative optimization of cardiac output with targeted fluid challenges reduces postoperative

complications and mortality. Targeting supranormal hemodynamic targets in patients with traumatic injuries and those with sepsis does not improve outcome and may be harmful. Similarly, in patients with sepsis attempting to increase oxygen delivery in response to an increased lactate concentration is illogical and potentially harmful.

Cardioversion and Defibrillation

Rohit R. Gupta, MD and Ylaine Rose T. Aldeguer, MD

KEY POINTS

- 1 Biphasic waveform cardioversion is safe and equally effective as monophasic cardioversion, using much lower energy with reduced post-shock complications such as cardiac dysfunction, dysrhythmias, and skin burns.
- 2 Defibrillation or unsynchronized cardioversion is indicated in any patient with pulseless VT/VF or unstable polymorphic VT, where synchronized cardioversion is not possible.
- 3 Synchronized cardioversion is utilized for the treatment of persistent unstable tachyarrhythmia in patients without
- loss of pulse. Amongst this category, AF remains the most frequently encountered.
- 4 In critically ill patients, unstable supraventricular tachyarrhythmias benefit from individualized therapy such as inotrope and vasopressor support, antiarrhythmic medications or mechanical ventilation and not necessarily electrical cardioversion as the first treatment.
- 5 It is important to become familiar with the cardioversion device available, the appropriate energy settings and the correct placement of the paddles to ensure effective and timely shock administration.

INTRODUCTION

The incidence of cardiac arrhythmias in critically ill patients has been shown to be considerable, ranging from less than 50% in trauma patients to more than 90% in those admitted with a primary cardiac illness.¹ In the ICU, the most common arrhythmias are atrial fibrillation (AF) and ventricular tachycardia (VT).² These arrhythmias vary in their presentation from incidental findings on telemetry to symptomatic episodes with profound compromise in cardiac and pulmonary function. Rapid diagnosis and critical interventions are important as these arrhythmias cause hemodynamic instability, prolong ICU length of stay, and increase morbidity and mortality.^{2,3}

Electrical current or shocks delivered to the chest to terminate ventricular fibrillation (VF) was first reported in the 1950s.⁴ Today, defibrillation is an established component of the Advanced Cardiovascular Life Support (ACLS) algorithm for pulseless VT/VF. The delivery of an electrical shock results in simultaneous depolarization of the myocardium making the heart refractory to the ongoing disordered electrical activity. This allows for the interruption of the underlying malignant rhythm and reestablishment of the normal electrical rhythm of the heart.^{5,6}

In the case of tachyarrhythmias where the rhythm is organized and the patients have a palpable pulse, an electrical shock is given as a

synchronized cardioversion. Cardioversion refers to the delivery of an electrical shock that is timed to the peak of the R wave on the EKG. This synchronization ensures that the electrical stimulation occurs only during the refractory period of the cardiac cycle minimizing the risk of iatrogenic arrhythmias. The literature on cardioversion can be confusing as many alternate terms such as external cardioversion, synchronized cardioversion, DC cardioversion, and transthoracic DC cardioversion are used interchangeably.

Traditionally monophasic waveform cardioverters were used until the introduction of biphasic waveform cardioversion in the mid-1990s. Increasingly more cardioverters in the ICU are biphasic. Biphasic waveform cardioversion is safe and as equally effective as monophasic cardioversion, using much lower energy with reduced post-shock complications such as cardiac dysfunction, dysrhythmias, and skin burns.⁷⁻⁹ It is important for the intensivist to be aware of the type and model of cardioverter/defibrillator available in the units they cover so as to ensure appropriate delivery of electrical shocks.

INDICATIONS

Synchronized cardioversion is utilized for the treatment of persistent unstable tachyarrhythmia in patients without loss of pulse. Amongst this category, AF remains the most frequently encountered. Other unstable tachyarrhythmias with intact pulses where cardioversion has been demonstrated to be effective include atrial flutter, atrial ventricular nodal reentrant tachycardia (AVNRT), atrial ventricular reentrant tachycardia (AVRT) with pre-excitation pathways and monomorphic regular ventricular tachycardia.

Defibrillation or unsynchronized cardioversion is indicated in any patient with pulseless VT/VF or unstable polymorphic VT where synchronized cardioversion is not possible. These are fatal arrhythmias that require prompt recognition and early correction by administration of electrical shock. In these circumstances, defibrillation therapy would take precedence over all other treatments being provided to the ICU patient except when providing the initial cycles of CPR prior to shock delivery per ACLS protocol or establishing an adequate airway

when hypoxemia due to an inadequate airway is causing the arrhythmia.

The parameters for defining an unstable arrhythmia as mentioned in the advanced cardiovascular life support guidelines includes any arrhythmia that is causing hypotension, altered mental status, signs of shock, ischemic chest discomfort or acute heart failure. However, ICU patients are frequently admitted with similar symptoms as part of their primary critical illness. In such situations, unstable supraventricular tachyarrhythmias benefit from individualized therapy such as inotrope and vasopressor support, antiarrhythmic medications or mechanical ventilation and not necessarily electrical cardioversion as the first treatment. It is imperative that the intensivist is able to quickly discern if the arrhythmia is the primary cause of a patient's instability, and where it is merely a marker of the patient's illness.

Tachyarrhythmias seen in the ICU setting are often a product of the complex interplay between the patient's severe illness and the interventions being performed. The presence of multi-organ failure, concomitant sympathetic and neurohumoral surges, arrhythmogenic drugs and invasive surgical therapies modulate the pathways for arrhythmia generation as well as their response to conventional therapies. The use of vasopressors and inotropes present a challenge to the control of tachyarrhythmias that requires titrating the dose and duration of these therapies, avoiding more arrhythmogenic agents such as dobutamine or dopamine. Recognizing the need for prompt source control in septic patients, controlling electrolyte disturbances in diabetic ketoacidosis, minimizing autonomic fluctuation following a subarachnoid bleed, and closely monitoring and managing pain, anxiety, agitation, oxygenation, and delirium are some examples of addressing the primary illness which can aid in stabilizing cardiac issues.

Cardioversion is still warranted in situations where the patient's hemodynamic status remains compromised despite the above interventions. While successful, post cardioversion tachyarrhythmias tend to recur in patients with sepsis and multi-organ failure. Furthermore the delivery of successive electrical shocks in these patients may be very poorly tolerated as compared to other patient populations. It is thus for the intensivist to make judicious

utilization of cardioversion therapy understanding all the benefits and risks involved.

AF AND ATRIAL FLUTTER

New onset AF occurs in about 46% of patients with septic shock and is associated with prolonged ICU stay and a trend towards increased mortality.³ It is believed that the increased adrenergic activity during sepsis and septic shock contributes to the frequent occurrence of arrhythmias in the ICU, and in these patients, rate control and maintaining sinus rhythm can be challenging unless the underlying pathology has been addressed. Patients with AF of more than seven days duration, dilated atria on echocardiogram, or heart failure also have an increased risk of recurrence after cardioversion.¹⁰ The use of amiodarone infusion before and after electrical cardioversion increases the chances of maintaining sinus rhythm.

SUPRAVENTRICULAR TACHYCARDIA (SVT)

Narrow complex tachycardias include atrial flutter, atrioventricular nonreentrant tachycardia (AVNRT), atrioventricular reciprocating tachycardia (AVRT) and junctional tachycardia. These rhythms tend to occur in a paroxysmal manner often converting back and forth on their own. Hemodynamic instability or persistent and symptomatic SVT despite medical therapy (IV beta-blocker, calcium channel blocker, or adenosine administration) is an indication for urgent cardioversion.

MONOMORPHIC VT WITH A PULSE

Synchronized cardioversion can be performed in unstable patients with a regular monomorphic VT in the presence of a pulse. Patients with irregular or polymorphic VT should however be managed with defibrillation. It is important to note that synchronization of the electrical discharge with the QRS complex in monomorphic VT may be very challenging to achieve. Thus, patients who present with signs of

clinical instability such as hypotension, chest pain, acute pulmonary edema, heart failure, and change in mental status, should receive urgent unsynchronized defibrillation if attempts at synchronization are unsuccessful.

VF AND PULSELESS VT

VF and pulseless VT are managed by defibrillation and CPR until return of spontaneous circulation (ROSC) with a perfusing rhythm has been established as outlined in the advance cardiac life support (ACLS) protocol. Although improved survival has been linked to early defibrillation in VF, recent guidelines by the American Heart Association (AHA) emphasize the importance of immediate high quality chest compressions during cardiac arrest before attempting defibrillation even in the setting of VF or pulseless VT arrest.¹¹ Care should be taken to observe for fine VF that can often appear on the cardiac monitor as asystole resulting in an overlooked opportunity for defibrillation.

ENERGY SETTINGS

See [Table 92–1](#) for the initial energy requirements commonly used during cardioversion using monophasic and biphasic waveform cardioverters. In patients with AF causing hemodynamic compromise, start synchronized cardioversion at 120 Joules (J) using a biphasic defibrillator and increase up to 200 J during the subsequent shocks. Unstable atrial flutter or paroxysmal supraventricular tachycardia (PSVT) require much lower energy and cardioversion may be initiated at 50 J biphasic (100 J monophasic) initially, then 100 J if unsuccessful. If it fails to terminate the SVT, a higher follow-up shock of 200 J (360 J monophasic) may be delivered. Monomorphic VT with a pulse is treated with synchronized cardioversion with initial 100 J biphasic (100 J monophasic), and escalation of energy to 200 J biphasic (360 J monophasic) with each successive shock until sinus rhythm is achieved. Delivering an initial 120 J (200 J monophasic) defibrillation shock is usually sufficient to terminate VF or pulseless VT. If unsuccessful, energy can be escalated to 200 J (360 J monophasic) for subsequent shocks. In the case of polymorphic VT with pulse, defibrillation with similar energy

TABLE 92–1 Initial energy requirements commonly used during cardioversion.

Type of Arrhythmia	Type of Cardioversion	Monophasic	Biphasic
Unstable AF	Synchronized	200 J	120–200 J
Unstable atrial flutter	Synchronized	100–200 J	50–100 J
Symptomatic or unstable SVT	Synchronized	100–200 J	50–100 J
Monomorphic VT with pulse	Synchronized	100–360 J	100–200 J
Polymorphic VT with pulse	Unsynchronized	100–360 J	100–200 J
VF or pulseless VT	Unsynchronized	200–360 J	120–200 J

AF: atrial fibrillation; SVT: supraventricular tachycardia; VT: ventricular tachycardia; VF: ventricular fibrillation.

settings (120 to 200J biphasic) are used as with pulseless VT.

PATIENT PREPARATION FOR CARDIOVERSION

Sedation and Analgesia

Delivering shocks can be painful, traumatic and may cause great anxiety in conscious patients receiving synchronized cardioversion or defibrillation. Short acting sedatives such as midazolam (0.02–0.03 mg/kg over 2–3 min) and or ketamine (1–2 mg/kg over 1–2 min), and analgesics such as fentanyl (0.5–1 mcg/kg) can be administered before the procedure. In patients who have a secured airway (eg, endotracheal intubation) and are more hemodynamically stable, propofol (eg, 0.3–1 mg/kg) is an effective short acting sedative that may be used in combination with an analgesic such as fentanyl. Only in the presence of experienced personnel (eg, anesthesiologist, intensivist), propofol can also be administered in smaller doses in nonintubated patients. In the elderly, administering lower doses of sedatives at less frequent intervals and at slower rates may be appropriate.

Application of Electrodes (Paddles or Pads)

The survival rate goes down 2.3% per minute until CPR is started and 1.1% per minute until a defibrillation shock is delivered.¹² The early application of paddles or pads (electrodes) is a critical link in the

management of arrhythmias with hemodynamic compromise. It allows for a shorter analysis time and quicker delivery of electric shocks.

The positioning of the electrodes on the thorax determines the transthoracic pathway and the flow of current delivered during cardioversion and defibrillation. Currently, there are two conventional positions accepted for electrode placement: the anterolateral and anteroposterior orientation [Figures 92–1(A) and 1(B)]. In the anterolateral position, a first electrode is placed on the right edge of the sternum along the second or third intercostal space (ICS), while the second electrode is placed laterally on the left at the level of fourth or fifth ICS along the mid-axillary line. In the anteroposterior position, the first paddle is placed as above and the second paddle is placed on the back between the tip of the scapula and the spine. The anteroposterior placement of the electrodes is preferred in patients with implantable cardioverter-defibrillator devices (ICDs) to avoid shunting of energy and damage to the implantable device. The electrodes should be maintained in contact with the skin using either conductive gel (with paddles) or by using self-adhesive pads instead. In the case of pads, care should be taken to ensure that they are well secured. This may be particularly difficult in the patient with excess hair or sweat. The electrode pads are then connected to the cardioverter through a wire with a plastic adaptor (usually colored) as indicated in Figure 92–2. Each cardioverter is provided with disposable electrode pads designed for that model.

(a)

(b)

FIGURE 92–1 Placement of the pads in an (A) anterolateral configuration and (B) anteroposterior configuration.

FIGURE 92–2 Attach cables to ensure tight connection between electrode pads and the cardioverter.

CPR Before Cardioversion

In cases such as in VF or pulseless VT, CPR should not be delayed and should be initiated immediately while preparing for defibrillation. The 2010 AHA Guidelines for cardiopulmonary resuscitation (CPR) and emergency cardiovascular care (ECC) recommends high quality CPR to be initiated for at least 90 to 180 seconds while the defibrillator pads and electrodes are being applied and before first defibrillation is attempted. It is believed that during VF, the myocardium is being depleted of oxygen and energy and that delivering CPR during this crucial period will provide the needed oxygen and energy, as well as increase the likelihood of terminating VF during defibrillation and rapid return of spontaneous circulation. Electrolyte imbalances such as hypocalcemia, hypokalemia and hypomagnesemia should also be corrected to improve successful cardioversion.

APPLICATION AND DELIVERY OF CARDIOVERSION

The following are basic steps for using the cardioverter:

1. Press the “ON” button to start operation of the defibrillator.
2. Most defibrillator brands are multifunctional and can be used as an automated external defibrillator (AED), manual defibrillator, external pacer or for ECG monitoring. Make sure that the device is set to defibrillator mode.
3. Apply the self-adhesive electrode pads to the patient’s bare chest using anterolateral or anteroposterior orientation [Figure 92-1(A) and 92-1(B)], then connect the electrode pads wire into the cardioverter via a plastic adaptor (usually color-coded, as in Figure 92–2).
4. Place the 3-wire ECG leads on the patient and connect them to the ECG slot of the defibrillator. Once connected, the monitor will display the ECG tracing and the heart rate.
5. Press the “ENERGY SELECT” button to set the initial or preferred energy for defibrillation (Figure 92–3).

FIGURE 92–3 Use the Energy Select button to choose the energy level delivered during the cardioversion.

6. For synchronized cardioversion, press the “SYNC” button and a marker above every QRS is displayed. The monitor also displays “Sync” once this function is turned on. The device automatically returns to asynchronous mode after each synchronized discharge. This means that the “Sync” button needs to be turned on if the first synchronized cardioversion is unsuccessful and a second synchronized shock is indicated. Note again that the defibrillator will not be able to deliver a shock for rhythms requiring unsynchronized cardioversion if the “Sync” button is turned on.
7. Once the preferred energy level is set, pressing the “CHARGE” button charges the defibrillator. A charge tone indicates that the charge is complete to the selected energy level (Figure 92–4).
8. Once the defibrillator is fully charged, a shock can be delivered by pressing the flashing “SHOCK” button. It is utmost important that the person in charge states “all clear” and checks that all personnel are clear of contact with patient, bed, or equipment before delivery of the shock. Occasionally, the defibrillator may not be able to deliver the required shock even after the “Shock” button is pressed. Check to make sure that the defibrillator is connected to a power supply or that battery power is sufficient as displayed by the battery indicator

FIGURE 92–4 Use the Charge button to charge the cardioverter.

- on the monitor, and that the “Sync” button is not inadvertently on in the setting of rhythms requiring unsynchronized cardioversion (Figure 92–5).
9. After the shock is delivered, the energy for each subsequent shock is automatically selected based on the energy level configured on the set-up. To escalate or change the energy level for the next shock, press the “ENERGY SELECT” button and return to step 5.
10. At anytime, an unwanted charge can be discharged by pressing the “DISARM” button.

FIGURE 92–5 Arrow- Synchronize Cardioversion On/Off Button.

FACTORS AFFECTING SUCCESS OF CARDIOVERSION AND DEFIBRILLATION

There are a number of variables that influence the outcome of a cardioversion and/or defibrillation attempt. These can be grouped as patient characteristics such as body habitus, device characteristics including paddle size, waveform morphology and iatrogenic factors including administration of medications and ventilator support.

Electric shocks used in cardioversion and defibrillation are quantified by the amount of energy delivered. While this allows for the standardization of shocks delivered, it is important to understand that the determinant of an adequate shock is not the energy itself but the amount of electrical current that travels across the heart depolarizing the myocardium. The transmural current generated is dependent directly on the energy level set and inversely related to the resistance/impedance offered by the circuit.

Resistance, termed as thoracic impedance, is determined by the electrode-to-skin interface, electrode pressure, body habitus and the phase of ventilation. Decreasing the interface between the skin and the paddle by placing more pressure on the paddles, applying adhesive or more conductive gel as well as delivering shocks during expiration decreases thoracic impedance and increases the effectiveness of cardioversion and defibrillation. Hairs should also be shaved off the chest if necessary to facilitate attachment of electrode pads to the skin.

Pad size is also an important determinant of transthoracic flow during delivery of shocks. A paddle or pad size with larger surface area has been associated with less thoracic resistance and less chances of myocardial injury.¹⁰ A standard adult electrode pad size usually measures about 8 to 12 cm and is commercially packaged and available for single use.

Observational studies have shown that persistent AF may be more easily converted using a hand-held paddle and the improved electrode-to-skin contact and reduced thoracic impedance are likely contributing to the higher success rate of cardioversion.¹¹ However, there is no current data comparing the use of hand-held paddles and

self-adhesive pad electrodes for other arrhythmias requiring cardioversion or defibrillation. Therefore, the decision to use which type of electrodes should base on equipment availability and the operator's opinion regarding which electrodes are more likely to be effective in a particular patient.

There has been ongoing debate about the relative impact of the positioning of the electrodes on the outcome of the cardioversion attempt. An initial study from Germany demonstrated a statistically significant difference in the successful cardioversion of AF with anteroposterior positioning of the electrodes (96%) as compared to anterolateral position (78%).¹³ However subsequent studies have not demonstrated this benefit in a consistent manner.¹⁴ In the ICU it is often difficult to position patients for placement of posterior pads often resulting in delays in the delivery of shocks. Consequently we do not recommend a particular position for electrode placement over another.

A final point should be made about the use of antiarrhythmic drugs prior to attempted cardioversion. While evidence is limited, in patients who have been pretreated with amiodarone, ibutilide, propafenone or sotalol, the restoration of a sinus rhythm from AF required less electrical energy, fewer attempts and lower number of recurrences.¹⁵⁻¹⁸ Further studies however are required to determine if these findings are representative within the ICU population.

USE OF CARDIOVERSION/DEFIBRILLATION UNDER SPECIAL CIRCUMSTANCES

Pregnancy

Among the various cardiac pathologies complicating pregnancy, arrhythmias are the most common. Often diagnosed for the first time during pregnancy, tachyarrhythmias are the commonest form of arrhythmias reported during pregnancy. Cardioversion and defibrillation during pregnancy is relatively safe without documented adverse effects to the fetus. However, antepartum fetal monitoring is recommended to monitor fetal heart rate during the procedure. Special consideration of the duration

of pregnancy should be made while choosing drugs used for sedation pre-procedure, for example, avoid midazolam. Positioning of patients in the left lateral position if possible also allows the patient to better tolerate the hemodynamic changes associated with cardioversion/defibrillation.

CARDIOVERSION WITH IMPLANTABLE CARDIOVERTER DEFIBRILLATOR

Since the implantation of the first ICD in 1980, there has been a great increase in the use of these instruments and their presence in ICU patients. Occasionally patients continue to have unstable tachyarrhythmias despite having a functioning device. In certain instances, the ICD can be successfully reprogrammed to deliver the shock internally or implement tachycardia-pacing strategies for managing tachyarrhythmia.

The application of electrical current during synchronized and unsynchronized cardioversion in patients with an ICD or permanent pacemaker can potentially cause damage to the ICD circuit and cause malfunction of these devices. However, hemodynamically unstable tachyarrhythmias that are not being controlled by the implanted device need to be treated without hesitation in a manner similar to any other patient in the ICU.

As a strategy for minimizing risk of device damage, it is recommended to place the pads at least 12 cm away from the pulse generator and to use the anteroposterior positioning of electrodes. All ICDs and permanent pacemakers should be interrogated after cardioversion is performed to ensure the proper functioning of these devices.

CARDIOVERSION AND DIGOXIN

A common concern that is raised with the use of cardioversion refers to its use in patients on digoxin and the risk of post-cardioversion ventricular ectopy/arrhythmias. An initial study from 1966 revealed a significant increase in the incidence of serious post-cardioversion ventricular ectopy in patients that had ECG evidence of digitalis toxicity precardioversion.¹⁹

It is however noted to occur most commonly in patients that received monophasic shocks with energy greater than 200 J. Subsequent studies have confirmed that sustained ventricular ectopy post cardioversion is exceedingly rare and tends to occur with higher energy cardioversion along with other concomitant factors such as hypokalemia. As with all tachyarrhythmias it is important to identify and treat the underlying cause. If cardioversion is deemed necessary it should be carried out starting with a lower energy level and ensuring the correction of any electrolyte abnormalities.

COMPLICATIONS OF CARDIOVERSION

Complications of cardioversion include skin burns, transient hypotension (commonly from sedation), and EKG changes (such as nonspecific ST-T wave changes or transient ST segment elevation). High-energy shocks may also result in myocardial necrosis, which may present as a small rise in cardiac enzymes.²⁰ In contrast acute myocardial ischemia causes significant elevations of cardiac enzymes and may not be directly related to cardioversion itself. Myocardial dysfunction may also occur due to myocardial stunning and is usually related to ischemia during cardiac arrest. This complication usually improves in 24 to 48 hours post resuscitation. Rarely, pulmonary edema may occur as a result of left atrial standstill or LV dysfunction after cardioversion in patients with longstanding AF.

The two most common potentially life-threatening complications associated with cardioversion and defibrillation are arrhythmia and thromboembolism. Arrhythmias include sinus tachycardia, non-sustained VT, bradycardia and occasionally complete heart block that may require temporary cardiac pacing. Clinically significant VT or VF may also occur infrequently. Previous studies in patients with atrial fibrillation have reported a post cardioversion stroke risk of 1.1% if anticoagulated for 3 weeks and 7% if not anticoagulated.²¹

Much of these studies are retrospective analyses of data from emergency room visits and their results have not been reproduced in the ICU setting. The benefits of cardioversion in unstable AF outweighs the risk of clot embolization and therefore, urgent

synchronized cardioversion should not be delayed in these patients. The process of oxygenating at the time of delivery of shock has come under scrutiny as a result of the risk for potential arcing/sparks leading to a fire. Despite defibrillation being used for several decades there have been only 2 reported cases of fire as a result of cardioversion/defibrillation.²² We do not recommend any special precautions with regards to oxygenation and the delivery of electrical shocks.

Central Venous Access

Amit Pandit, MD; Leon Chen, MSc, AGACNP-BC, CCRN, CEN
and Daniel Miller, MD

INTRODUCTION

Central venous catheterization is a commonly performed procedure and is an essential skill for critical care physicians. Common indications for placement of a central venous catheter (CVC) include hemodynamic monitoring, lack of peripheral venous access, administration of vasoactive agents, nutritional support, and long-term vascular access. Although traditionally performed by emergency and critical care physicians, anesthesiologists and surgeons, it has been shown that with proper training, this procedure can be safely performed by advanced practice practitioners such as nurse practitioners and physician assistants.¹

Central venous catheter placement can be attempted via two methods: surface landmark approach or using real-time ultrasound guidance. While the landmark method is the traditional approach taught, real-time ultrasound guided CVC placement has emerged as the preferred and recommended practice, and is endorsed by majority of quality assurance agencies and professional societies. Knowledge of surface and deep anatomy is crucial in minimizing complications related to placement of internal jugular, subclavian, and femoral venous catheters.

ANATOMY

Internal Jugular Vein

The internal jugular (IJ) vein is formed by the inferior petrosal sinus and sigmoid sinus. It forms the brachiocephalic vein after it runs under the clavicle at the level of the sternum. The IJ vein, internal carotid artery and vagus nerve form the carotid sheath which runs under the sternocleidomastoid muscle. The IJ vein runs anterolateral to the common carotid artery, however it may be directly

anterior to the common carotid artery on the right side in 26% and in 20% on the left side.² The right IJ vein follows a direct course to the superior vena cava (SVC) joining the right subclavian vein and forming a short and steeply angled right brachiocephalic vein. The left IJ vein forms a longer and shallow angled left brachiocephalic vein as it joins the left subclavian vein. The right IJ vein is larger than the left IJ vein given its direct relationship with the right ventricle.

Subclavian Vein

The subclavian vessels are a valveless continuation of the axillary veins. Similar to the IJ veins, the path of the right and left subclavian veins is not symmetrical. The right subclavian vein forms an angled arc as it merges with the right IJ vein forming the right brachiocephalic vein which enters the SVC, whereas the left subclavian vein merges into the left brachiocephalic vein along a shallow trajectory. The subclavian vein lies posterior to the clavicle after crossing the first rib. This isolated region is the only area where the subclavian vein directly communicates with the clavicle. The subclavian artery runs superior and posterior to the subclavian vein. The subclavian artery and vein are separated by the anterior scalene muscle. The phrenic nerve also runs over the lateral aspect of the anterior scalene muscle. The apices of the lungs may reach as far as the first rib.

Femoral Vein

The femoral vein is located in the femoral triangle (of Scarpa). The femoral triangle is a subfascial space secured superiorly by the inguinal ligament, medially by the medial border of the adductor longus muscle, and laterally by the medial border of the sartorius muscle. The femoral vein lies medial to the femoral artery. The femoral nerve travels down the leg lateral

to the femoral artery. The mnemonic NAVEL (nerve, artery, vein empty space, and lymphatics) is commonly used to remember the location of the femoral structures from lateral to medial. Cannulation of the femoral vein is performed below the inguinal ligament. Femoral anatomy is the least complex when compared to the neck and the subclavian spaces especially as the course of the femoral veins is symmetric unlike the locations mentioned above. It is important to note that as the femoral vein progresses distally, the artery and vein may rotate on each other and the femoral artery may lie anterior to the vein.

TECHNIQUE

General Considerations

Successful placement of a CVC requires careful pre-procedure setup and patient assessment. A recent complete blood count and coagulation profile should be available to ensure that the platelet count is $> 50,000$ and the prothrombin time/International Normalized Ratio (INR) is < 2.0 and the activated partial thromboplastin time (aPTT) is < 50 seconds. Consent must be obtained from the patient or a healthcare agent and discussion of the risks, benefits and alternatives to CVC placement must be documented.

Equipment (Figure 93–1)

Typically central venous catheters are available in a prepacked sterile kit. “Bundling” has demonstrated a reduction in central line-associated bloodstream infections (CLABSI).³ It is important to choose a catheter that has the correct lumen size to deliver medications, blood products, and length to reach the cavoatrial junction. Remember to “know your kit” and the structure of the catheter.

PREPARATION

After pre-procedure laboratory values, consent, and ultrasound (US) imaging have been reviewed, the site of cannulation must be selected. The insertion site must be tailored to the patient’s anatomy and clinical scenario. It is advisable to choose insertion sites with easily identifiable anatomical landmarks. If an ultrasound is available, we recommend performing a pre-procedural bedside US survey or

reviewing previously obtained US images to evaluate the selected site’s anatomy and vessel patency. Sites with anatomical defects, infections, masses, or areas of recent surgery or trauma should be avoided. [Table 93–1](#) lists the advantages, disadvantages, and complications associated with each anatomical site.

POSITIONING

Position the patient to gain optimal access to the vessel. In all cases, the patient should be placed at a height and position comfortable for the operator.

Internal Jugular Vein

The patient should be placed in a flat supine Trendelenburg position (lower extremities higher than the head) in order to engorge the vein and create a larger target. Additionally, this decreases the risk of an air embolism. The head should be turned to the contralateral side to expose the neck and landmarks. Too generous contralateral rotation of the neck can impede cannulation as the sternocleidomastoid muscle may move into an anterior position over the IJ vein hindering cannulation.⁴ Rotation beyond 40° increases the risk of arterial puncture as overlapping of the IJ vein with the carotid artery occurs.⁵ Generally rotating the neck by an angle of 15° to 30° to the contralateral side allows for optimal vessel access and does not increase the risk for arterial cannulation. Pillows should be removed from under the head in order to extend the neck.

Subclavian Vein

The patient should be placed in a flat supine Trendelenburg position with the head in a neutral position. Many authors have argued that a roll placed between the scapulae in order to elevate the subclavian vessels anteriorly and widen the sternoclavicular angle. However, magnetic resonance imaging studies have demonstrated that placing a roll between the scapulae leads to compression of the subclavian vein between the first rib and clavicle hindering cannulation. The arm should be placed adducted to the torso.

Femoral Vein

The patient should be placed in a flat supine reverse Trendelenburg position with the targeted side’s leg slightly abducted and rotated laterally at the hip.

Legend: 1 = chlorhexidine, 2 = sterile full body drape, 3 = 1% lidocaine without epinephrine, 4 = 22- and 25-gauge needles for local anesthetic, 5 = 18-gauge angiocatheter with an introducer needle, 6 = introducer needle attached to a 5-ml syringe, 7 = guidewire in sheath, 8 = 11-blade scalpel, 9 = tissue dilator, 10 = triple-lumen catheter, 11 = catheter clamps, 12 = needle driver and silk suture, 13 = Tegaderm™ and Biopatch® dressing.

STERILITY

Maximal sterile barriers should be used when central venous cannulation is attempted to decrease the risk of CLABSI. These include using a cap, mask, sterile gown, gloves, and a sterile full-body drape. Chlorhexidine has been shown to be the most efficacious antiseptic.⁶ The exposed cutaneous surface should be coated with chlorhexidine thoroughly prior to cannulation.

CANNULATION AND PLACING THE GUIDEWIRE

Prepare the catheter by flushing each lumen it with sterile saline. Anesthetize the cannulation site using 1 to 2 ml of 1% lidocaine or equivalent with a 25-gauge needle. Attach a 10-ml syringe to the finder/introducer needle and puncture the skin applying constant negative pressure approaching

TABLE 93–1 Advantages, disadvantages, and considerations with the CVCinsertion site.

	Advantages	Disadvantages	Miscellaneous
Internal jugular vein	Easily visualized with ultrasound External landmarks easily visualized Direct trajectory into the cavoatrial junction Bleeding and hematoma can be recognized and easily controlled Low risk of pneumothorax	Uncomfortable for awake patients Higher risk of infection and thrombosis than subclavian vein Highest risk for arterial cannulation	Left IJ may be slightly challenging to place in the cavoatrial junction A 20-cm catheter should be used when the left IJ is cannulated
Subclavian vein	External landmarks easily visualized Lowest risk for infection and thrombosis Shallow angle of left subclavian is ideal for pacemaker placement	Highest risk for pneumothorax and hemothorax Difficult to achieve hemostasis given non compressibility of the vessel High risk for malpositioning (ascending into IJ or crossing over to the contralateral subclavian vein)	Natural curve of guidewire allows easy threading
Femoral vein	Good external landmarks Easy access during cardiopulmonary arrest Bleeding and hematoma can be identified and controlled	Highest risk for infection Highest risk for thrombosis Should be avoided in the setting of urinary/stool incontinence Close proximity to the peritoneal cavity Cannot measure CVP	

IJ = internal jugular; CVP = central venous pressure.

the target vessel (ultrasound or landmark-guided). As the needle enters the vessel lumen, blood enters the syringe. Ensure that blood is aspirated with good flow. Sluggish blood flow with aspiration suggests that the needle tip is not optimally positioned in the vessel lumen. Stabilize the hub of the needle and

remove the syringe. Ensure that the blood flow from the needle is nonpulsatile. Bright red pulsatile blood flow suggests arterial cannulation; however, in states of hemodynamic compromise arterial cannulation may mimic venous cannulation (dark red nonpulsatile blood). Place your thumb over the needle hub to minimize the risk of air embolism before passing the guidewire.

If arterial cannulation is suspected, send a blood gas and compare the results with a confirmed arterial blood gas. Alternatively, introduce the flexible distal end of the guidewire into the cannulated vessel and directly visualize the guidewire in the vein with the ultrasound. Placing a single lumen 18-gauge angiocatheter over the guidewire and then connecting the catheter to a pressure transducer can also confirm venous cannulation in the presence of a transduced venous waveform and pressure. A simpler method of transducing venous pressure can be achieved by using standard IV tubing or the guidewire sheath as a manometer. Connect the IV tubing or remove the connectors of the guidewire sheath and uncurl the plastic guidewire sheath. Attach the

TABLE 93–2 Complications of central venous catheterization by insertion site.

Approach	Complications
Internal jugular and subclavian vein	Neck hematoma Pneumothorax Hemothorax Chylothorax Tracheal perforation Endotracheal cuff perforation Phrenic nerve injury Brachial plexus injury Stroke
Femoral vein	Retroperitoneal hematoma Psoas muscle hematoma Bladder perforation Bowel perforation Femoral nerve injury

IV tubing or uncurled guidewire sheath directly to the hub of the angiocath. The operator should hold the IV tubing or sheath vertically and wait for a blood column to rise in the sheath. If the angiocath is in the vein, the blood column will rise and correspond to the central venous pressure and variate with the respiratory cycle. If the angiocatheter is in the artery, the blood column will fill the entire tubing.⁷ Venous cannulation must be confirmed prior to dilation of the soft tissue and vessel. Once venous cannulation is confirmed, introduce the soft end of the guidewire through the needle hub. The guidewire should thread smoothly without resistance. If resistance is met, do not force the wire, but remove it and attach the syringe to the introducer needle and aspirate blood and confirm that the needle tip is in the lumen of the targeted vessel. Retracting the needle slowly and changing the angle of entry may facilitate passing the guidewire. Ultimately, if the guidewire cannot be passed, new cannulation of the same vessel can be attempted or a new site should be chosen. Maintain control of the guidewire throughout the entire process.

Once the wire is placed in the vessel, make an incision at the level of the guidewire entering the skin to ease placement of the tissue dilator. Ensure that the incision completely enters the dermis and is about the width of the catheter. Firmly thread the dilator over the guidewire with a turning motion several centimeters into the vessel, as the dilator does need to be “hubbed.” Again, maintain control of the guidewire at all times. Remove the dilator and expect bleeding around the guidewire. Thread the central venous catheter over the guidewire and grasp the guidewire once it emerges from the distal port of the catheter. Advance the catheter into the vessel and remove the guidewire once the catheter has been placed at the correct depth. Remember to cover the open port with the thumb to minimize the risk of air embolization. Next aspirate and flush all ports of the catheter and suture securely into place using non-absorbable silk. Finally clean the skin around the entry site of the catheter, place a Biopatch[®] and a simple transparent dressing. In the nonemergent setting for internal jugular and subclavian approaches, always confirm line placement with a chest X-ray and evaluate for immediate complications.

LANDMARK-GUIDED “BLIND” APPROACH

Internal Jugular Vein

Anterior Approach

Insert needle at an angle of 30° to 45° along the medial border of the sternocleidomastoid muscle 2 to 3 fingerbreadths above the clavicle aiming towards the ipsilateral nipple. Palpate the carotid artery during cannulation and direct the needle away from the carotid pulse.

Central Approach

Insert the needle at angle of 30° at the apex of the triangle formed by the sternocleidomastoid muscle. Direct the needle towards the ipsilateral nipple. Palpate the carotid pulse; the vein lies lateral to the artery.

Posterior Approach

Insert the needle at a 45° angle at the lateral border of the sternocleidomastoid muscle at the midpoint between the mastoid process and the clavicle. The operator should aim towards the suprasternal notch; note that the vein is accessed at a depth of approximately 7 cm.

Subclavian Vein

Infraclavicular Approach

The aim of this approach is to access the subclavian vein as it passes the first rib and travels under the clavicle. The operator places the index finger in the suprasternal notch and places the thumb at the costoclavicular junction. The skin is punctured approximately 2 cm below the junction of the medial two-thirds and the lateral third of the clavicle aiming towards the index finger. The operator “walks the needle” under the clavicle with vessel entry occurring at 3 to 4 cm. Note that entering the skin close to the clavicle makes it difficult to maneuver the needle tip below the clavicle. Prior to puncturing the skin, ensure that the bevel of the needle is pointed inferomedially as this will facilitate directing the guidewire towards the brachiocephalic vein rather than the opposite vessel wall or IJ vein. During cannulation, the risk of pneumothorax is highly dependent on the angle needle. Keeping the trajectory of the needle

“parallel to the floor” decreases the risk of hitting the pleural dome and causing a pneumothorax.

Supraclavicular Approach

T is less traditional approach to subclavian vein catheterization aims to access the subclavian vein as it meets the internal jugular vein superior to the clavicle. T e clavisternomastoid angle is formed by the junction of the lateral head of the sternocleidomastoid muscle and the clavicle. T e needle is inserted 1 cm posterior to the clavicle and 1 cm lateral to the lateral head of the sternocleidomastoid muscle and aimed towards the contralateral nipple at an angle. T e needle tip is angled posteriorly 5° to 15° relative to the coronal plane, following this trajectory the vein is accessed between the clavicle and the anterior scalene muscle. Note the right-sided approach is often preferred given the absence of the thoracic duct and the direct route to the superior vena cava. Additionally the dome of the pleura is lower on the right.⁸

Femoral Vein

T e aim of this approach is to access the femoral vessel below the inguinal ligament. T e operator palpates the femoral artery pulse 2 fingerbreadths inferior the inguinal ligament and punctures the skin at 45° angle in a cephalad direction 1 cm medial to the femoral pulse. Alternatively, a line can be drawn between the anterior superior iliac spine and midpoint of the pubic symphysis. T e femoral artery lies at the midpoint of this line with the corresponding vein 1 cm medial to it. Note that pressure on the femoral artery may distort the anatomy impeding cannulation. T e depth of accessing the femoral vein is dependent on body habitus. In a normal sized adult, the vein can be reached at a depth of 2 to 3 cm.

REAL-TIME ULTRASOUND GUIDANCE

In recent years, there has been a significant increase in the use of real-time ultrasonography as a safety-enhancing adjunct during CVC placement. With US guidance, anatomical variations that cannot be readily visualized and pathologies such as vessel stenosis and thrombosis can be detected. T e two

approaches in US guidance for CVC placement are the short-axis (SA) approach and long-axis (LA) approach. In the SA approach, the operator’s US probe is placed perpendicular to the target vessel with the indicator dot pointed to the left, in line with the position of the indicator dot on the US screen. T e advantage of the SA approach is that the surrounding structure of the target vessel can be clearly visualized. T e disadvantage of the SA approach is that the central line needle shaft can be mistaken for the needle tip on the US screen and as a result, the needle tip can advance beyond US visualization and cause posterior wall puncture. In contrast, in the LA approach, the operator places the US probe parallel and above to the target vessel with the indicator dot cranially. T us, on the US screen, the left of the screen would represent the cephalic direction and the right would be caudal. T e advantage of the LA approach is that the needle tip can be better visualized. However, the surrounding structure cannot be visualized since the US beam is only in line with the vessel. T e SA approach is associated with shorter cannulation time while the LA approach is associated with decrease in incidence of posterior wall puncture.⁹ With either approach, a standard CVC placement technique such as sterile preparation and Seldinger technique as previously described should be employed.

GENERAL CONSIDERATIONS

Prior to sterilization of the site, the operator should examine the target area with US to determine the size and patency of the target vessel. Alternative target vessel should be selected if pathologies such as thrombosis or stenosis are noted (Figure 93–2). T e US machine should be positioned at the ipsilateral side and across from the operator so that direct visualization of the US screen is maintained throughout the procedure (Figure 93–3). T e operator should also scan the patient’s lung on the ipsilateral side of the procedure for lung sliding prior to procedure to establish the baseline condition (Figure 93–4). In the SA approach, the needle tip should be visualized at all time using the “creep” technique where the US probe is fanned ahead of the needle trajectory to maintain visualization.¹⁰ In the LA approach, the operator must secure the US probe so that the

FIGURE 93–2 Clot within internal jugular vein. IJ = internal jugular vein; CA = carotid artery.

entire target vessel in a sagittal plane can be visualized. Visualization of the entire needle shaft and tip should be maintained during cannulation. The target vessel should be centered on the US screen in either approach and proper adjustments should be made to the depth and gain in order to optimize visualization under US.

FIGURE 93–3 Ultrasound machine being ipsilateral to the site of procedure.

FIGURE 93–4 Ultrasound image of lung.

Internal Jugular Vein

The internal jugular vein is beneath the sternocleidomastoid muscle and is lateral to the trachea and medial to the carotid artery (Figure 93–5). However, anatomical variations exist and the relative position of the vessel may vary. With US guidance, the carotid artery and internal jugular vein can be easily differentiated using direct visualization or with the aid of color flow and Doppler.¹¹ The needle should be inserted directly beneath the needle guide on the US probe and would appear as a hyperechoic object on the US screen. The US probe should be advanced as the needle is advanced so that the needle tip does not advance beyond the US beam and cause inadvertent posterior wall puncture. Once the

FIGURE 93–5 Ultrasound image of internal jugular vein. IJ = internal jugular vein, CA = carotid artery.

FIGURE 93–6 Ultrasound image of guidewire within the vessel after cannulation. IJ = internal jugular vein.

needle tip is visualized within the vessel, the operator can release the US probe and proceed with the cannulation. After the guidewire is inserted into the vessel, the operator can use US to visualize the guidewire within the vessel to confirm placement prior to dilation of the vessel ([Figure 93–6](#)). After the completion of the procedure, lung sliding on the ipsilateral side can be evaluated using US to look for pneumothorax.

Subclavian Vein

Subclavian vein cannulation using US guidance is difficult technically due to the position of the clavicle in relation to the target vessel.¹² There are two potential approaches to cannulation: supraclavicular approach and infraclavicular approach. Concern for mechanical complications has limited the use of the supraclavicular approach.¹³ Although the US-guided infraclavicular approach is technically difficult, it has been shown to be safer than landmark approach in the hands of an experienced operator. Both the short axis (SA) and long axis (LA) approaches can be used. The US probe can be placed over the clavicle perpendicularly with indicator dot directed cranially, and the probe should be moved laterally. As the probe moves towards the axilla, the subclavian vein and artery can be visualized to extend beyond the shadow created by the clavicle ([Figure 93–7](#)). Color flow and Doppler can be used to differentiate between the artery and vein. After identification of the target vessel, the vessel should be centered on US

FIGURE 93–7 Subclavian vessels under ultrasound.

screen and the SA or LA approach can be utilized to cannulate the vessel. Due to the proximity of the lungs to the subclavian vein, extra attention should be paid to keep track of the needle tip since losing track can inadvertently result in a pneumothorax.

Femoral Vein

With US guidance, direct visualization of the femoral vein can facilitate CVC placement. The US probe should be placed transverse to the target vessel right below the inguinal crest. The common femoral vein should be in the medial position with the common femoral artery laterally positioned ([Figure 93–8](#)). Ideally, the CVC placement should be in the common femoral vein since it is proximal to the branching points and is largest in diameter. Compression of the vessel prior to cannulation attempt should be conducted to evaluate for common femoral vein thrombosis and an alternative site should be selected if there is a positive finding.

IMMEDIATE COMPLICATIONS OF CENTRAL VENOUS CATHETERIZATION

Immediate complications are of mechanical nature and related to operator technique and experience. It is important to know, recognize, and manage the immediate complications as they can become rapidly life-threatening in nature. Risk factors for immediate complications include operator inexperience,

FIGURE 93–8 Ultrasound image of the common femoral vasculature. L CFA = left common femoral artery; L CFV = left common femoral vein.

number of needle passes, and larger catheter size. Mechanical complications include puncture of adjacent artery, hematoma, air embolism, arrhythmia, pneumothorax pericardial tamponade, catheter/wire embolus, arteriovenous fistula, vessel obstruction, vessel perforation, pseudoaneurysm formation, catheter malposition, and catheter knotting.¹⁴⁻¹⁹ Subclavian vein catheterization has been associated with the highest risk of pneumothorax.

DELAYED COMPLICATIONS

Major delayed complications include infection and catheter related thrombosis.¹⁶⁻¹⁹ Some of the rarer late complications include delayed pneumothorax, and vascular and ventricular erosion or perforation, leading to hemothorax or pericardial tamponade. The incidence of delayed pneumothorax occurs around 0.5% to 2%. Time of onset can occur as late as 6 hours after the procedure. The type of damage caused by vascular erosion or perforation depends on the anatomical location of the vascular catheter tip. Erosion leading to pericardial tamponade can occur up to 0.2% of patients and erosion without

pericardial tamponade occurs in 0.4% to 1% of patients.

Infectious complications from CVC placement is a significant cause of increased morbidity and mortality in hospitalized patients. The most common bacterial agents causing catheter-related infections are *Staphylococcus aureus* and *Staphylococcus epidermis*, both of which are natural skin flora. Infection can be caused by catheter contamination from skin flora, contamination from access port or hematogenous spread from other sites. The rate of infection is highest in the femoral site, followed by internal jugular, and finally the subclavian vein.¹⁹ Multiple attempts at CVC are associated with an increased incidence of CLABSI; this can be reduced with US guidance. Thus, professional societies recommend US guided CVC as the preferred method because of the lower incidence of CLABSI.

CVC-related thrombosis after 1 week range from 33% to 67%. There are 2 types of thrombosis: the first type forms as a fibrin sheath around the catheter resulting in the occlusion of the cannulated vessel, whereas the second type forms at the tip of the catheter. Cannulated vessels are at higher risk for thrombosis due to the disrupted endothelium resulting activation of the coagulation cascade. Platelet aggregation subsequently forms at the site of damaged endothelium forming thrombus. Risk factors for thrombus formation include small diameter of the target vessel, site of the cannulation, and difficult cannulation. Less common risk factors include external compression of the target vessel due to mass or tumor. The treatment of choice for catheter-related thrombosis is removal of the catheter and infusion of heparin or injection of low-molecular weight heparin. Instillation of fibrinolytics (eg, tissue plasminogen activator) can also be considered if the thrombus is suspected to be within the catheter lumen.

Chest Tube Insertion

Lewis Eisen, MD

KEY POINTS

- 1 Chest tubes vary in size from 6 to 40 French. For patient comfort and to avoid complications, the smallest tube that will drain the pleural space should be chosen.
- 2 When available bedside ultrasound should be used for pleural diagnosis and to guide chest tube insertion.
- 3 For a hemothorax, continued drainage of more than 250 mL of blood per hour warrants a surgical consult.
- 4 The most common complications of chest tube insertion include malposition, blockage, infection, dislodgement, re-expansion pulmonary edema, subcutaneous emphysema, nerve injuries, intrathoracic organ injuries, and residual pneumothorax.
- 5 Chest tube systems should be examined daily for the amount of drainage, the presence of an air leak and the presence of respiratory variation of the fluid column.

INTRODUCTION

Tube thoracostomy is the procedure of insertion of a sterile tube or catheter into the pleural space. It is used to remove air and/or fluid to restore negative pressure to the pleural space. The various indications, diagnostic techniques, procedural approaches, and complications will be discussed in this chapter.

ANATOMY AND PHYSIOLOGY

The pleural cavity is a closed space that exists between the visceral and the parietal pleura. The visceral and parietal pleura contain a single layer of mesothelial cells with multiple layers of connective tissue.¹ The parietal pleura is innervated by the intercostal nerves while the visceral pleura is not innervated. In a healthy individual, the mesothelial

cells on the visceral pleura create a thin film of fluid that allows the pleura to glide smoothly during respiration. See [Table 94–1](#) below for the characteristics of normal pleural fluid versus transudate and exudate.

TYPES OF TUBES

Chest tube sizes are based on the external diameter, ranging from 6 to 40 French (Fr). Adult small bore chest tubes (SBCT) are tubes ≤ 14 Fr. Chest tubes also come in a variety of shapes; the majority of chest tubes used in common practice are either straight, right angle, or pigtailed. Each tube has length markers to guide insertion and fenestrations for pleural drainage. Chest tubes can be “tunnelled” to decrease the rate of dislodgement and infection and to allow for long-term, outpatient management of pleural

TABLE 94–1 Characteristics of normal pleural fluid versus transudate and exudate.

	Normal Pleural Fluid	Transudate	Exudate
pH	7.60-7.64	> 7.20	< 7.20
Glucose	Similar to plasma	> 60 mg/L	< 60 mg/L
Protein	1-2 g/dL	Pleural fluid/serum

effusions. See [Table 94–2](#) for a summary of choice of tubes based on indication.

INDICATIONS FOR TUBE THORACOSTOMY

When air or fluid enters the pleural space, drainage may be necessary based on the clinical condition of the patient.

Pneumothorax

Pneumothorax occurs when air enters into the pleural cavity. When a pneumothorax occurs unprovoked in a person without any underlying pathology, this is labeled primary spontaneous pneumothorax (PSP). Patients with a PSP can be managed in a number of ways based on their clinical picture and the size of the pneumothorax. To measure the size of a pneumothorax, computed tomography (CT)

TABLE 94–2 Summary of choice of tubes based on indication.

	Intervention	Comments
Primary spontaneous pneumothorax	Small—observation Large or symptomatic— manual aspiration or SBCT	Consult a thoracic surgeon for an air leak > 48 hours Patients on mechanical ventilation may require LBCT if there is a large air leak but SBCT is usually sufficient
Secondary spontaneous pneumothorax	SBCT	
Traumatic pneumothorax	SBCT or LBCT	
Iatrogenic pneumothorax	Manual aspiration or SBCT	
Malignant pleural effusion	SBCT or tunneled catheter	
Parapneumonic pleural effusion or empyema	SBCT or LBCT	Ultrasound guidance important
Hemothorax	LBCT	Evidence is increasing toward use of SBCT
Postoperative	LBCT	Evidence is increasing toward use of SBCT

of the chest gives the most accurate 3-dimensional volume. CT is not always necessary, however, plain upright chest radiographs or bedside ultrasound are generally adequate for clinical decisions. The two most utilized methods of determining the size of a pneumothorax are by the American College of Chest Physicians (ACCP) and the British Thoracic Society (BTS). ACCP guidelines recommend measuring the distance from the outer edge of the pleural space to the most apical portion of the collapsed lung.³ Using this measurement, ≤ 3 cm is considered small. BTS recommends measuring at the level of the hilum from the outer edge of the pleural space to the collapsed lung.⁴ According to BTS guidelines, a measurement < 2 cm is considered small.

For clinically stable patients with small pneumothoraces, recommended care includes observation for 3 to 6 hours followed by a repeat chest radiograph. If the repeat radiograph does not show progression of the pneumothorax, the patient can be safely discharged home and should return for a follow-up chest radiograph in 24 hours.³⁻⁶ Uncomplicated pneumothoraces will reabsorb at a rate of 2% of the volume of the hemithorax every 24 hours.⁷ For patients with a large PSP or patients experiencing significant symptoms, needle aspiration or SBCT are the recommended treatments. In a study of 60 patients, needle aspiration and small bore catheters had similar failure rates but patients undergoing needle aspiration were hospitalized less.⁸ In addition, studies have demonstrated that small catheters are well tolerated and as effective as large bore chest tubes (LBCT).⁹ All individuals should have a follow-up within 2 to 4 weeks and avoid all air travel until full resolution of the pneumothorax is confirmed.

Secondary spontaneous pneumothorax (SSP), in contrast to PSP, occurs in patients with underlying lung pathology. Patients with a SSP are likely to have worsened clinical symptoms than patients with a PSP. Patients with SSP should be admitted to the hospital and most will require intervention. SBCT have been found to be as effective as LBCT and are thus recommended.¹⁰ It is largely recommended that these patients be admitted but in some circumstances, patients may be discharged home with a Heimlich valve and follow-up within 2 days.³ If an air leak persists beyond 2 to 4 days, a thoracic

surgeon should be consulted for consideration of further intervention.^{3,4}

Provoked or traumatic pneumothoraces can occur from blunt or penetrating injuries or from barotrauma. In the case of trauma victims, the number of pneumothoraces being identified has increased with the availability and ease of CT scanning and bedside ultrasonography. Many of these are considered occult pneumothoraces (OP), defined as a pneumothorax identified on CT or ultrasound, which was not suspected on the preceding chest radiographs. Most experts agree that OP in clinically stable patients can be managed conservatively with observation.¹¹⁻¹⁴ For patients with OP undergoing positive pressure ventilation (PPV), however, there remains controversy regarding whether or not to intervene. The traditional teaching was to perform tube thoracostomy on patients with occult pneumothorax if they were to undergo any period of PPV, including both prolonged mechanical ventilation during an ICU stay or for a limited time under general anesthesia.¹⁵ Recent literature, however, has shown that careful observation and directed intervention when needed of an OP may be safe and there is no difference in mortality or morbidity for these patients.¹³⁻¹⁶ For patients chosen for tube thoracostomy, the historical teaching has also been to place a LBCT but recent literature has shown that in many situations, SBCT are considered safe and effective.¹⁷

The most feared complication of pneumothorax is that it will progress to tension physiology. Tension pneumothorax occurs when there is a disruption in the visceral or parietal pleural or tracheobronchial tree. A one-way valve forms, which allows air to flow into the pleural space with inhalation and prohibits air from flowing out. With each breath, the volume of air in the intrapleural space and pressure within the hemithorax increases. As the pressure increases, the ipsilateral lung collapses and causes hypoxemia. Eventually, the mediastinum will shift toward the contralateral side and impair the venous return to the heart, causing cardiovascular collapse. The treatment is immediate decompression. The historical treatment for a tension pneumothorax is immediate needle decompression in the second intercostal space at the midclavicular line and subsequent tube thoracostomy. However, many studies have shown that the suggested 14-gauge needle for needle

decompression is not long enough to penetrate the chest wall in many patients at this location.¹⁸ Alternative approaches for needle decompression are at the fifth intercostal space in the anterior axillary line where the chest wall is generally thinner.¹⁹ Studies have also shown that needle decompression is associated with failure rates as high as 58%.²⁰ Despite this evidence, needle decompression is still recommended as first line treatment for tension pneumothorax followed by tube thoracostomy.

Hemothorax

Hemothorax is the accumulation of blood in the pleural space. Although the majority of hemothoraces occur as a result of trauma, some do occur in the ICU spontaneously. Also, they may arise as complications from procedures such as thoracentesis and central venous catheterization. These occur due to injuries to the intercostal or internal mammary arteries or pulmonary parenchyma. For traumatic hemothoraces, most surgeons recommend early (within 7 days) drainage of the hemothorax using large bore tubes (36F-42F). If the initial blood drainage is > 1500 mL or > 250 mL/h, surgery may be indicated. Complications such as fibrothorax and empyema can complicate hemothoraces that are not fully drained.

Pleural Effusion

Pleural effusions are abnormal, excessive fluid collections in the pleural space. The differential diagnosis of a pleural effusion is wide and occurs in many

conditions, not exclusive to the thoracic cavity. For example, 20% of patients with pancreatitis have accompanying pleural effusion.²¹ Pleural effusions are divided into two types: transudative and exudative. Transudative effusions develop when systemic factors affecting the formation and absorption of the pleural fluid are altered, causing the pleural fluid to accumulate.²² Conditions where transudative effusions form are with increased interstitial fluid (heart failure), increased peritoneal fluid (cirrhosis), and decreased serum oncotic pressure (hypoproteinemia). Exudative effusions, conversely, develop due to the local alteration of the pleural surfaces or capillaries causing fluid to accumulate. The most common causes of exudative effusions are pleural malignancies, infection, and pulmonary embolism.

Traditionally, supine chest radiograph has been used in critically ill patients to identify acute processes such as pleural effusions. This modality, however, has a low sensitivity and specificity and can often miss large effusions. CT scanning is an excellent tool for identifying and characterizing lung, mediastinal, and pleural disease and quantifying the pleural fluid. Often, initial CT scanning has been replaced by bedside ultrasonography. This modality is noninvasive, low risk, and can be repeated as much as necessary. It can be used to evaluate the pleural space for fluid and often can characterize the complexity of the pleural space. In the hands of a trained user, it is highly sensitive and specific and can identify as little as 5 mL of pleural fluid.²³

Figure 94–1 shows ultrasound images of a simple versus complex pleural effusion. If a pleural effusion

FIGURE 94–1 Ultrasound of the right chest showing a pleural effusion marked with *. The image on the left shows a simple effusion while the image on the right demonstrates a complex effusion.

is identified and if clinically indicated, a thoracentesis and/or tube thoracostomy should be done guided by bedside ultrasonography. For patients with pleural effusion and continued respiratory compromise, drainage of pleural effusions has shown to lead to quick symptomatic improvement in many patients.²⁴

Pleural Infections

Parapneumonic effusions are any pleural effusion secondary to pneumonia or lung abscess.² Parapneumonic effusions represent a range of disease beginning with a dynamic, often self-resolving exudative effusion to a complex multiloculated fibrotic and often purulent collection to a thick pleural peel. Patients with pneumonia with an associated parapneumonic effusion have a higher morbidity and mortality than patients who have pneumonia without an effusion.²⁵ Although most simple parapneumonic effusions resolve with antibiotics, about 10% proceed to empyema and fail medical therapy.² When the effusion worsens, bacteria will cross the damaged endothelium and propagate pleural inflammation. Neutrophils then migrate into the pleural space and the coagulation cascade will be altered, decreasing fibrinolytic activity, causing septations to form within the fluid. Following this, fibroblasts will proliferate and a solid fibrous pleural peel will form over the lung and re-expansion is prevented, creating a persistent pleural space for continued infection.²⁶

For patients with parapneumonic effusions, the current recommendations are to perform a diagnostic thoracentesis to evaluate for empyema.²⁷ If the diagnostic testing reveals a fluid with a pH < 7.2, LDH > 1000, or a glucose < 60 mg/dL, drainage with tube thoracostomy may be indicated. For drainage of an empyema, LBCT are typically used because smaller pigtail catheters have a higher propensity for becoming clogged or dislodged.²⁸ For patients with continued symptoms, fibrinolytic enzymes may be attempted followed by consultation with a thoracic surgeon for resection and open drainage or decortication as indicated.

Chylothorax

Chylothorax is a collection of lymphatic fluid in the pleural space. It occurs due to malignancy, congenital abnormalities or injury to the thoracic duct

or one of its main branches due to trauma or iatrogenically during a surgical procedure. Diagnosis is made by fluid analysis showing triglyceride level greater than 110 mg/dL or a cholesterol-to-triglyceride ratio of less than 1.²⁹ Treatment, again, depends on the clinical situation. Most patients require initial drainage due to the large volume (2-4 L/d) of chyle produced. Other strategies range from dietary restrictions to surgery.

CONTRAINDICATIONS

When performing tube thoracostomy, landmark anatomy and bedside ultrasound is generally sufficient for placement. In some instances, however, CT mapping may be indicated. For example, patients with bullous lung disease may be misdiagnosed as a pneumothorax and tube thoracostomy in these patients may cause prolonged air leak from a bronchopleural fistula. For patients who have undergone procedures such as pleurodesis, pleurectomy, and previous thoracotomy, consider CT scanning prior to non-emergent tube thoracostomy to help with directing the tube.⁴ Also, patients who have had significant blunt abdominal trauma may be at risk for diaphragmatic injury and again, if the procedure is not emergent, further workup may be indicated.

ULTRASOUND EVALUATION

Ultrasound is a valuable tool when evaluating the thoracic cavity for pathology as well as real-time direction during the procedure. A recent meta-analysis concluded that chest radiography is 39.8% sensitive and 99.3% specific in diagnosing pneumothorax whereas ultrasound is 78.6% sensitive and 98.4% specific.³⁰ For pleural effusions, ultrasound can help identify the size and characterization of the effusion and localize an area acceptable for tube thoracostomy. Whenever available, bedside ultrasound should be used to identify and map the thoracic anatomy and pathology.

SETUP

Prior to attempting any procedure, it is advisable to review the patient's previous imaging and laboratory results. Appropriate consent should be

TABLE 94–3 Equipment.

Sterile gloves
Sterile gown

Guidewire with dilators (optional)
Trocar (optional)
Chest tube
Suture
Closed drainage system
Dressing
Silk tape

obtained, when possible. Benefits and risks should be discussed and possible complications should be explained. The patient should be properly pretreated for pain and anxiety associated with the procedure. All of the appropriate equipment should be gathered and a time out should be performed before beginning. See Table 94–3 for a list of common items required at the bedside.

TECHNIQUE

For the mid-axillary approach, place the patient supine, in a position of comfort and place the ipsilateral arm above the head. The BTS guidelines recommend placement of the tube in the “safe triangle” consisting of the anterior border of the latissimus dorsi, the lateral border of the pectoralis major muscle, a line superior to the horizontal level of the nipple, and an apex below the axilla.³¹ Identify and mark the fourth and fifth intercostal spaces. For the mid-clavicular approach, place the patient supine, in a position of comfort. Identify and mark the second intercostal space at the mid-clavicular line.

Using sterile technique, prepare the area with either iodine or chlorhexadine. Infiltrate a 2 to 3 cm wheal one rib space below your mark with 1% lidocaine. Entering below and angling up will create a subcutaneous tunnel that will discourage air

entry into the chest after removal of the tube. Angle the needle cephalad and infiltrate deeper tissues with the lidocaine, aspirating with each advance of the needle to avoid intravascular administration. Once the tip of the needle is over the chosen intercostal space being entered, angle the needle more perpendicular to the chest wall. Continue advancing the needle and anesthetizing until aspiration generates fluid or air, at which point the needle has entered the pleural space. Infuse the remaining lidocaine into the pleural space being careful not to exceed the subcutaneous toxic dose of lidocaine (3-5 mg/kg).

When entering into the thoracic cavity, you must pass first through skin and subcutaneous tissue then through three layers of muscle before entering the parietal pleura. Care must be taken to avoid the intercostal neurovascular bundle that runs inferior to each rib. Traditional teaching has been to place the tube just superior to the rib, however, recent studies show that the anatomy of the intercostal spaces is variable and the tube should be placed in the lower half to two-thirds of the intercostal space.³²

Blunt Dissection Technique

After the patient has been adequately anesthetized as above, make a 2 to 3 cm incision superior and parallel to the rib. Create a short tunnel using blunt dissection with Kelly clamps, following the previously anesthetized path. Once the parietal pleura is encountered, carefully push the closed clamps through the pleura; this may require some force. Once in the pleural space, do not advance more than 1 cm past the parietal pleura to avoid potential damage to the lung. Widen the pleural defect to accommodate the tube by spreading the clamps to create a defect approximately 1 to 2 cm long. This may cause a gush or air or fluid from the pleural space. Remove the clamps and insert a finger into the pleural space and explore the anatomy, feeling for the lung surface and adhesions. Loose adhesions may be broken, but avoid breaking strong adhesions since this may generate bleeding. Grasp the end of the chest tube with the clamp and gently guide the tube into the pleural space with a finger. Once the tube is in the pleural space, remove the clamp and advance the chest tube. For pneumothorax, advance the tube anteriorly and

apically. For pleural effusions, aim the tube basally. Advance the tube until all side ports are within the pleural space. Attach the tube to the closed drainage system and secure into place.

Trocar Technique

This technique involves the use of a sharp tipped rod (trocar) that is inserted into the chest tube prior to placement. A skin incision is made similar to the blunt technique and the trocar/chest tube combination is pushed into the pleural space. Care must be taken not to advance the trocar more than 1 to 2 cm into the pleural space to avoid damage to the intrathoracic organs. The chest tube is then slid off the trocar and left in the pleural space. Since this technique has been associated with increased complication rate, it is generally not recommended for routine situations.

Seldinger Technique

An alternative, often less painful technique, is the Seldinger technique involving a guidewire and serial dilation. Techniques may vary slightly based on kit used. After anesthetizing the subcutaneous tissues as above, make an incision in the skin one rib space below the desired intercostal entry space. Make the incision large enough to accommodate the size of the chosen drain. Following the path of anesthetic, advance the introducer needle and syringe into the pleural space while continuously aspirating until air or fluid is aspirated without resistance. Do not advance the needle more than 1 cm past the parietal pleura. Remove the syringe while anchoring the needle in the pleural space. Pass the guidewire through the needle hub and into the pleural space. The guidewire should pass freely without resistance. While holding the guidewire, remove the needle. Dilate the tract with the dilator(s) included in the kit. Only dilate to 1 cm past the parietal pleura. Advance the chest tube into the pleural space over the guidewire, ensuring that all side ports are within the pleural space. Some kits may include an introducer or trocar; pass these cautiously into the pleural space to avoid parenchymal damage. Remove the guidewire and introducer or trocar if included. Attach the tubing to the closed drainage device and secure the tube in place.

Securing the Tube

There are various methods of securing the tube at the site of insertion; none have been compared for failure or complication rate. Mattress sutures with securing ties are often utilized when securing LBCT. Purse string sutures are not recommended because they have been found to be painful and can cause additional scarring.³¹ Suture-free holding devices also exist. The tube should be secured to the drainage tubing with silk tape. The insertion site should be covered with sterile or petroleum gauze and taped securely to the patient. Avoid excessive taping or bandage because this may have a restrictive quality on the thoracic wall. Additionally, this may impede the speed that a malfunctioning tube can be evaluated.

Postplacement Management

After placing the tube, a chest radiograph or a lung/pleural ultrasound should be performed. Most chest tubes are designed with a radiopaque strip on the side of the tube to assist in visualization on chest radiographs. The sentinel eye is the most proximal side port; it will appear as a defect in the radiopaque strip. The sentinel eye should be located within the chest cavity.

The chest tube is connected to a closed drainage systems that acts as a one way valve to free air from the pleural space, collect any pleural fluid, and create negative pressure in the pleural space. Most drainage systems use three chambers based on previous three bottle systems. The first chamber is the collection chamber for any fluid drained from the pleural space. For hemothorax, initial blood drainage of > 1500 mL or drainage of > 250 mL/h at any time requires emergent thoracic surgery consult and/or open thoracotomy. The second chamber is the water seal that acts as a one way valve. Air in the pleural space will appear as bubbles in the fluid; this is known as an air leak. When performing tube thoracostomy for pneumothorax, an air leak should be expected until the lung fully expands. If an air leak is persistent, surgical consultation may be required. The last chamber regulates the negative pressure being applied to the pleural space.

Frequent monitoring of the tube as well as the drainage system is required. The chamber should

always be placed upright and should always be placed below the level of the patient. Monitor the fluid in the tubing for fluctuations during respiration or coughing, this indicates tube patency and placement in the pleural space. Cessation of this “tidaling” may indicate blockage or dislodgement of the tube.

Patients who develop excessive coughing, shortness of breath or chest pain as the pleural space is being drained may have re-expansion pulmonary edema. Temporarily stopping further drainage will be the best management.

Prophylactic antibiotics are recommended for trauma-related thoracic injuries requiring tube thoracostomy.³³ For patients with spontaneous pneumothorax or pleural effusions not related to an infection, antibiotics are not recommended.

Removal of Chest Tubes

Removal of a chest tube is usually a multifactorial decision based on the patient’s clinical condition and on the performance of the chest tube. Multiple studies have shown that chest tubes placed after surgery, for hemothorax and for pleural effusions can be safely removed when the drainage is less than 200 mL/d.³⁴ For pneumothorax, once there is no longer an air leak and the lung is fully expanded, the chest tube can safely be removed.³⁵ A step-wise practice can also be utilized by first taking the tube off of suction and placing the tube to water seal. If the patient is clinically stable, the tube can then be clamped. If the patient tolerates this and there is no change in chest radiograph, the chest tube can be safely removed. Clamping a chest tube once the air leak has resolved can often detect a small air leak not readily apparent at the bedside. Clamping of a chest tube with an active air leak is never recommended because of the potential for tension physiology to form.

When the clinician decides to remove a chest drain, the patient should be placed supine and in a position of comfort. The bandages should be removed and the sutures should be cut. The tube should be pulled out in one fluid movement. Traditionally, the teaching has been to pull the tube at end expiration or while the patient performs the valsalva maneuver to avoid recurrent pneumothorax. However, in a trial of removal of the tube during inspiration versus at end expiration while performing a

valsalva maneuver, there were similar rates of recurrent pneumothorax.³⁶

COMPLICATIONS

Tube thoracostomy is a highly effective, and often life-saving technique but it is also associated with a complication rate as high as 30%.³⁷ The most common complications include malposition, blockage, infection, dislodgement, re-expansion pulmonary edema, subcutaneous emphysema, nerve injuries, intrathoracic organ injuries, and residual pneumothorax. Less commonly, reports of esophageal perforation, cardiac injury, large vessel injury, chylothorax, fistula formation, and Horner syndrome have all been reported. Many of these complications can be avoided by adequate anxiolytics and analgesia, appropriate training and supervision, adequate technique and use of ultrasound guidance, and proper sterile technique. The most common complication is tube malposition where the tube is placed into somewhere other than the pleural space, including the lung parenchyma, lung fissures, into the chest wall, into the mediastinum, and into the abdomen.³⁷ The most common site of malposition is in the fissure and the greatest risk factor for this complication is lateral placement.

If fluid within the tube fails to fluctuate with coughing or respiration, the tube should be

TABLE 94–4 Troubleshooting common problems.

Problem	Cause (solution)
No further drainage	Lung fully expanded Tube blocked Tube kinked
No tidaling	Lung fully expanded Chest tube not in pleural space Chest tube blocked
Prolonged air leak	Bronchopleural fistula (consult thoracic surgery to consider surgical or endoscopic therapies)
Increased air leak	Chest tube holes may be outside pleural cavity (remove chest tube and place new tube if indicated) Disconnection

examined for a blockage or kinking tube. It is a common practice to milk or strip the tubes to clear the clot or debris. Although this practice is often effective in clearing the debris, this practice is controversial because it theoretically could cause damage to the lung tissue due to negative pressure.³⁷ Flushing with sterile saline every 6 to 8 hours can be considered as a method to prevent blockages.

Critical Care Echocardiography 95

Yonatan Y. Greenstein, MD and Paul H. Mayo, MD, FCCP

KEY POINTS

- 1 The frontline intensivist uses echocardiography on a routine basis to aid in the diagnosis and management of patients with hemodynamic failure.
- 2 Critical care echocardiography (CCE) is divided into basic and advanced levels of competency, with this chapter focusing on the fundamentals of basic CCE.
- 3 The basic CCE examination comprises five standard transthoracic echocardiography (TTE) views: PSL, PSS, AP4, SCL, and IVC longitudinal axis.
- 4 The intensivist performing basic CCE is capable of acquiring and interpreting the necessary images, has a strong foundation in the cognitive aspects of CCE, and understands the pitfalls inherent to the various echocardiographic views.
- 5 Transesophageal echocardiography may be used within the scope of the basic CCE. It is typically used when TTE image quality is suboptimal.

INTRODUCTION

Echocardiography has major applications in the intensive care unit (ICU) for rapid assessment of the patient with hemodynamic failure. Critical care echocardiography (CCE) is an essential skill for the frontline intensivist. This chapter will review key aspects of CCE with emphasis on the basic CCE examination.

LEVELS OF COMPETENCE

The American College of Chest Physicians/Société de Réanimation de Langue Française (ACCP/SRLF) statement on competence in critical care ultrasonography divides CCE competency into basic and advanced levels.¹ Basic CCE requires competence in a limited number of transthoracic echocardiography

(TTE) views with an option to use limited transesophageal echocardiography (TEE). Basic CCE is a fundamental skill for all intensivists, and requires a relatively short training period. Competence in advanced CCE requires the intensivist to have a skill level comparable to a cardiology trained echocardiographer in both TTE and TEE, and requires a long training period by comparison to basic TTE.²⁻³ Only a small proportion of intensivists need this level of skill, so this chapter will focus on basic CCE. The Accreditation Council of Graduate Medical Education has recently established that knowledge of critical care ultrasonography is a mandatory component of critical care fellowship training in the United States.⁴ Within a few years, all graduating fellows will be competent in this essential skill; attending level intensivists will need to develop competence in basic CCE as well.

TABLE 95–1 Required cognitive skills in image interpretation for basic CCE

Global LV/RV size and systolic function
LV contraction pattern
Echocardiographic patterns
Assessment for pericardial fluid/tamponade
IVC size and respiratory variation
Basic color Doppler assessment for severe valvular regurgitation

TRAINING

Competence in basic CCE requires training. Non-cardiologists can become competent in basic CCE.⁵ Exact requirements for training methods have not been standardized, but a recent statement suggests that basic CCE training include at least 10 hours of course work (comprised of lectures, didactic cases, and image interpretation) and a minimum of 30 fully supervised TTE studies (image acquisition and interpretation).² While these numbers offer some guidance, they do not guarantee that the trainee is sufficiently trained. Competency based testing at the end of the training period provides assurance that the clinician has achieved the requisite skill. Competence in basic CCE includes the ability to acquire and interpret the necessary images, but also mastery of the cognitive elements of the field (Table 95–1). Key clinical syndromes and their associated CCE findings are summarized in Table 95–2.

THE BASIC CCE EXAMINATION

The ACCP/SRLF Statement on Competence defines the basic CCE examination as including five standard views: parasternal long-axis (PSL) view, parasternal short-axis (PSS) midventricular view, apical four-chamber (AP4) view, subcostal long-axis (SCL) view, and inferior vena cava (IVC) longitudinal axis view. There are several methods described for the performance of a goal directed cardiac examination that have a variety of acronyms. They all have in common a limited number of views designed to rapidly assess cardiac anatomy and function in the patient with hemodynamic failure.

TABLE 95–2 Key clinical syndromes.

Recognition of Clinical Syndromes	Key CCE Findings
Hypovolemic shock	End-systolic effacement of the LV; small IVC with significant respiratory variation
Cardiogenic shock	Global LV systolic dysfunction
Obstructive shock from massive pulmonary embolism	RV dilation
Tamponade	Pericardial effusion plus RA/RV diastolic collapse; dilated IVC
Acute massive left-sided valvular regurgitation	Large color Doppler regurgitant jet
Circulatory arrest during resuscitation	Asystole

CCE= critical care echocardiography; LV= left ventricle; RV= right ventricle; RA= right atrium; IVC= inferior vena cava.

Acquiring adequate CCE views is often challenging due to the nature of ICU patients. Imaging conditions may not be optimal due to the presence of equipment at the bedside and poor lighting conditions. Electrodes and wires may need to be repositioned to allow for optimal placement of the probe. Ribs and aerated lungs do not allow the transmission of ultrasound, and thus can obscure TTE windows. Left-arm abduction may increase the size of the intercostal space, and placing the patient in the left lateral decubitus position may move the heart laterally from behind the sternum making image acquisition easier; however, this may be difficult in the critically ill patient. Image quality may be suboptimal in the obese, edematous, or muscular patient. Frequently, some views may not be obtainable, so every examination must include an attempt at all views. For this reason, the examiner should establish a set scanning routine that includes the same sequence in every patient, as well as a methodical approach to interpreting each image.

With modern-generation portable ultrasonography machines, most medical ICU patients will yield serviceable images. In some situations, image acquisition may not be successful, for example, in the patient who is morbidly obese or following cardiac surgery. In this case, TEE may be required.

TRANSTHORACIC ECHOCARDIOGRAPHY PROBE SELECTION

A convex probe with a small footprint capable of imaging at frequencies between 2.5 and 5 MHz should be used. Harmonic imaging is a preferred feature, which enhances image resolution. The image orientation marker is set in the upper right of the screen.

THE STANDARD VIEWS (TABLE 95–3)

Parasternal Long-Axis View

The transducer is placed in the left 3rd or 4th intercostal space adjacent to the sternum with the orientation marker pointing towards the patient's right shoulder (Figure 95–1). The probe position is adjusted in order to line up the aortic valve (AV), mitral valve (MV), and the largest left ventricular (LV) areas (Figure 95–2).

This view allows for assessment for pericardial effusion, LV/RV size and function, septal kinetics, and valve anatomy. Pitfalls inherent to this view include underestimation of RV size, inaccurate assessment of LV size and function with off-axis

FIGURE 95–1 Parasternal long-axis view—probe positioning.

views (false end-systolic effacement), and underestimation of regurgitant jets with color Doppler.

Parasternal Short-Axis at the Mid-Ventricular Level

From the parasternal long-axis view, the transducer is rotated 90° clockwise without angulation or tilting (Figure 95–3), resulting in a cross-sectional view of the heart at the midventricular/papillary muscle level with the orientation

TABLE 95–3 Utility and pitfalls of basic critical care echocardiography (CCE) views.

Mandatory Views	Utility	Pitfalls
Parasternal long axis	Assessment for pericardial effusion; LV/RV size and function; septal kinetics	Underestimation of RV size; inaccurate assessment of LV size and function with off-axis views; underestimation of regurgitant jets with color Doppler
Parasternal short axis at the mid-ventricular level	Assessment for pericardial effusion; LV/RV size and function; septal kinetics	Inaccurate assessment of LV if off-axis view obtained; difficulty to visualize RV free wall
Apical four chamber	Assessment of LV/RV size and function, particularly identifying RV enlargement by the RV/LV ratio. Assessment of pericardial effusion	Difficult to obtain an on-axis image, which can result in inaccurate assessment of LV/RV size and function and an incorrect ratio
Subcostal four-chamber	Preferred view in a cardiac arrest and often the best view on a mechanically ventilated patient. Assessment of LV/RV size and function, RV/LV ratio	Inaccurate assessment of cardiac structures when view is off-axis
Inferior vena cava longitudinal view	Determination of preload sensitivity in a hypotensive patient	Misidentification of the aorta for the IVC; off-axis view; translational artifact

CCE = critical care echocardiography; LV = left ventricle; RV = right ventricle; RA = right atrium; IVC = inferior vena cava;

FIGURE 95–2 Parasternal long-axis view. LV= left ventricle; LA= left atrium; LVOT= left ventricular outflow tract; RVOT= right ventricular outflow tract;

marker pointing towards the patient's left shoulder (Figure 95–4).

This view allows for assessment for pericardial effusion, LV/RV size and function, and septal kinetics. Pitfalls inherent to this view include inaccurate assessment of the LV if off-axis views are obtained (ie, imaging the apex of the LV can create false end-systolic effacement and overrotation of the transducer may result in septal fattening).

Apical Four-Chamber View

The transducer is placed on the lower lateral chest with the orientation marker pointed towards the patient's left shoulder and the tomographic plane adjusted to

FIGURE 95–3 Parasternal short-axis view—probe positioning.

FIGURE 95–4 Parasternal short-axis view. LV= left ventricle; RV= right ventricle;

bisect the anatomic apex of the LV and the two atria (Figures 95–5 and 95–6). This view is best achieved with the patient in the left lateral decubitus position.

This view allows for assessment of LV/RV size and function, particularly identifying RV enlargement by the RV/LV ratio, and for assessment for pericardial effusion. Pitfalls inherent to this view include difficulty obtaining an on-axis image, which can result in inaccurate assessment of LV/RV size and function and an incorrect RV/LV ratio.

Subcostal Long-Axis View

The transducer is placed just below the xiphoid process with the orientation marker pointing towards

FIGURE 95–5 Apical four-chamber view—probe positioning.

FIGURE 95–6 Apical four-chamber view.
LV= left ventricle; LA= left atrium; RV= right ventricle;
RA= right atrium;

FIGURE 95–8 Subcostal long-axis view.
LV= left ventricle; LA= left atrium; RV= right ventricle;
RA= right atrium;

the 3 to 4 o'clock position and the tomographic plane adjusted to bisect the LV and left atrium (LA). The transducer must be held at the top of its surface in order to allow it to lay as flat as possible on the patient's abdomen ([Figures 95–7](#) and [95–8](#)).

This is often the best view on a mechanically ventilated patient as the liver serves as an acoustic window to the heart and the ultrasound is not blocked by an aerated lung. This view allows for assessment for pericardial effusion, LV/RV size and function, and the RV/LV ratio. This view is the best for a rapid assessment of cardiac function during pulse checks when performing cardiopulmonary

resuscitation. Pitfalls include inaccurate assessment of cardiac structures when the view is off-axis.

Inferior Vena Cava Longitudinal View

From the SCL view, the transducer is rotated counterclockwise 90°, tilted inferiorly, and angled laterally to visualize the IVC in the longitudinal axis ([Figures 95–9](#) and [95–10](#)).

This view allows for assessment of preload sensitivity in a hypotensive patient and when assessing a patient for the presence of pericardial tamponade. Pitfalls inherent to this view include the misidentification of the aorta for the IVC, off-axis view of the

FIGURE 95–7 Subcostal long-axis view—probe positioning.

FIGURE 95–9 Inferior vena cava longitudinal view—probe positioning.

FIGURE 95–10 Inferior vena cava longitudinal view. RA = right atrium; IVC = inferior vena cava.

IVC, and translational artifact mimicking respiratory variation of the IVC.

CLINICAL APPLICATIONS OF BASIC CCE

CCE differs from standard cardiology style echocardiography in that the intensivist personally performs and interprets the examination at point of care and integrates the results into the overall clinical assessment and management plan. The examination is limited in scope and may be repeated as often as needed to track response to therapy and the evolution of illness. This avoids the problems inherent to standard cardiology style echocardiography in the ICU: the delay between ordering and obtaining the study, the time gap before the image is interpreted, the clinical dissociation between the image interpreter from the clinical reality at the bedside, the perception that a full study is required in all circumstances, and the resistance to the performance of repeated study in close succession while the patient is in the ICU.

The basic CCE examination, being performed by the clinician in charge of the case, is always combined with the history, the physical examination, other imaging studies, and laboratory analyses. It is not performed in vacuo. When combined with other elements of critical care ultrasonography, Volpicelli et al achieved near perfect concordance with final diagnosis of the cause for shock using an approach that included basic CCE.⁶ Laursen et al report similar results with focused ultrasonography diagnosing

previously missed life-threatening conditions.⁷ The basic CCE examination may be performed in two to three minutes. When combined with other aspects of critical care ultrasonography, Volpicelli required on average 4.9 minutes to perform an ultrasonography examination, which included basic CCE. Given its ease of use and demonstrated diagnostic utility, the basic CCE examination should be a standard part of the evaluation of every patient with hemodynamic failure. It can be productively combined with other aspects of critical care ultrasonography.

In performing the basic CCE examination, the intensivist needs to consider the following questions:

1. Is there an imminently life-threatening cause for the shock such as cardiac tamponade, marked hypovolemia with an empty ventricle, massive valvular failure, or acute right heart failure?
2. What is the category of shock? Is it hypovolemic, obstructive, cardiogenic (valvular or pump failure), or vasoplegic?
3. What is the best initial management strategy? Does the patient need fluids, inotropes, vasopressors, mechanical assist, thrombolytics, surgery, or another intervention?
4. Is there more than one cause for the shock state or a coexisting condition that will complicate management of the primary cause such as sepsis with aortic stenosis, preexisting LV failure, or pulmonary arterial hypertension with a myocardial infarction?
5. What are the results of repeated CCE studies during the course of treatment? For example, is there improvement in global LV systolic function with treatment of a sepsis induced cardiomyopathy or unloading of the RV with decreasing levels of positive-end expiratory pressure as a patient's acute respiratory distress syndrome improves?

KEY ASPECTS OF THE BASIC CCE EXAMINATION

Global LV Systolic Function

The intensivist who performs basic CCE needs to assess global LV systolic function. Systolic function can be characterized qualitatively as: severely

reduced, moderately reduced, normal, or hyperdynamic.⁸ Qualitative assessment of LV function is useful for determining a management strategy for the patient with shock, that is, to guide the use of inotropes and/or volume resuscitation. Useful examples of video clips demonstrating degrees of LV dysfunction can be found at www.critcaresono.com. For the purposes of managing an unstable patient in shock, hyperdynamic is defined by end-systolic effacement of the LV cavity. Reduced diastolic excursion of the anterior leaflet of the MV is associated with severely decreased LV function. LV function is best assessed with the PSL view and its orthogonal view, the PSS view at the papillary muscle level. Detailed segmental wall motion analysis is beyond the scope of basic CCE.

Acute Right Heart Failure

There are two findings with basic CCE, which support the diagnosis of right heart failure.⁹ Flattening of the interventricular septum during systole is characteristic of RV pressure overload. This is best identified in the PSS view and results in a D-shaped LV (Figure 95–11). Dilatation of the RV is characteristic of RV diastolic overload. This is best identified by comparing the size of the RV and LV at end diastole in the AP4 or SCL views. An RV/LV ratio < 0.6 is normal, between 0.6 and 1 is moderate dilatation, and ≥ 1 is severe RV dilatation (Figure 95–12). Qualitative visual assessment of the ratio is as

FIGURE 95–11 Right ventricular pressure overload—parasternal short-axis view.
LV= left ventricle; RV= right ventricle;

FIGURE 95–12 Right ventricular volume overload—apical four-chamber view.
LV= left ventricle; LA= left atrium; RV= right ventricle; RA= right atrium;

accurate as quantitative planimetry measurement.¹⁰ Normal RV free wall thickness is $3.3 \text{ mm} \pm 0.6 \text{ mm}$. Dilatation of the RV in the setting of normal RV free wall thickness supports an acute process, whereas a thickened RV free wall is likely secondary to a subacute or chronic process.

Pericardial Tamponade

Pericardial tamponade remains a clinical diagnosis and the echocardiographic features associated with it support the diagnosis in the appropriate clinical setting. A pericardial effusion is identified as an echo-free space surrounding the heart. Care must be taken to distinguish a pleural effusion from a pericardial effusion. A pericardial effusion is located anterior to the descending thoracic aorta compared to a pleural effusion which is located posterior to the descending thoracic aorta. Figure 95–13 demonstrates a PSL view of a patient with both a pericardial and pleural effusion.

Pericardial tamponade is associated with a dilated IVC without size variation in the respiratory cycle; swinging of the heart within the large pericardial effusion is characteristic as well. Early diastolic right atrial (RA) collapse has a sensitivity and specificity for tamponade of 92% and 100%, respectively, and occurs earlier than RV diastolic collapse, which carries a sensitivity of 64% and specificity of 100%.¹¹

FIGURE 95–13 Pericardial and pleural effusion—PSL view.

LV= left ventricle; LA= left atrium; LVOT= left ventricular outflow tract; RVOT= right ventricular outflow tract;

Assessment of Preload Responsiveness

Inferior vena cava size and its respiratory variation may predict fluid responsiveness in the patient with shock. Acquiring a longitudinal view of the IVC and placing an M-mode scan line through it allows the examiner to measure the size of the IVC during inspiration and expiration (**Figure 95–14**). Using the IVC size and its respiratory variation to assess fluid responsiveness in passively breathing mechanically ventilated patients is well established.^{12–14} Respiratory variation cutoff

FIGURE 95–14 Inferior vena cava size and respiratory variation—M-mode.

IVC= inferior vena cava.

values of 12% (by using max – min/mean) and 18% (by using max – min/min) separates fluid responders from nonresponders. Data for assessing preload responsiveness in the spontaneously breathing patient are less robust. Expert opinion suggests that if the IVC diameter is < 1 cm, there is a high likelihood of fluid responsiveness; and if the diameter is > 2.5 cm, there is a low probability of fluid responsiveness.¹⁵

Valve Function and Pathology

Basic CCE allows the intensivist to identify major valve abnormalities that are visible on 2D imaging such as papillary muscle or chordal ruptures, severe aortic stenosis, or large valvular vegetations. Skill at color Doppler analysis of valve function is within the scope of basic CCE; however, more sophisticated Doppler analysis is not. If the clinician suspects significant valve pathology, an advanced CCE examination may be required.

LIMITATIONS OF BASIC CCE

1. Competence in basic CCE requires adequate training. The results of basic CCE may have major implications for the diagnosis and management of the critically ill patient, so it is incumbent upon the intensivist to have a high level of skill. To some trainees, skill at basic CCE appears easy to acquire. This is not the case. The training sequence should include multiple studies initially on normal subjects and then progressing to patients. Recent technological advances now allow trainees to learn on high fidelity TTE and TEE simulators which have the advantage of being able to demonstrate numerous pathologies for the trainee to experience.^{16–18} The trainee should have access to a comprehensive image set that features multiple variations of normal and abnormal findings. The trainee must also master the cognitive base of the field, now widely available in articles, textbooks, and internet based resources. In order to assure proficiency, the training sequence should also include formal competency based testing.
2. By definition the basic CCE examination is limited in scope. It does not include a comprehensive image set, nor does it include

Doppler measurements. The intensivist performing basic CCE must understand and accept this limitation and know when to call for a more comprehensive study. Inherent to ICU based echocardiography are the problems related to obtaining high quality images in the critically ill. Often the images of both basic and advanced CCE would be considered inadequate in quality by cardiology standards. Despite this, the critical care clinician needs to be able to interpret and apply the results at the bedside.

3. Documentation for CCE remains a challenge. Ideally, the entire CCE examination image set should be recorded and stored in a durable and accessible format for later review, and a formal report should be entered into the patient's medical record for every study. This requires a well-designed picture archiving and communication system which is fully integrated into the portable ultrasonography machines. To compound the problem, in a busy ICU, the team may perform multiple examinations in rapid sequence in emergency situations, where documentation cannot take precedence over patient care. If the infrastructure to fully integrate CCE studies into the medical record does not yet exist at an institution, at a minimum, a short report should be entered into the medical record documenting the findings of the exam.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY AND ADVANCED CCE

A common indication for TEE in the ICU is when TTE imaging fails due to poor image quality. This may occur due to reasons of body habitus, where TTE images are simply not adequate for interpretation. TEE is also useful in the cardiothoracic ICU, where dressings, wires, and tubes block TTE studies. Depending on the clinical circumstance, the TEE examination may be a comprehensive study; alternatively, a goal directed examination with a limited number of views may suffice.¹⁹

Advanced CCE requires the intensivist to achieve competence in all aspects of echocardiography that are standard to cardiology-type echocardiography,

in addition to mastering elements of echocardiography that are particular to critical care medicine.²⁰⁻²² Competence in advanced CCE requires a long training period similar to the cardiologist who is trained in echocardiography. This includes training in TEE. The majority of intensivists do not have need for advanced level of training; as competence in basic CCE is sufficient for their clinical function. Although it is not known what proportion of intensivists should acquire skill at advanced CCE, one approach for the large ICU operation is for several team members to have advanced CCE training, whereas all other team members have basic CCE skill.

Competence in advanced CCE includes mastery of image acquisition and image interpretation of all standard echocardiography views and Doppler measurements.²³⁻²⁴ Use of Doppler allows the intensivist to determine hemodynamic function through a wide variety of pressure and flow measurements. This permits the quantitative measurement of stroke volume, cardiac output, intracardiac pressures, preload sensitivity, and valve function.

Extracorporeal Membrane Oxygenation

Muhammad Adrish, MD; Sharon Leung, MD, MS;
William Jakoblef, MD and Anthony Carlese, DO

KEY POINTS

- 1 Extracorporeal membrane oxygenation (ECMO) can provide cardiac/ cardiopulmonary support via venoarterial (VA) ECMO or pulmonary support via venovenous (VV) ECMO.
- 2 The indications typically being bridge to recovery, bridge to transplant, or bridge to decision.
- 3 Early use of ECMO showed poor response leading to a loss of interest in ECMO as a potential therapeutic modality, reappraisal of early results suggests patient selection, and technological limitations precluded successful results.
- 4 The results of the CESAR trial and H1N1 experience along with technological improvements and a general improvement in the care of critically ill patients have led to renewed interest in the use of ECMO.
- 5 Modification of cannulation options either at central or at peripheral locations can affect unloading of the heart as well as impacting the ability to oxygenate the cardiac and cerebral circulations.
- 6 Improvement in skill of critical care ultrasonography by intensivists has allowed cannulation to move from the operating room and catheterization laboratory to the bedside for VVECMO and peripherally cannulated VA ECMO.

INTRODUCTION

Extracorporeal membrane oxygenation (ECMO) is a form of partial heart–lung bypass for patients with severe but potentially reversible respiratory and/or cardiac disease who have failed conventional therapies. There are 2 basic types of ECMO: venovenous (VV), which provides the support for the lung only, and venoarterial (VA), which provides support for both heart and lung. In both modalities, blood drained from the venous system is oxygenated outside the body. VA ECMO is similar to standard cardiopulmonary bypass in that both lungs

and heart are bypassed. The purpose of ECMO is to allow time for intrinsic recovery of the lungs and/or the heart, also known as salvage therapy. It can also be used as a bridge to destination therapy such as patients waiting for heart/lung transplant or in certain instances as bridge to decision. During VV ECMO, gas exchange can be supported even in the absence of any pulmonary function but no direct cardiac support is provided. However, the cardiac functions often improve owing to increased oxygen delivery to the heart and concurrently reduced mechanical ventilation. In VA ECMO,

HISTORY OF ECMO

ECMO utilization in adults with respiratory failure dates back to 1970s. A multicenter trial evaluating prolonged venoarterial (VA) ECMO for patients with severe acute respiratory failure failed to show reduction in mortality ($> 90\%$ mortality in both groups).¹ The study was later criticized for several reasons such as premature closure, lack of established ECMO experience in some centers, exclusive use of VA ECMO, extensive blood loss during the procedure, and lack of “lung rest” ventilator settings among ECMO patients.² ECMO regained cautious attention in the 1990s after several trials showed successful application in neonates and children.³⁻⁵ In an uncontrolled study by Gattinoni and colleagues, venovenous (VV) ECMO improved survival in patients with acute respiratory failure while keeping lungs “at rest” (actual mortality 51.2% vs expected mortality 90%).⁶ A subsequent uncontrolled study involving only 10 patients showed similar results but also emphasized that ECMO should be applied early in the course of the disease.⁷ In a series of subsequent publications by Bartlett and colleagues showed that ECMO is a successful therapeutic option in patients with severe ARDS who do not respond to conventional mechanical ventilator strategy with survival in such patients in excess of 50%.⁸⁻¹⁰ H1N1 influenza emerged as a major cause of respiratory failure during the 2009 epidemic. Favorable outcomes were reported with ECMO use in several studies with survival approaching 80% in patients who were otherwise not responsive to conventional treatment.^{11,12} In a multicenter randomized controlled trial published in 2009, ECMO showed a survival benefit at 6 months.¹³ Nonetheless, results of this trial need to be interpreted with caution as all patients with ECMO were treated at a different center whereas control patients remained at referring center. More recent meta-analysis published in 2013 concluded that benefit of ECMO on hospital mortality is unclear.¹⁴ Currently, a multicenter randomized trial is underway, evaluating the impact of ECMO instituted early after the diagnosis of ARDS that is not evolving favorably after 3 to 6 hours of maximum medical treatment. (clinicaltrials.gov identifier: NCT014470703).

Clinical Use

ECMO should be considered in patients with life threatening but potentially reversible cardiorespiratory failure who do not have contraindications to extracorporeal support.

Indications

1. Respiratory indications:

A. Inability to ventilate or oxygenate patients in situations where reversal of underlying condition is expected. Some examples include:

- Pneumonia
- Pulmonary embolism
- Adult respiratory distress syndrome
- Asthma/COPD exacerbation
- Aspiration pneumonitis
- Near drowning
- Wegener granulomatosis
- Acute chest syndrome, etc
- Lung transplantation (graft failure)

B. Bridge to lung transplantation

2. Cardiac indications:

A. Patients with cardiogenic shock as manifested by inadequate tissue perfusion, hypotension and low cardiac output.

Typical etiologies include:

- Acute myocardial infarction
- Decompensated heart failure
- Peripartum cardiomyopathy
- Fulminant myocarditis
- Heart transplantation (graft failure)
- Right heart failure

B. Bridge to heart or heart–lung transplant

C. During cardiac procedures such as:

- CABG
- Aortic valve replacement

Contraindications

ECMO should not be considered for irreversible or non-acute illnesses. Some relative contraindications include:

- Contraindication to anticoagulation
- Preexisting medical conditions affecting quality of life such as advanced malignancies, advanced malignancies

- Multiorgan failure
- End-stage organ failure in a patient not a candidate for destination therapy (ECMO is never used as a destination therapy)
- Medical futility

PHYSIOLOGY OF ECMO

- VV ECMO: In VV ECMO, deoxygenated blood is drained from the cannula placed in large central vein, typically inferior vena cava (IVC), and oxygenated blood is returned through a cannula with its tip lying in or at a close proximity to the right atrium (RA). The oxygenated blood mixes with deoxygenated blood from patient's systemic venous return and therefore it is not possible to obtain normal arterial oxygen saturation especially if the lungs are not contributing to the oxygenation. Usual target for oxygen saturation in a patient on ECMO circuit is 86% to 92%. Ideally, the blood from the return cannula passes through the tricuspid valve and then into pulmonary circulation thereby avoiding recirculation through the ECMO circuit. Pulmonary arterial blood is a combination of systemic venous return and oxygenated blood from the return cannula. Preoxygenator oxygen saturation is often used as a surrogate for systemic venous oxygen saturation. As there is always some recirculation present, the preoxygenator oxygen saturation is higher than the venous oxygen saturation. Depending on the positions of cannula, a variable proportion of oxygenated blood from the return cannula enters the drainage cannula, called recirculation. Recirculation reduces the delivery of oxygenated blood into the pulmonary circulation. Recirculation is influenced by several factors such as position of the drainage and return cannula, ECMO circuit flow, intravascular volume status, cardiac output, and position of the patient. High preoxygenator saturation in combination with low systemic arterial saturation suggests clinically significant recirculation. Conversely,

low pre-oxygenator saturation along with low arterial saturation suggests that either the cardiac output is abnormally high or ECMO flow is low. High difference between the 2 variables usually suggests minimal recirculation. In the absence of an abnormally high cardiac output or hypermetabolic state, arterial oxygen saturation above 85% can be achieved with VV ECMO even in the absence of pulmonary function.

- VA ECMO: In VA ECMO, systemic venous blood drains into the circuit via a cannula placed in vena cava. The blood then passes through the pump and the oxygenator/heat exchanger prior to returning to the patient via a cannula placed in a large artery. This mode works on similar principals to cardiopulmonary bypass in that both heart and lungs are bypassed. Blood is returned to the arterial system and systemic arterial blood pressure is the sum of the ECMO circuit flow plus any ejection from the left ventricle. Likewise, systemic blood pressure is determined by the total blood flow and intrinsic arterial tone. Flow and FiO_2 of the sweep gas which controls the gas exchange by the oxygenator, it is usually the FiO_2 that determines oxygen tension and the flow which determines carbon dioxide tension. In the absence of LV function, the patient's systemic oxygenation depends on the oxygenation in the circuit. However, if there is LV function, the systemic oxygen saturation will depend upon the flow through the ECMO circuit and the amount of blood ejected by the LV. In situations where lung function is severely impaired, placing the return cannula in femoral circulation can lead to upper body hypoxemia as the proximal branches of aorta receive predominantly deoxygenated blood ejected from the LV. Arterial CO_2 tension is determined by balance between carbon dioxide production and its elimination (from the lung or by the oxygenator). It can usually be easily controlled by adjusting flow through the circuit even if the lung is severely damaged.

ECMO CIRCUIT

An ECMO circuit consists of (1) a drainage and return cannula, (2) a oxygenator/heat exchanger, (3) a blood pump, and (4) a tubing. Except for differences in the cannula, identical circuits are used for both VV and VA ECMO.

- **Oxygenator:** Membrane oxygenators can be classified by their structure as either hollow fiber or flat sheet and by their membrane as either microporous or nonmicroporous. Microporous have large number of tiny holes through which gas exchange takes place where in nonmicroporous membrane oxygenators, gas exchanges occurs through diffusion. A decade ago, most of the adult ECMO was performed by using silicone membrane oxygenators that contain nonmicroporous membrane in a rolled flat sheet construction. While having excellent biocompatibility and durability, compared to hollow fiber oxygenators, provided less efficient gas exchange and were more bulky with higher resistance and difficult to prime. Polypropylene hollow-fiber oxygenators are the standard oxygenators used during CPB. These microporous oxygenators while being highly efficient for gas exchange over short term, but over time the micropores become permeable to fluid causing plasma leaks into the gas phase and out the exhalation port. More recently a new generation of oxygenator containing nonmicroporous hollow fibers constructed of polymethylpentene (PMP) have been introduced. These oxygenators combine the durability of silicone membrane with ease of use and efficient gas exchange of hollow fiber construction. These oxygenators not only have improved durability, but also reduce the requirement of blood transfusion.
- **Blood pump:** There are two basic types of pump: (1) roller and (2) centrifugal. Roller pumps consist of flexible tubing in a curved raceway and are mounted on a rotating arm thus pushing the blood ahead. This pump is usually used with blood-filled bladder that is sited between drainage cannula and the

pump to allow continuous pumping despite changes in intravascular volume. As the drainage into the bladder occurs via gravity, these pumps must be kept below the level of the patient. Roller pumps are usually afterload independent; thus, in the presence of obstruction distal to the pump, extremely high pressures can develop leading to circuit rupture. A centrifugal pump consists of a disposable pump head with magnetically driven impeller. The impeller spins rapidly, thus creating a pressure difference across the pump head that causes blood to flow. These are small, easy-to-prime pumps and have a very low volume. The blood flow is preload and afterload dependant such that there is no fixed relation between pump speed and blood flow. For the same reason, a large rise in blood pressure may reduce the blood flow and the pump failure during VA ECMO can even cause flow reversal. Hemolysis occurs with both roller and centrifugal pumps, although it is less with centrifugal pumps.

- **Cannulae and tubing:** Adequate size cannula is essential for adequate blood flow. For most adults, drainage cannula should be 23F to 25F and return cannula should be 17F to 21F. Tubing for the adult ECMO is 3/8 inch in diameter constructed of polyvinylchloride.

INITIATION

In most ECMO centers, perfusionists provide a primed, clamped ECMO circuit into the operative field. The circuit is usually primed with crystalloids, however, for anemic patients a blood prime can be used. It is important to correctly distinguish drainage cannula from return cannula. Both limbs of the circuit are clamped and the tubing is cut 10 cm distal to the clamp. Once connected, all clamps are released except for the clamp between the pump and the oxygenator. The pump is turned on to 1000 to 1500 rpm and the last clamp is slowly released. The sweep gas should initially be set at the same flow as ECMO circuit flow and then adjusted according to PaCO₂ and pH. It is common for patients to become hypotensive once ECMO is initiated and appropriate

medications for its treatment should be available ahead of time. Patient is heparinized to achieve an activated coagulation time of 1.5 to 2.0 times the normal. Circuit flow is titrated to clinical parameters, which for VA ECMO are mean arterial pressure and arterial oxygen saturation, and, for VV ECMO are arterial oxygen saturation and oxygen saturation in the drainage cannula.

MAINTENANCE

Once ECMO is established, ventilator is set to rest settings. Typical rest ventilator settings are pressure controlled ventilation with peak inflation pressure of 20 to 25 cm H₂O, positive end expiratory pressure of 10 to 15 cm H₂O, and a respiratory rate of 4 to 8 breaths/min. Patients typically develop systemic inflammatory response in the first few days as a consequence on ongoing critical illness and blood contact with ECMO circuit. This may lead to a vasodilator shock, worsening of acute lung injury, and third space fluid losses. If SaO₂ remains low despite adequate circuit flow or if the flow is low despite adequate pump speed, flow pattern in the cannula should be checked using color Doppler with transesophageal echocardiography to rule out any obstruction. The same technique can also be used to check reversibility in the flow. Several other aspects of care need to be managed alongside the ECMO while taking care of these patients. As ECMO support for respiratory failure may extend for weeks, patient may become tolerant to benzodiazepines and opioids. Similarly, weaning off the patients from these medications could be difficult after prolonged use. Thus, administration in low doses is recommended for these medications. Some centers even wake up and extubate some patients although this can be technically challenging. Anticoagulation with unfractionated heparin is required while patient is on ECMO circuit. Patients need to be monitored for the signs of bleeding which can result from anticoagulation, thrombocytopenia (heparin-induced, sepsis), disseminated intravascular coagulation or from gastrointestinal sources. Performing coagulation studies, monitoring the blood counts, and checking a thromboelastogram (TEG) will help in diagnosing the etiology in such circumstances.

In certain instances, ECMO circuit can be run heparin free for around 48 to 72 hours.

Maintaining fluid balance is another important consideration in these patients as they often get flooded with volume during the initial resuscitation period. Thus, it is recommended to limit fluid administration and ideally maintain a negative balance even if it leads to use of vasopressors.

WEANING AND DISCONTINUATION

VV ECMO: Recovery of the pulmonary functions may take days to weeks. Signs such as improvement in oxygen saturation for a given circuit flow, progressive increase in SaO₂ above SvO₂, improving lung compliance and chest radiography. Once a patient is able to maintain a saturation of > 90% at a circuit flow of 1 to 2 L/min, weaning trial can be instituted. Circuit flow is progressively decreased while fully ventilating patient with the ventilator. Once flow is reduced to zero and patient is able to tolerate, ECMO is decannulated.

VA ECMO: Pulsatility is an early sign of recovery of myocardial function. Inotropic support is started prior to planned weaning and circuit flow are slowly reduced to 1 to 2 L/min. Echocardiography is done during the process to assess cardiac function. Once patient is stable on minimal or no support, ECMO can be discontinued. Majority of the patients who are able to be weaned of VA ECMO do so within 2 to 5 days.¹⁵

COMPLICATIONS DURING ECMO

Circuit Complications

ECMO is a complex procedure performed on critically ill patients, thus have high potential for complication.

Gas embolism:

Large negative pressure generated with the centrifugal pumps can lead to air entrainment and significant air embolism. A major obstruction in the circuit can also force the gas out solution causing

gas embolism. This complication, though life threatening, is rare and occurs in fewer than 2% of adult ECMO runs.¹⁶

Blood clots: Blood clots can occur at multiple sites in the ECMO circuit. Clot in the pump head usually results in change in sound of the pump and rising plasma hemoglobin. A clot in the oxygenator can result in increasing pressure gradient along with fall in post oxygenator PO_2 and increasing sweep gas needed to maintain $PaCO_2$. Other markers such as increasing d-dimers or fibrin degradation products can also suggest clot formation.

Loss of circuit flow: Loss or reduced flow is most commonly caused by hypovolemia. Other causes such as obstructive shock from cardiac tamponade or tension pneumothorax and malpositioned cannula can also decrease the flow. With a roller pump, a decreased flow can lead to slowing or stopping of the pump. In ECMO devices with a centrifugal pump, a decreased flow can lead to increased negative which can progress to suck down at the drainage cannula eventually causing loss of circuit flow.

Circuit failure or breakage: As the name sounds, this complication may lead to a catastrophic complication. Bedside staff trained to check circuit integrity and to react promptly in the case of acute failure can prevent this problem.

Patient Complications

Hemodynamic instability: Circuit flows above 7 L/min are rarely possible even with the optimal cannula. In patients on ECMO support, severe sepsis can lead to significant hypotension as it normally would lead to increase in cardiac output. Left ventricular (LV) distension can occur in patients on VA ECMO especially in patients with mitral or aortic regurgitation, which can lead to pulmonary edema. Increasing pump flow may be helpful in such situations.

Hypoxemia: Upper body hypoxemia can occur in VA ECMO patients with significant LV ejection and impaired lung function. This situation typically occurs when return cannula is placed in lower extremity arteries. Detecting higher saturation in lower extremity compared to upper extremity diagnosis this problem.

Infections: Infective complications related to access sites, indwelling lines or primary pathology can occur. Of note, signs of sepsis may be completely

evident; in particular, fever may be absent due to control of temperature via heat exchanger. Thus, any evidence of deteriorating hemodynamics or rising white cell count should be taken seriously. Strict aseptic precautions need to be taken during this process.

Bleeding: Bleeding, in particular from the surgical site, is common during ECMO. In one series, approximately 31.4% patients developed cannulation site bleeding and 26.7% developed surgical site bleeding.¹⁷ Other less common but potentially more serious bleedings could be gastrointestinal and intracranial bleeding which were 7% and just fewer than 3% in same series respectively. Most important mechanism of dealing with this complication is prevention. All unnecessary procedures should be avoided as much as possible while patient is on ECMO.

OTHER USES

VV ECMO may be used as an alternative to cardiopulmonary bypass during procedures involving airway and lungs. Examples include surgical construction of carina,¹⁸ laser resection of tracheal masses,¹⁹ whole lung lavage for alveolar proteinosis,²⁰ during high risk rigid bronchoscopy,²¹ and in adult burn patients with severe inhalational injury.²² Successful use of VA ECMO has been reported in several different clinical situations such as in patients with toxic shock-induced cardiomyopathy,²³ ARDS with septic cardiomyopathy,²⁴ to facilitate combined pneumonectomy and transesophageal fistula repair,²⁵ as a “bridge to bridge” in heart failure patients,²⁶ in patients with cardiac arrest,²⁷⁻²⁹ and as a bridge to organ donation.³⁰ These examples show that ECMO can be used successfully to support vital organ perfusion in patients with profound but potentially reversible medical conditions.

FUTURE DIRECTIONS

ECMO is highly technical, advanced life support system used for patients with severe cardiac and or pulmonary disease requiring intensive support with a potential for reversibility. With improvements in ECMO device and increasing ECMO experience, there is potential for further improvement in

outcomes inpatient on this support. Some experts have started to suggest early implementation of ECMO as a part of lung protection in patients with ARDS.^{31,32} ECMO is currently being offered in equipped centers for ARDS patients with severe hypoxemia ($\text{PaO}_2\text{-to-FiO}_2$ ratio < 80 mm Hg) who are unresponsive to conventional treatment. The feasibility and efficacy of ECMO for in-hospital cardiac arrest patients have been reported.³³ However such efficacy and cost effectiveness for out-of-hospital cardiac arrest remain unclear and further studies are needed to assess this modality. Extracorporeal removal of CO_2 , a function of ECMO circuit, can be potentially used in critically ill patients with acute exacerbation of bronchial asthma and COPD who are unable to tolerate standardized management, although definite guidelines are lacking. Safe application of this device would require multidisciplinary team approach, and experience with its use and improvements to minimize device related complication, before this modality can be applied across the board.

Airway Management in the Critically Ill Patient

Elvis Umanzor, MD and Andrew Leibowitz, MD

KEY POINTS

- 1 In the intensive care unit (ICU), endotracheal intubation is usually marked by an urgent need in face of cardiorespiratory instability, poor physiologic reserve, and an unknown airway history.
- 2 The incidence of difficult intubation and complications during intubation in the ICU are considerably higher than reported in operating room settings.
- 3 Preoxygenation should take place prior to any airway intervention.
- 4 Flexing the neck and extending the head at the atlantooccipital joint, called the “sniffing” position is probably the best starting position for direct laryngoscopy.
- 5 In recent years, the use of bladed indirect laryngoscopes (eg, Glidescope, C-MAC, McGrath) has increased in the operating room, the emergency department, and the ICU.

INTRODUCTION

Endotracheal intubation in the ICU differs significantly from when performed by anesthesiologists in the operating room, with availability of special airway equipment, and trained staff support.¹ In addition, ICU endotracheal intubation is usually marked by an urgent need in face of cardiorespiratory instability, poor physiologic reserve, and an unknown airway history.²

The incidence of difficult intubation in the ICU is 12% to 22%, considerably higher than reported in operating room settings.³⁻⁵ The rate of severe complications is very high, including severe hypoxemia (26%), hemodynamic collapse (25%), cardiac arrest (1.6%), and death (0.8%).² The Fourth National Audit Project Report (NAP4), a review of major

airway-related events occurring in the United Kingdom over a period of a year, revealed that 61% of the airway events that occurred in the ICU resulted in death or brain damage. More concerning is that after qualitative analysis of the events, reviewers assessed airway management as good in only 11%.³

AIRWAY ASSESSMENT

Airway assessment must be performed before any procedure. The purpose of this evaluation is to identify possible difficulty with bag-mask ventilation, intubation, supraglottic device placement, or cricothyroidotomy/tracheostomy. Even in the ICU, where most intubations are performed emergently, an abbreviated assessment is warranted.⁶⁻⁸

Predicting Difficult Bag-Mask Ventilation

If endotracheal intubation is difficult or impossible, ventilation with a bag-mask will maintain oxygenation until the airway is secured. Difficult ventilation is a serious problem, and every effort should be made to anticipate this complication.⁹ Five independent predictors have been identified: age greater than 55, body mass index greater than 26 kg/m², lack of teeth, history of snoring, male gender, and presence of beard.^{7,9}

Predicting Difficult Direct Laryngoscopy

Indicators of potentially difficult direct laryngoscopy include inability to prognath (move the lower teeth in front of the upper teeth), high Mallampati-Samsoon classification score ([Figure 97–1](#)), interincisor distance of less than 4 cm (~2 fingerbreadths), short thyromental distance (< 6.5 cm or 3 fingerbreadths) measured from the top of the thyroid cartilage to the anterior border of the mandible with the head in full extension, range of neck extension less than 35°, and previous history of a difficult intubation.^{7–11}

It is important to note that all these indicators have poor sensitivity and specificity and that no single factor reliably predicts difficulty. The positive predictive value of any of these tests alone is low, but

prediction is improved with the presence of multiple concerning factors.^{6,10,12}

Predicting a Difficult Surgical Airway

The techniques of needle or surgical cricothyroidotomy depend on the cricothyroid membrane being accessible, which may not always be the case. Some features that may cause difficulty in accessing this membrane include obesity, neck immobility, and local blunt, or penetrating trauma.^{6,9}

SECURING AN AIRWAY

Indications for Intubation

Indications for intubation include airway obstruction, airway protection (any cause of depressed level of consciousness, eg, stroke, trauma, or intoxication), facilitation of mechanical support for respiratory failure (hypoxemic or hypercapnic), and circulatory failure (shock).

Equipment

All necessary equipment should be available and checked prior to any intubation attempt regardless of predicted difficulty^{7,8} ([Table 97–1](#)). The patient should be monitored with at least pulse oximetry, blood pressure cuff, and continuous electrocardiogram. Intravenous access should be secured.

FIGURE 97–1 The Mallampati-Samsoon classification attempts to correlate the ability to observe intraoral structures and the difficulty to intubate. The patient sits erect with the head in neutral position and is asked to open the mouth as wide as possible and to protrude the tongue maximally. The examiner sits opposite and observes various intraoral structures. Classes I and II predict a low risk of difficulty while with class III or IV there is a greater chance of problems visualizing the glottis during direct laryngoscopy. Positioning

The airway contains three visual axes: (1) mouth, (2) oropharynx, and (3) larynx. In the neutral position, these axes form acute and obtuse angles with one another and the glottic opening is not visualized.¹¹ The traditional teaching is that the “sniffing the morning air” position (Figure 97–2) helps align the oral, pharyngeal, and laryngeal axes.¹³ This is achieved by flexing the neck and extending the head at the atlantooccipital joint.^{7,8} Cervical flexion approximates the pharyngeal and laryngeal axes, and extension at the atlantooccipital joint brings the oral axis into better alignment with the other two.¹¹ However, over the past decade, several authors have controversially challenged this issue.^{14–16} Adnet et al studied magnetic resonance imaging (MRI) scans of healthy volunteers in 3 anatomic positions (neutral, simple extension, and in the sniffing position) and concluded that the “sniffing position” does not achieve alignment of the 3 important axes.¹⁵ Despite this, we consider that the sniffing position is probably the best starting position for direct laryngoscopy.

In patients at risk of aspiration, compressing the cricoid cartilage posteriorly against the vertebral body (ie, Sellick maneuver) may reduce the diameter of the upper esophageal sphincter and prevent regurgitation of stomach content into the trachea during intubation, but may also interfere with laryngoscopy and endotracheal tube insertion.

Preoxygenation

Preoxygenation should take place prior to any airway intervention. The two primary goals of

preoxygenation are (1) maximization of the arterial PaO_2 and (2) denitrogenation of the functional residual capacity. A beneficial secondary goal of the process is hypocarbia.

FIGURE 97–2 Three-axis alignment. (A) Head in neutral position. (B) Elevation of head approximates the laryngeal and pharyngeal axes. (C) Extension at the atlantooccipital joint brings the visual axis of the mouth into better alignment with those of larynx and pharynx. (Reproduced with permission from Hagberg C, Benumof and Hagberg’s Airway Management, 3rd edition. Philadelphia: Elsevier Saunders; 2013.)

Preoxygenation can temporarily raise the SpO_2 and PaO_2 , maximizing blood oxygen content. Although dissolved oxygen adds little to the oxygen content of blood as the SpO_2 nears 100%, critically ill patients often suffer from anemia, increased oxygen consumption and regional hypoperfusion, so any increase in dissolved oxygen (eg, 1.5 mL O_2 /100 mL of blood) is desirable. More importantly, preoxygenation replaces the nitrogen in the functional residual capacity with oxygen. The functional residual capacity is approximately 30 mL/kg, oxygen consumption is 3 to 4 mL/kg/min, and in healthy patients this “oxygen reserve” may allow up to 8 minutes of apnea before the SpO_2 decreases below 90%. However, efficiency of denitrogenation and the time to critical SpO_2 decrease is markedly reduced in critically ill patients and apnea rarely tolerated for more than 60 to 120 seconds; but, any increase in the time to desaturation will decrease morbidity and mortality.

Encouragement of hyperventilation during preoxygenation may result in hypocarbia that is desirable in the soon to be apneic patient. During the first minute of apnea the Pco_2 will increase by 6 mm Hg and afterward by 3 mm Hg per minute. Hypercarbia will cause hemodynamic instability, cardiac arrhythmias, and increase the intracranial pressure, even while the SpO_2 remains in a safe range.

Preoxygenation may be achieved by administration of 100% oxygen with a tight-fitting face mask, application of continuous positive airway pressure (CPAP) or bilevel positive airway pressure (BiPAP), or manually assisted bag-mask ventilation. The choice of method is highly dependent on personal preference or unit policy and the emergent nature of the procedure. The authors of this chapter recommend that while setting up for intubation at minimum a tight-fitting Fio_2 1.0 face mask should be applied and if time allows BiPAP be initiated.

Face Mask and Bag-Valve Device

Face masks are designed to form a seal around the mouth and nose and connect to a bag-valve device.⁶ The operator stands at the patient's head and presses the mask onto the patient's face with the left hand. The thumb should be on the nasal portion of the mask, the index finger near the oral portion, and the rest of the fingers spread on the left side of

the patient's mandible so as to pull slightly anterior.⁸ The 2 key elements are to establish a tight fit with the mask, covering the patient's mouth and nose to prevent air leaks, and an unobstructed airway.^{6,8} The minimum effective insufflation pressure should be used to decrease the risk of insufflating the stomach and increasing the risk of aspiration.⁸

If ventilation is not effective, 2 maneuvers can be performed to improve airflow obstruction. Head extension, by stretching the anterior neck structures and moving the hyoid bone and attached structures anteriorly, is probably the most important single maneuver for maintaining space between the pharyngeal soft tissues (caution is advised in patients with unstable cervical spine). Jaw thrust, achieved by exerting anterior pressure behind the angles of the mandible, can also reduce the airway obstruction.⁶

Airway Adjuncts

If ventilation is not adequate despite proper positioning of the patient and proper use of the bag-valve device, several airway adjuncts may be helpful.⁸

An oropharyngeal airway (Figure 97–3) is semicircular and made of plastic. The 2 types are the Guedel airway, with a hollow tubular design, and the Berman airway, with airway channels along the sides.⁷ Both are inserted with the curved portion toward the mouth floor with the help of a tongue depressor to lower the tongue if needed. It should be inserted only when the pharyngeal reflexes are depressed, to minimize the risk of coughing and laryngospasm.⁶

The nasopharyngeal airway is a soft tube approximately 15-cm long that is inserted through

FIGURE 97–3 Oropharyngeal airway (Guedel).

the nostril into the posterior pharynx. This device may be preferable in patients with limited mouth opening and poor dentition. It is also better tolerated in conscious patients. The airway should be lubricated and a vasoconstrictor should be applied before insertion. Its use is contraindicated in patients with skull base trauma, rhinorrhea, and severe coagulopathy.^{6,8}

Induction Agents/Muscle Relaxants

Endotracheal intubation is safer and the success rate is higher in the sedated paralyzed state. Given the frequency of difficulty encountered, persons who are not experts and not comfortable with the administration of hypnotics and paralytics should defer to experts.

The choice of sedative hypnotic agent should emphasize hemodynamic stability and short duration of action. Hypotension is best avoided if etomidate (2-3 mg/kg) or ketamine (1-5 mg/kg) are used. Etomidate may cause myoclonus, does not promote muscle relaxation, burns on injection, and is associated with decreased endogenous steroid production, but its hemodynamic stability is unmatched. The administration of propofol to critically ill patients, even in low doses (eg, 1-1.5 mg/kg), almost always causes hypotension.

The choice of paralytic should emphasize short onset of action (ie, “rapid-sequence intubation”, ~ 60-75 seconds) and limits the choice to the depolarizing agent succinylcholine, and the nondepolarizing agent rocuronium. Succinylcholine (1-1.5 mg/kg) is the most rapid in onset (30-45 seconds) and shortest in duration (5-10 minutes), but in normal patients may raise the potassium level, and in certain conditions (eg, paralytic stroke, major burns) this rise may be quite profound and result in a hyperkalemic arrest. In these conditions, rocuronium (0.6-1.2 mg/kg) is preferable, although its duration of action is longer than succinylcholine (30-50 minutes).

Given the frequency of hemodynamic instability accompanying intubation in the ICU, preparation and administration of vasoactive medications should occur simultaneously with preparation and probably should precede administration of sedative hypnotics and paralytics. Patients who are already hypotensive prior to endotracheal intubation need reliable venous access through which a vasopressor can be

infused. If the mean arterial pressure (MAP) is less than 60 mm Hg the vasopressor infusion should be increased, or alternatively a bolus of vasopressor can be administered. Ephedrine (5-10 mg), phenylephrine (100 µg), and vasopressin (0.5-1 units) have all been frequently used by the authors, usually determined by availability and heart rate. Bradycardic patients should all have at minimum atropine 0.4 mg or glycopyrrolate 0.2 mg administered. Hypertensive patients, especially those with intracranial lesions, may benefit from titrated doses of short-acting hypotensive agents such as nitroglycerin (40-100 µg) and esmolol (0.5 mg/kg).

Direct Laryngoscopy and Endotracheal Tubes

Direct laryngoscopy is performed to visualize the laryngeal opening (Figure 97-4). To see through the airway, light must travel from the glottic opening to the laryngoscopist's eye. Since light travels in a straight line, the technique requires an uninterrupted linear path between the larynx and the observer.¹¹ The tongue and the epiglottis are the anatomic structures that intrude into this line of sight.⁶ One of the main objectives of direct laryngoscopy is to move the tongue anteriorly into the mandibular space, allowing direct view of the glottic opening.

FIGURE 97-4 Glottic opening view. (Reproduced with permission from Calder I, Pearce A: Core Topics in Airway Management, 2nd edition. New York: Cambridge University Press; 2011.)

FIGURE 97-5 Macintosh (curved) and Miller (straight) blades.

The laryngoscope has a handle and a blade that snaps securely into the top of the handle. Many blades' shapes and sizes are available, however, 2 types are commonly used (Figure 97-5). The Macintosh blade is curved along its long axis, has a broad, flat surface, and has a right-angled Z-shaped cross-section. The straight blades (Cranwall, Miller, Phillips, Wisconsin) tend to be narrower than the curve blades and have a D-shaped flange.⁶⁻⁸ Which blade to use is in many cases a matter of personal preference, but the straight blade could be of special use in patients with a larger than normal epiglottis, or with a larynx that is positioned more anterior.

The laryngoscope is held in the left hand and introduced into the right side of the mouth. While advancing the blade to the base of the tongue, the blade is simultaneously moved to the midline sweeping the tongue to the left. The tip is advanced and the epiglottis is lifted away from the glottic opening.⁷ With a curved blade the tip rests and applies upward traction to the base of the tongue at the vallecula; the straight blade tip rests in the posterior surface of the epiglottis and lifts it directly.^{7,8} Elevating the epiglottis through a lifting motion at 45° from the horizontal using the arm and shoulder exposes the vocal cords. Keeping the wrist stiff to avoid a prying motion that uses the teeth as fulcrum will prevent dental injury.^{7,8} Once the vocal cords are visualized, the endotracheal tube is advanced from the right corner of the mouth and into the trachea. The cuff is inflated with enough air to prevent a leak with positive pressure ventilation.

Correct placement is confirmed with visualization of symmetric chest expansion, auscultation

over epigastrium and lung fields, and an end-tidal CO₂ detection device (capnography or calorimetric chemical detection of CO₂). After confirmation, the tube is secured in place. A chest radiograph should be ordered in order to confirm correct placement and position of endotracheal tube tip above carina.

Endotracheal tubes are designed to provide a secure channel through the upper airway. The size of the endotracheal tubes is described as the internal diameter in millimeters.⁶ Tubes are available in 0.5 mm increments, starting at 2.5 mm. Selection of the proper diameter is important because small-diameter tubes increase airway resistance and work of breathing; moreover, certain procedures like bronchoscopy require large tubes. Common sized tracheal tubes are 8 mm for males and 7.5 mm for females. In general, the larger the patient, the larger the endotracheal tube that should be used.^{6,8} For oral intubation, an endotracheal tube insertion depth of 21 cm from the incisors in females and 23 cm from the incisors in males results in proper positioning about 4 cm above the carina in the majority of patients. The endotracheal tubes have a cuff near the distal end that is inflated to provide a seal to protect from aspiration and to allow positive pressure ventilation. Prevention of excessive cuff pressure may reduce the incidence of tracheal damage. Cuff pressure monitoring should be used whenever possible to maintain a pressure in the range of 25 to 30 cm H₂O.⁶

AIRWAY DEVICES

In addition to conventional laryngoscopes, many airway devices and techniques have been developed to manage difficult ventilation or intubation. However, no device or technique is universally successful in all situations.^{2,17}

Supraglottic Devices

The laryngeal mask airway (LMA) is a plastic tube attached to a shallow mask with an inflatable ring designed for blind insertion into the pharynx to fit the laryngeal inlet and form a seal around it.^{8,17} It was introduced in 1988 and is widely used in the operating room for elective cases. It has also been used as a rescue device and is the key in the

adaptive simulated annealing (ASA) algorithm for difficult airway used as a ventilatory device in patients that are difficult to ventilate and intubate, or as a conduit for fiberoptic bronchoscopic intubation in patients that can be ventilated but not intubated.^{6,17}

Rigid Indirect Laryngoscopy

Indirect laryngoscopy is a technique in which the glottic view is transmitted through fiberoptic bundles or video technology to the eyepiece of the instrument, or a monitor screen.¹⁸ There are several available devices differing in their design and technical features.

In recent years, the use of bladed indirect laryngoscopes (eg, Glidescope, C-MAC, McGrath) has increased, not only in the operating room, but also in the emergency department and in the ICU (Figure 97–6). Videolaryngoscopes consist of an angled blade with a camera at the tip. The image captured at the distal lens is transmitted to the proximal end of the device into a small screen. It is important to note that the Glidescope and the McGrath have an angulated blade, and provide a view of the glottic opening on the screen while the actual glottis is not directly in the operator's view line. Because of this the endotracheal tube requires the use of a curved stylet to be inserted around and behind the tongue.¹⁸ For this same reason, in some occasions, despite an improved visualization, it is difficult to advance the endotracheal tube into the trachea.

FIGURE 97–6 Glidescope.

Flexible Fiberoptic Bronchoscope Intubation

Fiberoptic bronchoscopes use flexible optical fibers to transmit images from a distal lens as it is steered under vision toward the larynx and into the trachea. The image transmitted is displayed on a monitor by attaching a camera to the eyepiece, or by using a bronchoscope with an integral camera. This device is the most versatile laryngoscope for tracheal intubation and can facilitate intubation that is otherwise impossible.⁶

Unfortunately, many of the relative contraindications for its use are encountered in the ICU, including poor patient cooperation, blood in the airway, and time constraints.

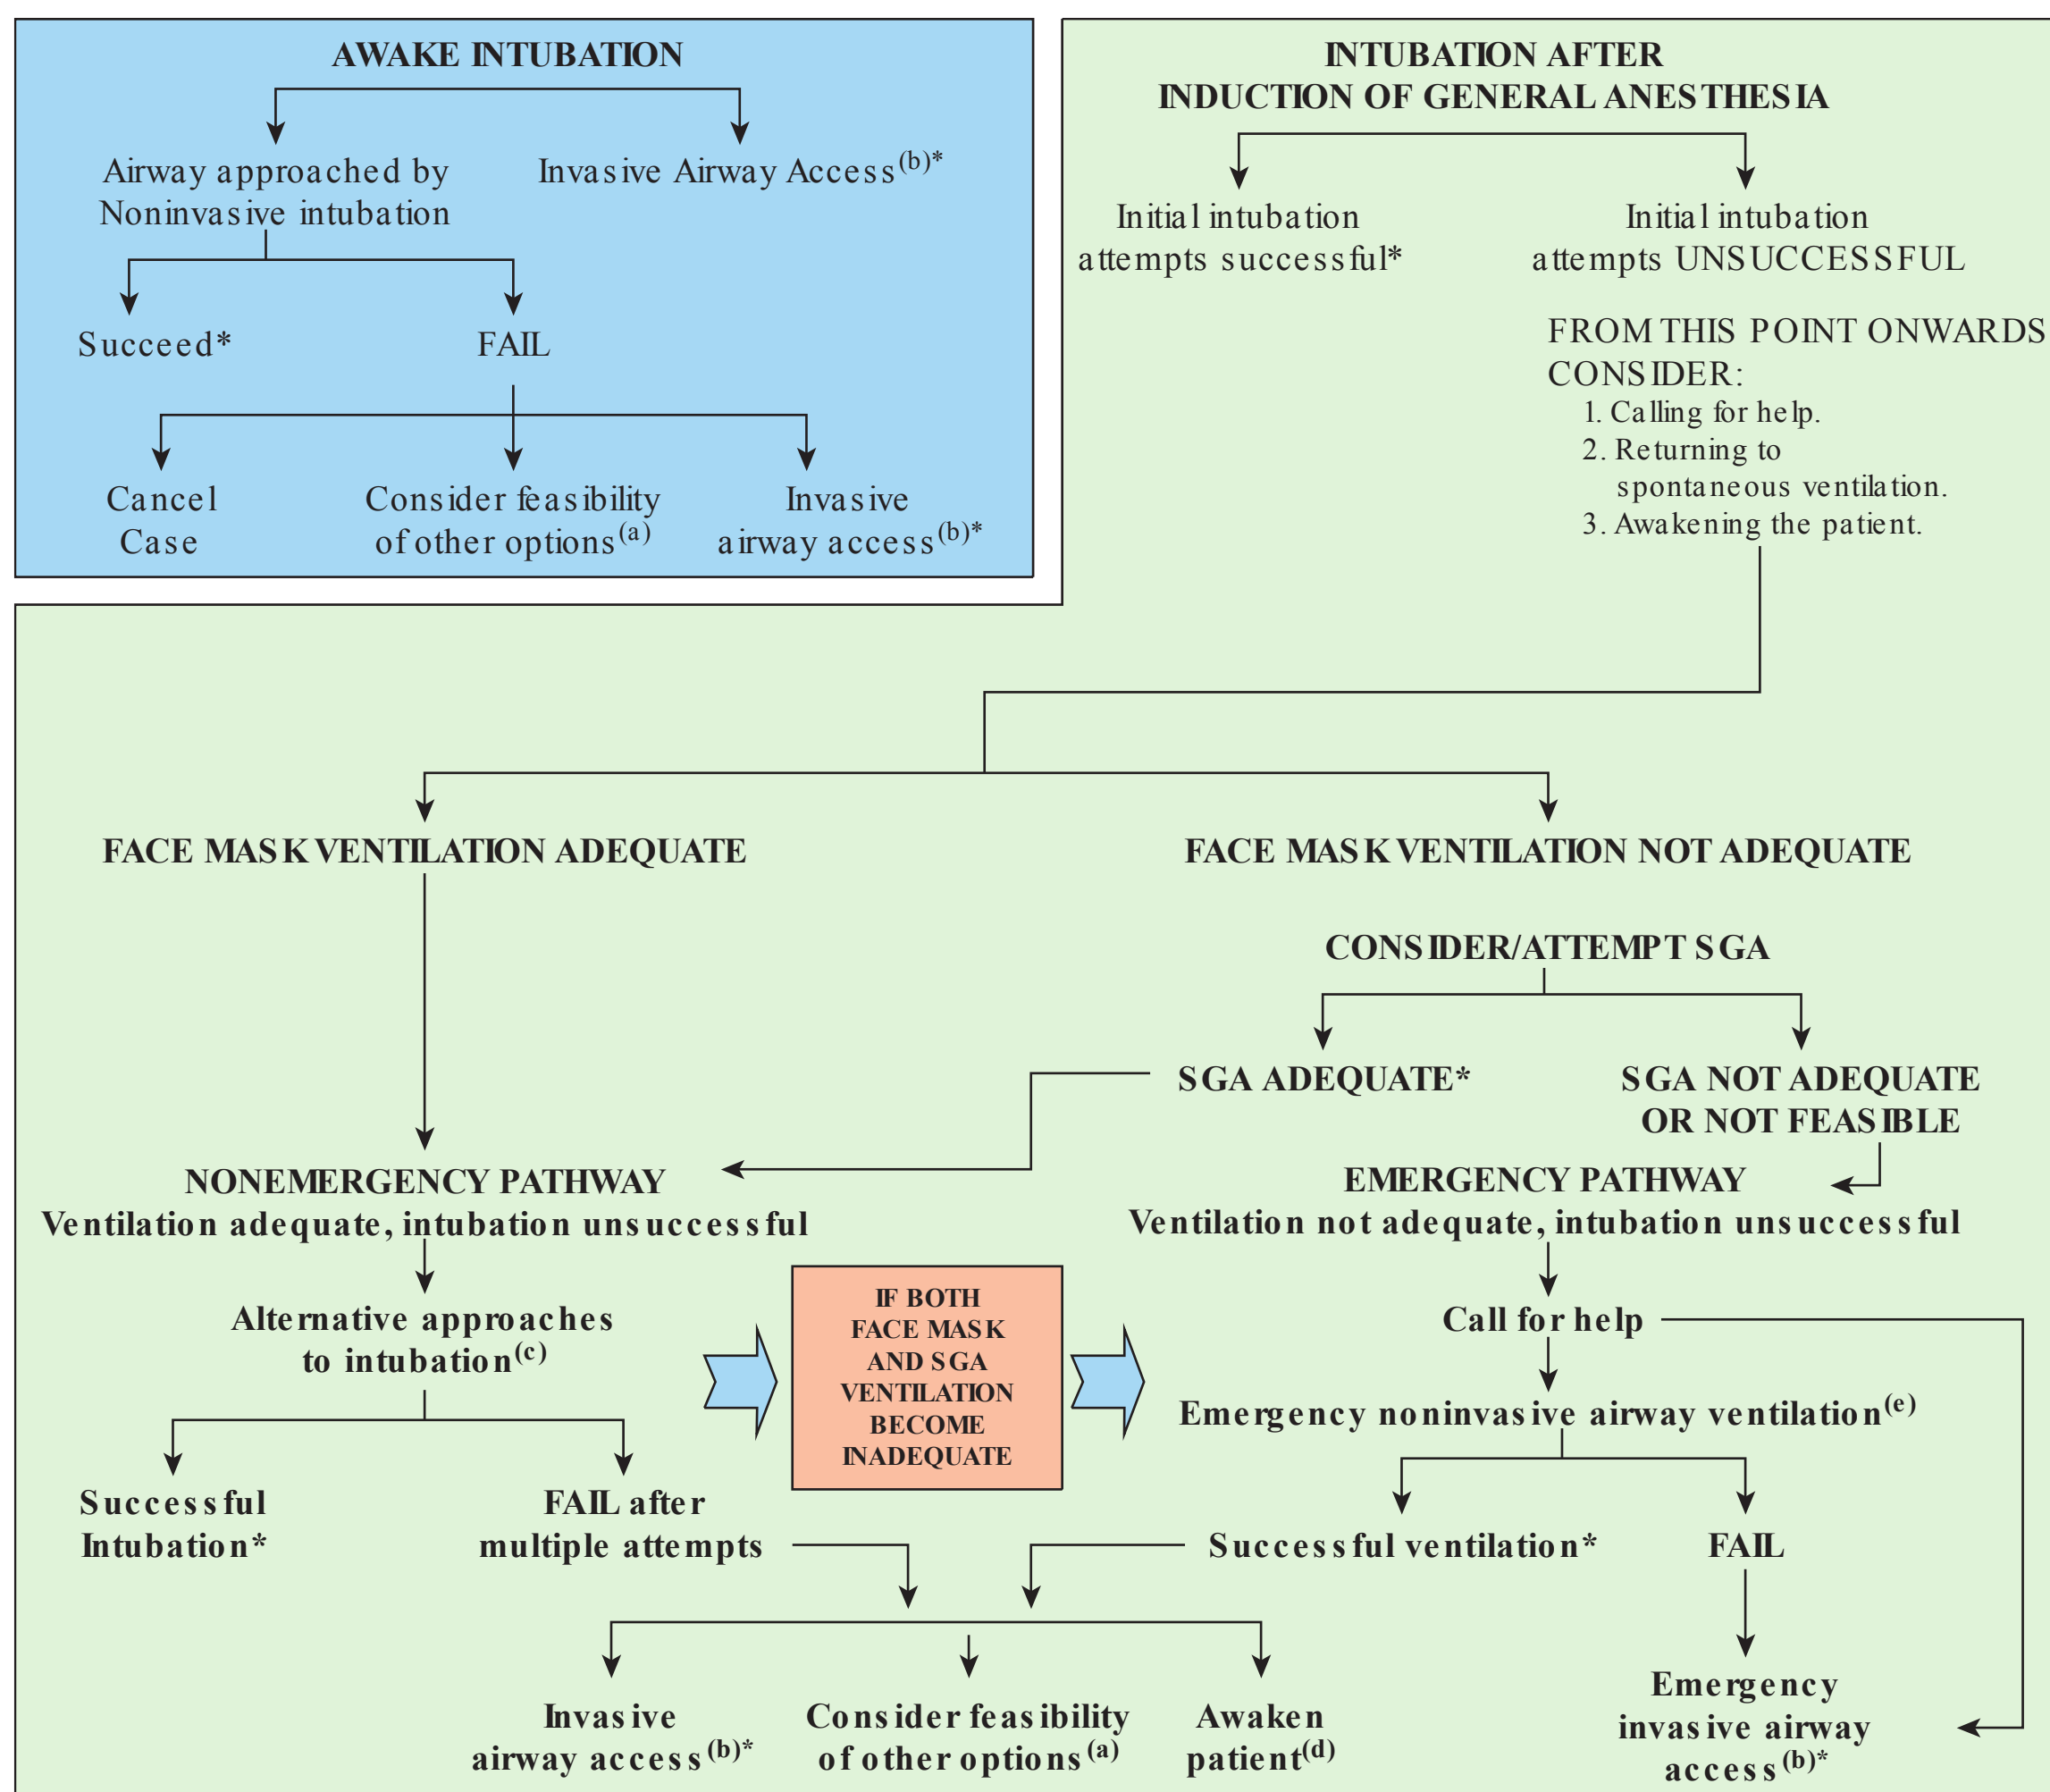

DIFFICULT AIRWAY ALGORITHM

For clinical or anatomic reasons, airway management may be difficult without specialized expertise or tools. One significant advance in the management of patients with difficult airways is the development of algorithms to standardize its approach.¹⁹

The American Society of Anesthesiologists recently published an update of the Practice Guidelines for Management of Difficult Airway. Although these guidelines were designed for its use in the operating room, and in the majority of cases in the ICU the elective pathway is not applicable, they offer a useful stepwise approach to anticipated and unanticipated airway problems (Figure 97–7).^{19,20}

AIRWAY MANAGEMENT DURING CARDIOPULMONARY RESUSCITATION

During low-blood-flow states such as patients in cardiac arrest, oxygen delivery is limited by flow rather than by arterial oxygen content. In these circumstances, rescue breaths are less important than chest compressions during the first few minutes of resuscitation. Moreover, rescue breaths could reduce cardiopulmonary resuscitation (CPR) efficacy due to interruption of chest compressions and increases in intrathoracic pressure. Advanced airway placement

*Confirm ventilation, tracheal intubation, or SGA placement with exhaled CO₂.

a. Other options include (but are not limited to): surgery utilizing face mask or supraglottic airway (SGA) anesthesia (eg, LMA, ILMA, laryngeal tube), local anesthesia infiltration or regional nerve blockade. Pursuit of these options usually implies that mask ventilation will not be problematic. Therefore, these options may be of limited value if this step in the algorithm has been reached via the Emergency pathway.

b. Invasive airway access includes surgical or percutaneous airway, jet ventilation, and retrograde intubation.

c. Alternative difficult intubation approaches include (but are not limited to): video-assisted laryngoscopy, alternative laryngoscope blades, SGA (eg, LMA or ILMA) as an intubation conduit (with or without fiberoptic guidance), fiberoptic intubation, intubating stylet or tube changer, light wand, and blind oral or nasal intubation.

d. Consider re-preparation of the patient for awake intubation or cancelling surgery.

e. Emergency non-invasive airway ventilation consists of a SGA.

FIGURE 97–7 ASA difficult airway algorithm. (Reproduced with permission from Apfelbaum JL, Hagberg CA, Caplan RA, et al: Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists Task Force on Management of the Difficult Airway, *Anesthesiology*. 2013 Feb;118(2):251-70.)

in cardiac arrest should not delay initial CPR and defibrillation.²¹

The current American Heart Association guidelines for CPR included several changes related to airway management.^{2,21} The traditional airway, breathing, circulation (ABC) was changed to compressions, airway, breathing (CAB).

Both bag-mask ventilation and ventilation with a bag through an advanced airway are acceptable methods of providing ventilation and oxygenation during CPR. The number and the duration of intubation attempts should be minimized, with a goal of no more than 10 seconds to minimize chest compression interruptions. Supraglottic devices may be reasonable alternatives to tracheal tubes.²¹

EXTUBATION

Extubation can be as challenging as intubation and is also fraught with potential complications. Reintubation can be complicated by the urgency of the situation, changes in airway anatomy (edema), and hemodynamic instability, among other factors already discussed.²

Planning for extubation should be performed immediately after intubation. The Difficult Airway Society Extubation guidelines published in 2012 suggest that patients should be approached as “low risk” and “high risk” for extubation. The high-risk patients with history of difficult intubation may be extubated using a supraglottic airway or an airway exchange catheter as a bridge to extubation, but more importantly a highly competent airway person should be at the bedside. Airway exchange catheters can be left in place as needed, are well tolerated by patients, and can be used as a conduit for reintubation.^{2,22}

Endoscopic Placement of Feeding Tubes

Isaac Soo, MD and Mark Schattner, MD

INTRODUCTION

Nutritional support is an important component of care for the critically ill. There are numerous modalities to provide specialized nutrition support including oral dietary therapy, enteral nutrition, and parenteral nutrition. For patients with a functioning gastrointestinal (GI) tract, enteral nutrition is preferred to parenteral nutrition. It is safer, more physiologic, and economical. In the intensive care unit (ICU) setting, enteral nutrition is associated with a decreased likelihood of developing infections when compared to parenteral nutrition.¹ In patients with acute pancreatitis, use of enteral nutrition is also associated with a reduction in hospital length of stay and a trend toward reduced organ failure when compared to parenteral nutrition.² Patients who have a functioning GI tract but are unable to safely ingest oral intake are fed via enteral access. In patients in whom long-term enteral access is required, endoscopically placed enteral access is recommended. Percutaneous endoscopically placed gastrostomy (PEG) and jejunostomy (PEJ) tubes are utilized for long-term enteral nutrition.

ENTERAL FEEDING TUBES

A majority of patients have enteral feeding tubes (EFTs) inserted through the mouth (orogastric) or nares (nasogastric) at the bedside that terminate in the gastric antrum. EFTs allow noninvasive access to the intestinal tract in patients who are unable to eat or drink. Examples of patients requiring EFT include sedated or unconscious patients such as those who are mechanically ventilated or have head injury. Severe oropharyngeal dysfunction that occurs in stroke patients or patients unwilling to have oral intake such as severe depression or anorexia are also candidates for EFT. Use of EFT

is short term, typically less than 30 days. If enteral access is required beyond 30 days, a PEG or PEJ tube should be inserted. Contraindications for the placement of EFT include bowel ischemia, intestinal obstruction, and ileus.

Endoscopy is not required for the insertion of most EFTs. Indications for endoscopy include the presence of an esophageal obstruction or to facilitate postpyloric EFT placement. For esophageal obstruction the gastroscope is passed to the stricture, the feeding tube guided through the stricture under direct vision and advanced to the desired depth. Alternatives include placement of a guidewire through the stricture using the gastroscope biopsy channel, exchanging the gastroscope and guidewire to leave the wire in place and then placing an EFT over the guidewire. Also, the stricture can be dilated endoscopically prior to bedside placement.

Postpyloric feeding should be considered in patients with delayed gastric emptying, those with a history of regurgitation^{3,4} as well as patients with acute severe pancreatitis. Jejunal feeds minimize pancreatic exocrine secretions by bypassing the upper GI tract and is a core aspect in treating acute severe pancreatitis. Comparisons between gastric and jejunal feedings have shown mixed results and a large prospective study is currently underway.⁵⁻⁷ Patients with acute severe pancreatitis should receive jejunal feeds until more evidence is available. There are 4 endoscopic methods of postpyloric feeding tube placement:

1. **Drag and pull.** A suture is placed at the distal tip of the feeding tube and then passed via nares to the stomach followed by the gastroscope. Biopsy forceps through the gastroscope grasp the suture and advance together into the small bowel. The feeding tube is then left in position by grasp, advancement,

FIGURE 98–1 A-E Endoscopic insertion of feeding tubes. (Memorial Sloan Kettering Cancer Center © 2014).

release, and regrasp of the feeding tube while the gastroscope is retracted. Friction of the feeding tube against the gastroscope may lead to retraction of the EFT. Helpful maneuvers include decompression of the stomach to reduce looping within the stomach, liberal lubrication applied to the EFT and gastroscope, and using a feeding tube with an internal guidewire to provide stiffening (one 0.052-in or two 0.035-in guidewires placed through the EFT tube without exiting the tip of the tube). Alternatively, rather than using biopsy forceps an endoscopic clip may be used to grasp the attached suture and advance the EFT as desired. At the desired depth of insertion the hemoclip can then be used to affix the EFT suture to the small bowel mucosa. This approach has been demonstrated to increase the initial success rate of EFT placement and decrease retrograde tube migration with subsequent need for repeat endoscopy.⁸

2. Over the guidewire. Advance a gastroscope into the small bowel and exchange with a guidewire down the biopsy channel leaving the guidewire in situ. The guidewire exits orally and is changed to achieve nasal exit. A nasopharyngeal transfer tube is placed via the nares into the pharynx. The distal tip of the tube is grabbed using forceps to allow the distal end to exit orally. The guidewire is fed through this catheter to exit at the nose. Next the catheter is retracted nasally to leave guidewire

in situ (Figure 98–1). The EFT is fed over the guidewire to the small bowel.

3. Through scope. A small-diameter feeding tube can be fed through the biopsy channel of a therapeutic scope. A 240-cm 8- or 10-Fr gauge feeding tube is placed through the endoscope biopsy channel. The scope is exchanged with the EFT once the distal end of the feeding tube is in a suitable position. The extended length of the feeding tube allows it to remain in position as the scope is exchanged and removed over the feeding tube. The feeding tube is then cut to the desired length and oronasal transfer performed as presented earlier.
4. Ultrathin gastroscope. An ultrathin gastroscope is passed through the nares down the upper GI tract into the small bowel. A soft-tipped guidewire can be inserted in the channel and then exchanged with the gastroscope, leaving the guidewire in place. The EFT is then advanced over the guidewire and guidewire is removed once a suitable depth on EFT insertion is achieved.

PERCUTANEOUS ENDOSCOPIC GASTROSTOMY

Endoscopically placed gastrostomy tubes were first described in 1980 as an alternative to open surgical gastrostomy placement.⁹ Since then numerous techniques have been developed and described. The

Ponsky-Pull method is the most commonly practiced method illustrated here.

Indications for PEG

Suitable candidates for insertion of PEG tubes for nutritional supplementation include the following:

- Inability to perform motor mechanisms of oral intake
- Functioning GI tract
- Anticipated requirement of nutritional support for over 30 days

Common indications for the placement of PEG tubes for nutritional supplementation include patients with stroke, head and neck cancer, as well as brain injury or neurologic disorders such as amyotrophic lateral sclerosis. Conversely, feeding tubes in patients with dementia have not shown improved clinical outcomes and are generally ineffective in prolonging life, improving function, or reducing risk of pressure sores or infections.¹⁰

Contraindications to PEG Placement

Absolute contraindications include a nonfunctional GI tract, active GI bleeding, uncorrected coagulopathy, hemodynamic instability, peritonitis, and abdominal wall infection over insertion site. The presence of ascites is a relative contraindication to PEG placement and depends on the amount, location, and type of ascites.

Complications

PEG tube insertion is a well-tolerated procedure with low incidence of complications; rates up to 4% have been reported. Complications may relate to either the insertion of the PEG tube or complications thereafter. These include stomal site infection, abdominal wall ulceration, necrotizing fasciitis, peristomal leakage, bleeding, transient gastroparesis, bowel perforation, gastric outlet obstruction from the internal bumper, buried bumper syndrome, colocutaneous fistula, peritonitis, and liver puncture. Pneumoperitoneum may be identified on radiologic imaging post-PEG insertion. This is an expected finding and is not worrisome in the absence of clinical signs of peritonitis.

Anesthesia

Insertion of endoscopically placed PEG or PEJ tubes is done with a combination of local anesthesia and sedation. A short-acting benzodiazepine (ie, midazolam) in combination with an opioid such as fentanyl is a common practice. In some instances patients may receive deeper sedation via propofol, or in some cases general anesthesia, under the guidance of a nurse anesthetist or anesthesiologist.

Equipment Required

See [Figure 98–2](#) for typical PEG kit components.

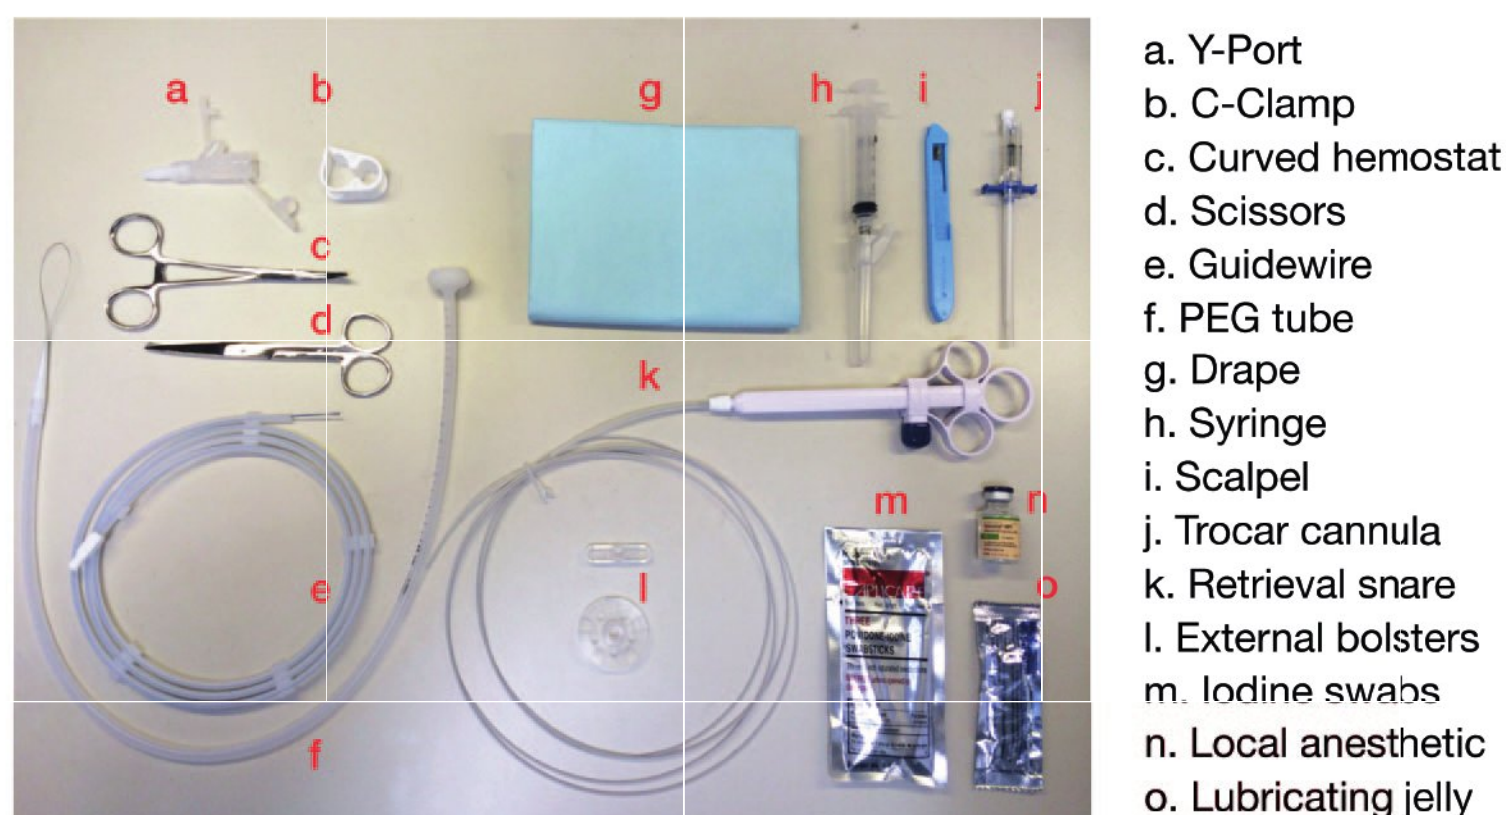

FIGURE 98–2 A–O Typical PEG kit components.

Personnel

PEG tube insertion generally requires 2 individuals to perform the procedure. One individual functions as the endoscopist and the other as the surgical assistant.

Preparation and Antibiotic Prophylaxis

The patient is kept NPO the night before the procedure. There is creation of a surgical wound during the creation of the gastrostomy and antibiotic prophylaxis is given to prevent abdominal wall infection. A single dose of a first-generation cephalosporin is given prior to PEG tube insertion to reduce the risk of infection. Patients in the ICU often receive significant antimicrobial coverage and as long as there is preexisting gram-positive organism coverage, additional antibiotics are not required. The patient is supine with the head turned to the side and suction available for significant oral secretions. A routine upper GI examination is performed prior to PEG insertion.

Landmarking

The epigastrium is the typical location for PEG placement but can vary. The final site is dependent on appropriate landmarking. The final location for the gastrostomy tube should be at least an inch away from the costal margins and clear of the xiphoid process.

The stomach is inflated to maximally appose the gastric wall with the abdominal wall. This facilitates the 2 maneuvers to identify a suitable PEG insertion site, the absence of any underlying vessel or interposing tissue such as bowel or liver edge. First

FIGURE 98–4 When point pressure is applied to the abdominal wall, the endoscopic image shows 1:1 transmission of movement. (Memorial Sloan Kettering Cancer Center ©2014).

is diaphanoscopy, adequate transillumination of the endoscopy light through the abdominal wall. The endoscopy suite lights are dimmed and transilluminated light from the endoscope should be clearly visible on the anterior abdominal wall (**Figure 98–3**). The second is 1:1 transmission of abdominal wall pressure. The endoscopic view is directed at the gastric wall corresponding to the point of external point pressure. When point pressure is applied to the abdominal wall, the endoscopic image shows 1:1 transmission of movement (**Figure 98–4**). Mark the site PEG placement with surgical pen marking.

Site Preparation

PEG placement requires sterile technique with skin disinfection, sterile gloves, and draping. The landmark is washed with povidone/iodine or

FIGURE 98–3 The endoscopy suite lights are dimmed and transilluminated light from the endoscope should be clearly visible on the anterior abdominal wall.

chlorhexidine wash, 3 times in concentric swirls starting from the landmark site outwards. After the surgical drape is applied local anesthesia with a total of 3 to 5 mL of 1% lidocaine should be injected subcutaneously, followed by injection toward the gastric lumen. Direct the syringe perpendicular to the abdominal wall and apply local anesthesia with periodic suction to inspect for blood return and possible puncture of a blood vessel. Significant heme return should prompt a different site for PEG insertion. The syringe will puncture into the gastric lumen, seen endoscopically to confirm an acceptable PEG location. The depth and direction of the syringe serves as a guide for insertion of the trocar/catheter apparatus.

GASTROSTOMY TUBE INSERTION

Infate the stomach to facilitate the trocar penetration through the muscular gastric wall. The trocar/catheter apparatus is applied to the abdominal wall in a firm and steady fashion. At all times the endoscope visualizes the point of trocar insertion to monitor the site for location confirmation and applied force of the trocar toward the gastric lumen. This avoids trauma of the posterior gastric wall and underlying structures by overzealous force. Remove the trocar from the trocar/catheter apparatus after it has entered the gastric lumen. A guidewire is inserted through the catheter. Advance a snare through the channel of the gastroscope and grasp the guidewire. One end of the guidewire and gastroscope are pulled out through the mouth. The surgical assistant must ensure that at all times a portion of the guidewire remains external to the catheter on the abdominal wall. Once out of the mouth, the guidewire is released from the snare and affixed to the gastrostomy tube. The loop of the guidewire is inserted through the loop of the gastrostomy tube and then opened and passed over top of the gastrostomy bumper. The 2 pieces of equipment are then pulled, interlocking the loops of the guidewire and gastrostomy tube. The abdominal wall is prepared to allow penetration of the large caliber PEG tube through the abdominal wall. Cut an approximately 1-cm epidermal incision along the trocar puncture site. A deeper incision is not required and will only

worsen postprocedural pain and possible bleeding. Apply a small amount of lubricant onto the gastrostomy tube. Significant amounts may result in pooling of lubricant in the hypopharynx increasing possible aspiration risk and airway compromise. The surgical assistant then pulls the guidewire with the attached gastrostomy tube away from the catheter/abdominal wall. The PEG tube slides down through the mouth and through the abdominal wall. The catheter remains in place during this motion to avoid damage to the surrounding tissue. While pulling on the guidewire resistance is met once the transition from the guidewire to the gastrostomy tube is encountered by the gastric wall. Brace the abdominal wall with taut pressure on the guidewire until the tip of the PEG tube passes through the abdominal wall. Gently continue pulling the PEG tube until resistance is again met, when the internal bumper rests up against the gastric wall ([Figure 98–5](#)). An alternative to tactile feedback to indicate appropriate PEG positioning is to insert the gastroscope into the esophagus with direct visualization of the gastrostomy tube while it is pulled into position. In either case the endoscope should visualize the internal gastrostomy site to ensure adequate hemostasis. Cut the guidewire from the PEG tube and slide the external bumper over the tube and down toward the abdominal wall to affix the tube in place. At an appropriate tautness, the external bumper should rest comfortably just above abdominal wall without evidence of significant tension on the skin surrounding the gastrostomy site. There should be no more than 1 cm of PEG tube between the external bumper and abdominal wall when the PEG tube is lifted taut. Decide an appropriate length for the gastrostomy tube, cut and discard the remainder, before placing the clamp and gastrostomy cap onto the PEG tube. The gastrostomy tube can be used for feeding and medication following insertion.

PEG WITH JEJUNAL EXTENSION

Patients with a PEG tube can have an extension placed through the PEG tube into the small bowel. For these cases a large-bore PEG (usually 24 or 28 Fr) is used and the jejunal extensions are 9 to

FIGURE 98–5 Gently continue pulling the PEG tube until resistance is again met, when the internal bumper rests up against the gastric wall. (Memorial Sloan Kettering Cancer Center ©2014).

12 Fr. For PEG-J extensions there are 3 methods described.

1. Pull method. A jejunostomy tube (JT) is advanced through the preexisting PEG tube and grasped by biopsy forceps through the gastroscopy channel. The gastroscopy is advanced into the small bowel and the biopsy forceps advance the JT distally. After a suitable placement is achieved, as the gastroscopy is retracted the biopsy forceps continue to advance the JT until the gastroscopy reaches the gastric body and is removed.
2. Guidewire. A gastroscopy is advanced from the mouth into the stomach and a guidewire is passed through the PEG tube into the stomach. The wire is then grasped by biopsy forceps and pulled as far as possible into the small bowel using the gastroscopy. The gastroscopy and forceps are removed and a JT is fed over the guidewire into position with subsequent guidewire removal.
3. Ultrathin gastroscopy: An ultrathin gastroscopy is advanced directly through the PEG. Via the biopsy channel a guidewire is placed. The gastroscopy is removed via exchange with the

guidewire to leave the guidewire in place. The jejunal extension is passed over the guidewire into the small bowel and the guidewire is subsequently removed.

DIRECT PERCUTANEOUS JEJUNOSTOMY TUBE INSERTION

The placement of direct percutaneous endoscopic jejunostomy (DPEJ) tubes has become more common in recent years. Indications for DPEJ insertion rather than PEG include (1) high risk for aspiration, (2) status postgastric resection, (3) status postesophagectomy, (4) gastric outlet obstruction, (5) obstructed or nonfunctioning gastrojejunostomy, and (6) gastric dysmotility. In comparison to PEG-J and nasojejunal (NJ) tubes, DPEJ has been found to decrease the risk of aspiration in patients.¹¹ The lack of effectiveness in preventing aspiration in NJ and PEG-J tubes may relate to their smaller caliber with a greater propensity for blockage and tube migration (DPEJ tubes are 18-20 Fr, larger than PEG-J tubes 9-12 Fr). Contraindications to DPEJ insertion are the same as for PEG tubes. Potential complications include bowel perforation, jejunal volvuli, bleeding, aspiration, chronic enterocutaneous fistulae, site infections, and persistent site pain.¹²

Procedure

Many of the maneuvers to insert a DPEJ are similar to PEG tube insertion. However, there are several notable aspects that differ between DPEJ and PEG placement. Employment of a pediatric colonoscope may be required to reach the jejunum; a gastroscope may be used if there has been a prior gastrectomy. For the choice of jejunostomy tube, balloon-type inflatable mechanisms should be avoided as they are prone to obstruct the bowel lumen. Bumper-style jejunostomy tubes are preferred.

Landmarking

In terms of location for DPEJ placement, the site may vary throughout the abdomen. It is not unusual for the DPEJ to be placed in the suprapubic or flank regions. In patients with prior surgery

the DPEJ operators should be aware of the altered anatomy and be cognizant for potential limitations or preferences for the site of DPEJ placement (ie, afferent vs efferent jejunal limb). Successful site landmarking requires a greater degree of precision in DPEJ in comparison to PEG. The diaphanoscopy may be falsely reassuring due to the existence of a “periscope effect” from the tortuous course of the small intestine. Transillumination on the abdomen may be the result of the endoscope light source reflecting throughout different points of the bowel wall rather than representing the true position of the endoscope tip. For this reason finger indentation must be particularly precise, in combination with diaphanoscopy, to locate an appropriate DPEJ site. Due to the mobile nature of the small bowel it may take several passes through the jejunum until a suitable location is identified. Once diaphanoscopy and finger indentation prospect a site the negative needle aspiration test can be performed. Following sterile preparation and during local anesthesia, aspiration of the needle is intermittently applied. The operator should look to the syringe now not only for blood that would indicate an underlying blood vessel, but stool as well that would indicate needle insertion into the colon. If this occurs, the needle should be withdrawn and a different location for DPEJ insertion sought. All landmarking maneuvers must be done swiftly due to the mobile nature of the small bowel.

JEJUNOSTOMY TUBE INSERTION

Following successful landmarking and injection of local anesthesia, once the needle has been identified endoscopically it remains held in place in the jejunum. This differs from PEG insertion where the needle is removed. The trocar is then applied beside the needle as close as possible to imitate its course through the abdomen. This reduces the likelihood of inadvertently penetrating abdominal vessels or structures. Once the trocar/catheter apparatus is successfully inserted into the small bowel the needle can be removed and the remainder of DPEJ insertion is similar to PEG insertion via the “pull” technique as presented earlier.

SUMMARY

Nutrition support is a vital component of care for critically ill patients. There are multiple modalities at the disposal of the medical team to ensure adequate nutrient delivery to the patient. The choice of intervention is dictated by the clinical scenario and technical expertise available.

Continuous Venovenous Hemofiltration

Anthony Manasia, MD, FCCP and Renzo H. Hidalgo, MD

99

KEY POINTS

- 1 Understanding the fundamental principles of continuous venovenous hemofiltration (CVVH), how it differs from hemodialysis, and its use in the critically ill patient is essential for all intensivists.
- 2 CVVH should be the intensivist's first choice as renal replacement therapy for any intensive care unit (ICU) patient with hemodynamic instability.
- 3 Continuous renal replacement therapy (CRRT) is most often prescribed based on body weight to an effluent flow rate target of 20 to 25 mL/kg/h. Effluent flow rates higher than 25 mL/kg/h do not improve outcomes in ICU patients.
- 4 Anticoagulation is generally recommended, as the clotting cascades are activated when the blood interfaces with the nonendothelial surfaces of the tubing and filter.
- 5 Administration of replacement fluid (RF) maintains fluid balance and lowers the plasma concentration of solute by dilution. Typical RF rates are 1000 to 2000 mL/h.

INTRODUCTION

CVVH is a form of CRRT that has a slower rate of solute or fluid removal per unit of time. It is generally better tolerated than conventional intermittent hemodialysis as many of the complications of hemodialysis are related to the rapid rate of solute and fluid loss as well as complement-induced hypotension. Acute kidney injury (AKI) occurs in up to 70% of patients admitted to the ICU and is associated with an increased mortality rate.¹ CRRT is the treatment of choice in critically ill septic patients in the ICU.^{2,3} Sepsis leads to renal hypoperfusion and subsequent volume resuscitation that cannot be autoregulated by the already insufficient kidney. This is further compounded by the numerous nephrotoxic medications and contrast agents used in diagnosis and treatment. Mortality from AKI is commonly the result of

multiorgan system failure (MOSF). Growing evidence suggests that AKI may also damage the lungs, brain, heart, or liver. Some forms of renal replacement therapy (RRT) may prevent MOSF.⁴ There is also evidence that fluid overload increases mortality and that volume control can improve outcomes.^{5–7} This has shifted the trend toward more aggressive and earlier RRT.

THE RIFLE AND ACUTE KIDNEY INJURY NETWORK CLASSIFICATIONS OF ACUTE KIDNEY INJURY

The acute dialysis quality initiative (ADQI) developed the following classification of AKI to foster uniformity in both research and clinical practice (Tables 99–1 and 99–2).

TABLE 99–1 RIFLE classification.

	GFR Criteria	Urine Output Criteria
Risk	Increased serum creatinine $\times 1.5$ or GFR decrease $> 25\%$	UO < 0.5 mL/kg/h $\times 6$ h
Injury	Increased serum creatinine $\times 2$ or GFR decrease $> 50\%$	UO < 0.5 mL/kg/h $\times 12$ h
Failure	Increased serum creatinine $\times 3$, GFR decrease $> 75\%$ or serum creatinine > 4 mg/dL (acute rise > 0.5 mg/dL)	UO < 0.3 mL/kg/h $\times 24$ h or anuria $\times 12$ h
Loss	Persistent AKI: complete loss of kidney function > 4 wk	
ESKD	End-stage kidney disease: complete loss of kidney function > 3 mo	
AKIN 1	Increased serum creatinine by 1.5-2 \times above baseline or by 0.3 mg/dL	UO < 0.5 mL/kg/h $\times 6$ h
AKIN 2	Increased serum creatinine by 2-3 \times above baseline	UO < 0.5 mL/kg/h $\times 12$ h
AKIN 3	Increased serum creatinine by $> 3\times$ above baseline or by ≥ 0.3 mg/dL in patients with baseline serum creatinine > 4 mg/dL	UO < 0.3 mL/kg/h $\times 24$ h or anuria for 12 h

AKI, acute kidney injury; AKIN, acute kidney injury network; GFR, glomerular filtration rate; RIFLE, risk, injury, failure, loss, end-stage renal disease; UO, urine output.

The acute kidney injury network (AKIN) classification is based on the risk, injury, failure, loss, end-stage renal disease (RIFLE) system with a few relevant modifications.⁸ First, it uses smaller increments in serum creatinine for the diagnosis of AKI. Second, it introduces a 48-hour time for diagnosis. Last, it eliminates the “loss” and “failure” categories as these represent outcomes, and should not be listed as part of the diagnosis. Recent evidence indicates that even minor declines in glomerular filtration rate

are associated with increased mortality in different populations of hospitalized patients. A meta-analysis of 8 studies observed a graded relationship between the amount of elevation of serum creatinine and mortality in AKI.⁹ Regardless of ICU type or clinical scenario, creatinine elevations of 10% to 24% above baseline resulted in a relative risk of 1.8 (1.3-2.5) for short-term mortality (30 days or less); patients with a rise of 25% to 49% had a relative risk of 3 (1.6-5.8), and those with greater than 50% increase had a risk of 6.9 (2-24.5). These data justify the “tighter” criteria proposed in the AKIN classification. Neutrophil gelatinase–associated lipocalin (NGAL) is a protein expressed in multiple tissues that is upregulated in proximal tubular cells immediately following ischemic injury has been studied as a biomarker of early kidney injury.¹⁰ Likewise, interleukin 18 (IL-18), cystatin C, and kidney injury molecule 1 (KIM-1) have all been studied and demonstrated the usefulness in early detection of acute renal injury.

TABLE 99–2 The presence of one the following indications suggests, 2 indications strongly suggest, and 3 indications mandate initiation of RRT.

<ul style="list-style-type: none">• Anuria/oliguria (diuresis ≤ 200 mL in 12 h)• Severe metabolic acidosis (pH < 7.10)• Hyperazotemia (BUN ≥ 80 mg/dL) or creatinine > 4 mg/dL• Hyperkalemia ($K^+ \geq 6.5$ mEq/L)
<ul style="list-style-type: none">• Clinical signs of uremic toxicity• Severe dysnatremia ($Na^+ \leq 115$ or ≥ 160 mEq/L)• Hyperthermia (temperature $> 40^\circ C$ without response to medical therapy)• Anasarca or severe fluid overload• Multiple organ failure with renal dysfunction and/or systemic inflammatory reaction syndrome (SIRS), sepsis, or septic shock with renal dysfunction

BUN, blood urea nitrogen.

RRT IN ACUTE KIDNEY INJURY
Intermittent hemodialysis has long been the preferred method of RRT in the United States. However, CRRT is gaining in popularity and is now reported to account for 36% of prescribed RRT treatments.¹¹ Internationally, continuous therapies had become the norm for AKI support.¹² “Beginning and Ending Supportive Therapy for the Kidney” (BEST Kidney),

a multinational, prospective study reported that CRRT with RRT support was used in 80% of treatments in the ICU, distantly followed by intermittent hemodialysis (17%).¹³ No evidence currently supports the superiority of one continuous modality over another or continuous over intermittent treatment. Choice of RRT modality should be based on clinical judgment and experience of the prescribing physician as well as the technologic, fiscal, and nursing resources available to deliver RRT.

PRINCIPLES OF SOLUTE CLEARANCE AND FLUID REMOVAL BY DIALYSIS AND CONVECTION

Dialysis therapies involve the movement of solute and plasma water across a semipermeable membrane separating a blood compartment and a dialysate compartment. This process occurs within a cartridge called a hemofilter or hemodialyzer. Characteristics such as membrane thickness and pore dimensions determine the size and transfer rate of molecules that move between the blood and dialysate. Removal of solute and water in RRT may occur by diffusion or convection (Figure 99–1). Diffusion involves movement of solute down a concentration gradient, from areas of high concentration to low concentration. Conversely, water will move from an area of low osmolality to an area of high osmolality. Solvent drag is a phenomenon by which large shifts of water pull some solute through the membrane. In a static system, net transfer (dialysis) ceases when solute concentrations equilibrate in the compartments. For RRT, blood and dialysate are continuously replenished to

maintain the high concentration gradients favoring maximum transfer of solute and water. Convection involves the transfer of solute across a semipermeable membrane driven by a hydrostatic pressure gradient. Those solutes small enough to pass through pores are swept along with water by solvent drag; substitution fluid is required to prevent excessive fluid removal. The membrane acts as a sieve, retaining molecules that exceed the pore size. All filtered solutes below the membrane pore size are removed at rates proportionate to their concentration. The convective removal of fluid in this manner is termed hemofiltration or ultrafiltration. This technique does not change the plasma concentration of small solutes (blood urea nitrogen [BUN], creatinine, electrolytes, glucose), as water is removed in proportion to solute. In contrast, the concentration of larger molecules, such as albumin, increase as they are sieved off by the smaller membrane pores. Thus, the chemical composition of the filtrate (ultrafiltrate) is almost identical to that of the plasma except for the absence of large molecules such as albumin. The administration of substitution fluid will dilute the plasma concentrations of those solutes (such as urea, creatinine, or potassium) not present in the substitution fluid.

In summary, whether or not a solute is diffused is inversely proportional to its molecular weight. The higher the molecular weight the more inefficient the diffusion.

INDICATIONS FOR INITIATION OF CVVH

The modern paradigm recognizes that AKI is an independent risk factor for death^{14–16} and that the aggressive management of RRT may affect outcomes

FIGURE 99–1 Renal replacement therapy in the ICU. (Data from Rimmelé T, Kellum JA: Renal Replacement Therapy in the ICU. PCCSU 24, 2010.)

and reduce mortality.¹⁷⁻¹⁹ However, there is no consensus on the optimal time to initiate RRT. This has led to a wide variation in clinical practice. Traditionally the indication for RRT²⁰ has been based on or a combination of the following: volume overload, such as pulmonary edema that is not controlled with diuretic use, hyperkalemia-induced arrhythmias, uncontrolled metabolic acidosis, intoxication with a dialyzable drug or toxin, and overt uremic signs such as encephalopathy, pericarditis, or even uremic bleeding diathesis.

Access for RRT

The optimal access for hemodialysis are arteriovenous fistulas (AVFs) that provide high blood flow (> 500 mL/min), durable long-term vascular access, relatively low thrombosis rates, and low infection rates. AVFs require months to mature and be functional, making them unsuitable for patients with AKI. AVFs cannot withstand prolonged cannulation associated with CCRT. Therefore with CVVH a temporary central venous catheter is needed. These catheters are generally noncuffed, nontunneled, double lumen with a large diameter of 12 to 15 Fr, providing a flow between 200 and 500 mL/min. They contain a venous and an “arterial” lumen although both lumens are in the same vein. The arterial lumen (typically red) withdraws blood from the patient and carries it to the CVVH machine, while the venous lumen (typically blue) returns blood to the patient from the machine. These catheters are typically constructed of materials such as polyurethane and are relatively stiff at room temperature, but become pliable at body temperature. They are inserted at the bedside. The internal jugular or femoral veins are preferred, over the subclavian vein due to the risk of developing venous stenosis after placement precluding future placement of an AVF in the ipsilateral arm.

Dosing

Despite the widespread use of CRRT, there is little consensus regarding the optimum delivery of RRT, resulting in wide variations in clinical practice.²¹ Some studies have suggested survival benefit from delivery of higher-intensity CRRT to patients with AKI, whereas other studies have been inconsistent in their results. CRRT is most often prescribed based on

the body weight to effluent flow rate target of 20 to 25 mL/kg/h. Recent studies have shown that effluent flow rate higher than 25 mL/kg/h does not improve outcomes in ICU patients.²² In our institution, the typical rates used for CVVH are a blood flow rate of 200 mL/min and RF rate of 2 L/h with ultrafiltration rate based on the individual need for fluid balance. This rate is variable and changes every hour depending on the total input and output of the previous hour. For example, if the desired fluid balance is -50 mL/h with a total input of 200 mL and output of 100 mL from the previous hour, the balance is $+100$ mL, therefore the ultrafiltration rate will be set at 150 mL/h.

Anticoagulation

Although CRRT can be run without anticoagulation, filters last much longer if some form of anticoagulation is used. Their fibers are prone to thrombosis, as removal of fluid through ultrafiltration leads to hemoconcentration at the distal end. Anticoagulation is generally recommended, as the clotting cascades are activated when the blood touches the nonendothelial surfaces of the tubing and filter. Multiple options exist for anticoagulation including heparin, prostacyclin, citrate, and even direct thrombin inhibitors. Unfractionated heparin is most commonly used, but can result in systemic anticoagulation and may be contraindicated in patients with active hemorrhage or heparin-induced thrombocytopenia (HIT). Any dose less than 5 units/kg/h is considered low-dose prefilter unfractionated heparin. This dose is reported to have minimal effect on the activated partial thromboplastin time (aPTT). A dose between 8 and 10 units/kg/h is considered medium-dose prefilter unfractionated heparin. This dose mildly elevates the aPTT and is recommended for patients with minimal risk of bleeding. Heparin may be administered using a pump integrated into the CRRT machine, or via a separate volumetric pump. Systemic unfractionated heparin is reserved for patients with other indications for systemic anticoagulation and is administered intravenously and titrated to achieve a target aPTT of about 1.5 to 2.5 times above the patient's baseline. For patients with high risk of bleeding regional unfractionated heparin to the CVVH blood circuit may be used. In this technique, a prefilter dose of 1500 units/h

of heparin combined with administration of protamine postfilter at a dose of 10 to 12 mg/h is used. This approach is monitored with the aPTT to keep it as close to normal as possible. Another option for these patients is the use of citrate. Citrate regional anticoagulation is widely used and has become the primary mode of anticoagulation in many centers. Citrate infused in the arterial limb of the CRRT circuit prevents hemofilter thrombosis by chelating calcium, a critical component of the clotting cascade. Calcium chloride infused into the venous line of the system restores normal systemic calcium levels. This approach appears to reduce the risk of hemorrhage and extend hemofilter patency.²³ In addition, citrate can be used for patients with HIT. Serum and ionized calcium levels should be carefully monitored, especially in patients with significant liver dysfunction, and the calcium infusion appropriately adjusted. Citrate is hepatically metabolized into bicarbonate and can cause metabolic alkalosis. In the setting of hepatic failure, citrate accumulation results in elevated serum but low ionized calcium levels, reflecting increased circulating calcium bound to citrate.

Filters

Semipermeable membranes are the basis of all blood purification therapies. The surface area of the membrane depends on the number and length of these fibers. Membrane surface area affects solute clearance and ultrafiltration. Membrane size or surface area varies with the specific model of hemodialyzer or hemofilter. Larger dialysis cartridges are used for patients with a larger surface area or those needing

high solute clearances. They allow water and some solutes to pass through the membrane, while cellular components and other solutes remain behind. The water and solutes that pass through the membrane are called the ultrafiltrate. Pore dimensions determine the size selectivity of molecular flux across the membrane, typically pore size membranes are 30,000 Da. Low-flux (< 500 Da) membranes clear small molecules (urea, potassium, and creatinine), but do not clear the larger “middle molecules” that may act as toxins. High-flux membranes (< 20,000 Da) clear middle molecules, such as β_2 -microglobulin and perhaps inflammatory cytokines generated by AKI and MOSF. There are 2 types of membranes used in RRT: cellulose and synthetic. Synthetic membranes are biocompatible, high flux, which allow clearance of larger molecules causing less trauma to platelets and white blood cells (WBCs), and are thus primarily used in CRRT. Filters are changed when they become contaminated, clogged, or according to individual hospital protocols.

REPLACEMENT FLUID

RFs are used to increase the amount of convective solute clearance in CVVH by replacing large volumes of ultrafiltrate with fluids that do not contain the solutes targeted for removal. Solute clearance and volume removal are adjusted by altering the ultrafiltration rate and the rate of infusion of RF. They can be replaced before or after the filter depending on individual needs (Figure 99–2). As the filtration fraction (FF), that is, the proportion of plasma flow

FIGURE 99–2 Early and intensive continuous hemofiltration for severe renal failure after cardiac surgery. (Reproduced with permission from Bent P, Tan HK, Bellomo R, et al: Early and intensive continuous hemofiltration for severe renal failure after cardiac surgery, *Ann Thorac Surg*. 2001 Mar;71(3):832-837.)

that is filtered, increases, the risk of filter thrombosis also rises. Higher rates of ultrafiltration, especially if coupled with low blood flows, predispose to hemofilter thrombosis. Poor filter performance and filter clotting increase sharply at FF greater than 20%. Higher blood flow rates permit greater rates of fluid removal, as hemoconcentration within the filter is limited by the short transit time of blood through the dialysis cartridge. In CVVH, blood flow rates are typically low and ultrafiltration rates are high, which is a significant barrier to effective implementation of these therapies. One approach called predilutional hemofiltration, which is preferred by the authors, involves infusion of RF into the CRRT circuit at a point before the filter, thus lowering the hematocrit through dilution. As a result, a higher ultrafiltration rate may be achieved without compromising filter life. Prefilter RF also dilutes the solute concentration of blood entering the filter and reduces effective clearance. The administration of RF maintains fluid balance and lowers the plasma concentration of solute by dilution. Typical RF rates are 1000 to 2000 mL/h. Rates slower than this are not effective for convective solute removal, but should not exceed one-third of the blood flow rate per hour. There are a number of variable RFs available including normal saline, plasmalyte, or specific commercial products for CVVH with variable electrolyte concentration depending on the clinical condition of the patient as well as the patient's fluid, electrolyte, acid-base, and glucose balance.

COMPLICATIONS OF CVVH

Local bleeding can occur at the vascular access site or might be subcutaneous and not obvious. The access site should be closely monitored for bleeding, hematoma, or ecchymosis. Femoral lines in particular may cause internal bleeding that is not immediately apparent. Monitor the hemoglobin or hematocrit and vital signs closely as they may indicate occult bleeding. Inadvertent disconnection of the CRRT blood circuit could lead to significant blood loss. Modern CRRT machines are equipped with alarms and cutoff switches to minimize this risk. Watch for low access pressure alarms and low return pressure alarms, as they could indicate a

disconnection. Generalized bleeding complications can occur as a side effect of anticoagulation or as a result of critical illness itself. It is vital to monitor the platelet count for thrombocytopenia, coagulation factors, and fibrinogen for signs of disseminated intravascular coagulation (DIC). Care should be taken when priming the tubing as to prevent air bubbles from entering the systemic circulation and causing an air embolism. Hypothermia is another potential complication because of the extracorporeal circulation during CVVH and exposure of RFs to room temperature. Patient's body temperature should be kept above 36°C to maintain adequate hemodynamics and effective hemostasis. Newer CVVH machines have blood warmers integrated into them. Inline fluid and blood warmers are also available so that fluids can be warmed prior to administration. Most CRRT protocols require monitoring of electrolytes and pH every 4 to 6 hours during the first 24 hours of therapy and whenever RFs are changed. CRRT is an invasive process that increases the risk of infection in a patient that is already vulnerable due to renal failure, critical illness, and other invasive lines and procedures. These patients must be monitored closely for signs and symptoms of infection so treatment can be initiated as rapidly as possible. Infections caused by CVVH may be local to the vascular access site or systemic. It is important to remember that when CVVH is in progress fever may be masked due to the cooling effect of extracorporeal circulation. Monitor for other signs of infection such as elevated white blood cell count, increased numbers of immature WBCs, and local symptoms like redness, swelling, and purulent drainage. All connections and vascular access sites must be handled with meticulous aseptic technique to minimize the risk of infection. As patients receiving CVVH will clear renally excreted drugs efficiently, dosing of these drugs should not be reduced for renal function while on CVVH unless clinically indicated. After initiation of CRRT drug levels may need to be drawn to ensure adequate plasma concentrations especially for antibiotics and anticonvulsants. Drips of renally cleared drugs may need to be titrated up while on CVVH and likewise may need to be decreased once CVVH is stopped. Special care must be taken when

discontinuing CVVH as certain drugs may build up to toxic levels.

Troubleshooting

Although there are many different types of CVVH machines and each one has its own individual characteristics, we will review some general issues. The access pressure is normally negative; however, excessive negative pressure usually indicates an occlusion somewhere in the access limb of the blood circuit. The complete tubing system should be inspected in search of kinks and stopcocks should be confirmed for proper position. Vascular access should also be evaluated for poor position or swelling at the site. The patient should be positioned properly to minimize flexion near the insertion site and the access port should be aspirated and manually flushed. The return pressure is normally positive and low return pressures could indicate a disconnection at some point, return tubing should be checked for proper connections. Low return pressures can also be encountered when patients are laterally rotated due to orthostatic changes in venous pressure. Alarms that occur due to position changes will usually resolve within a couple of minutes. High return pressures can occur because of occlusions. Filter pressure alarms usually only sound when the filter is clogged or clotted. Initial filter pressures should be measured each time a new filter is placed. Filter pressure usually remains stable throughout therapy. The filter pressure can be trended to help for predict clotting. CVVH machines can detect blood leaks indicating broken filaments in the filter by looking for the presence of blood in the effluent. The sensors will alarm if myoglobin or large amounts of bilirubin are detected in the effluent. A sample should be sent to the laboratory to confirm their presence. The bubble detector is designed to stop the blood pump if air is detected within the line. If it alarms, inspect all tubing carefully for the presence of air bubbles and either reprime or change the filter set. Make sure that all air is cleared from the system during priming, keep all connections tightly joined, and use Luer-lock type connectors. The fluid pump alarms when the bag is empty while the effluent pump alarms when full. Alarms will also sound if a clamp is left closed or a bag is improperly spiked.

High-Frequency Oscillatory Ventilation

Michael Duf, MD and
Stephen M. Pastores, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 High-frequency oscillatory ventilation (HFOV) is a form of ventilatory support which delivers very small tidal volumes (1-2 ml per kg) at very high rates (3-15 breaths per second).
- 2 The major indication for HFOV is for patients with severe acute respiratory distress syndrome (ARDS) whose lungs cannot tolerate high tidal distending pressure.
- 3 The main determinant of oxygenation during HFOV is the mPaw which is generally initiated at approximately 5 cm H₂O greater than the mPaw noted during conventional ventilation.
- 4 Carbon dioxide removal during HFOV is directly proportional to the oscillation amplitude and inversely proportional to the oscillation frequency setting.
- 5 Two recent multicenter randomized trials showed no benefit (OSCAR) and even harm (OSCILLATE) with the use of HFOV in adult patients with ARDS.

INTRODUCTION

High-frequency oscillatory ventilation (HFOV) is a form of ventilatory support that delivers extremely small tidal volumes (V_{Ts}) at very high rates and maintains a relatively constant and higher mean airway pressure (mPaw) than mechanical ventilation. These properties make HFOV an ideal mode of ventilation for lung protection, because it can allow clinicians to operate in a “safe” zone of the volume-pressure curve, avoiding zones of overdistension and derecruitment/atelectasis, provided an optimal mPaw is set and very small V_{Ts} are delivered.

BACKGROUND

HFOV was first described in 1972 and was used to improve oxygenation in neonates with severe respiratory distress syndrome. It was gradually

expanded into larger, more mature pediatric patients with severe respiratory failure. In 2001, the Food and Drug Administration approved HFOV devices for use in adult patients with acute respiratory distress syndrome (ARDS) who failed conventional mechanical ventilation (CMV).

PHYSIOLOGY AND MECHANISMS OF GAS EXCHANGE DURING HFOV

Conventional ventilation mimics the respiratory cycle with inspiration and expiration via positive pressure inhalation compared with the negative pressure that drives normal respiration. HFOV is based on several features of nonlaminar flow of gas into and out of a circuit. High-pressure gas flows down the center of the airway, displacing lower pressure gas via coaxial flow and bulk flow. Between

cycles and in distal airways, gases mix uniformly so that delivered, oxygen-rich gas saturates available alveoli to maximize the chances of diffusion of oxygen into the bloodstream. This mixing is called pendelluft and essentially accounts for dead space ventilation of any kind, but is especially useful in HFOV. “Exhaled” gases move by previously mentioned bulk and coaxial flows toward the negative pressure generated by the high-velocity “breaths” where they ultimately exit the endotracheal tube into the exhalation circuit. HFOV can be considered to have separated oxygenation and ventilation into 2 separate mechanisms.

Similar to CMV when the respiratory frequency exceeds the time for intrinsic exhalation phase, HFOV delivers breaths that can lead to developing auto-positive end-expiratory pressure (auto-PEEP). This can still occur with very small tidal volumes in HFOV. Whereas auto-PEEP in CMV can be deleterious, the typical small volumes and high rates used in HFOV allow the clinician to avoid auto-PEEP; however, patients with elevated airway resistance are relatively contraindicated for HFOV. The typical maneuver to reduce auto-PEEP is to increase the frequency, which decreases the inspiratory time, and allows for more exhalation and limits breath stacking. Other mechanisms of gas exchange during HFOV include cardiogenic mixing where the contracting heart causes mechanical agitation of gas, especially in lung units surrounding the heart, and molecular diffusion near the alveolar-capillary interface.

INDICATIONS FOR HFOV

HFOV is indicated for patients with severe ARDS whose lungs cannot tolerate high tidal distending pressure. In these patients, HFOV may provide a modality to improve oxygenation and maintain peak airway pressures that are nearly the same as the mean airway pressures. Although the pressure wave at the level of the endotracheal tube has a large gradient, the distending pressures exerted on the alveoli are much closer to the mean airway pressure and the theory suggests that the lung is maintained in a constantly open state. Conversely, the “tidaling” of CMV still exerts a gradient on the distal airways and alveoli. This means that if underrecruited, there

exists the possibility of “atelectrauma” as the lung is opened and closed with each cycle. In the setting of very poor lung compliance, barotrauma is common.

Patient selection begins with moderate to severe ARDS that by strict definition represents patients whose ratio of the partial pressure of oxygen from the arterial blood to the fraction of inspired oxygen ($P_{aO_2}:F_{IO_2}$) is less than 200, and who require PEEP greater than 10 to 15 cm H₂O to achieve this oxygenation. Patients with plateau pressures greater than 30 cm H₂O and/or mean airway pressures of greater than 24 cm H₂O can also be considered for HFOV. Similarly, patients ventilated by other alternative modes including airway pressure release ventilation (APRV) with P_{high} greater than 35 cm H₂O can be considered. Though not specifically studied, case reports of patients with bronchopleural fistulas have been successfully treated with HFOV.

CONTRAINDICATIONS

HFOV has not been studied in pregnant patients, those with severe chronic obstructive pulmonary disease (COPD), and in patients with hemoptysis or copious thick secretions. Patients with high airway resistance are at increased risk of developing auto-PEEP and should be carefully screened. Pneumothorax is not a contraindication to HFOV, and the clinician must be aware of the possibility that a pneumothorax can occur at any time.

SETUP AND INITIATION OF HFOV

Following patient selection for HFOV, the airway should be suctioned and adequate sedation and analgesia should be provided (Table 100–1). Many patients experience discomfort with the constant insufflation of the lung and vibrations associated with HFOV, and thus may require deeper sedation and occasionally neuromuscular blockade to ensure patient-ventilator synchrony and reduce peripheral oxygen consumption. However, complete cessation of patient respiratory efforts is not recommended and preferably, the patient should be allowed to generate small spontaneous breaths. Once the patient

TABLE 100–1 Initial settings for HFOV.

1. Set initial mPaw at 5 cm H₂O above conventional ventilator mPaw (consider initial alveolar recruiting maneuver with 40 cm H₂O for 40–60 s if severe hypoxemia).
2. Set power to achieve initial ΔP at chest wiggle to mid-thigh or “20+Paco₂”.
3. Set Hz at 5.
4. Set IT to 33% (may increase to 50% if difficulty with oxygenation; this may further raise carinal pressure an additional 2–4 cm H₂O).
5. If oxygenation worsens, increase mPaw in 3–5 cm H₂O increments Q 30 minutes until maximum setting (approximately 45–55 cm H₂O).
6. If Paco₂ worsens (but pH > 7.2), increase ΔP in 10 cm H₂O increments Q 30 minutes up to maximum setting. After maximum ΔP achieved, if necessary, may decrease Hz to minimum of 3 Hz.
7. If severe hypercapnea with pH < 7.2 bag patient, set maximum ΔP , Hz at 3, and try small cuff leak \approx (5 cm H₂O and then compensate bias flow); rule out obstruction in endotracheal tube with bronchoscopy.
8. If oxygenation improves, gradually wean FiO₂ to 40%, then slowly reduce mPaw 2–3 cm H₂O q 4–6 hours until 22–24 cm H₂O range.
9. When above goal met, switch to PCV (initial settings: peak pressure titrated to achieve delivered TV 6 ml/Kg, Pplat < 30–35 cm H₂O), IE 1:1 PEEP 12 cm H₂O, rate 20–25, mPaw should be 20 cm H₂O (+/- 2 cm H₂O).

Data from Derdak S. High-frequency oscillatory ventilation for acute respiratory distress syndrome in adult patients, Crit Care Med. 2003 Apr;31(4 Suppl):S317–S323.

is stable on HFOV, discontinuation of the paralytic agent should be attempted daily.

Initial bias flow should be set to 35 L/min and may be adjusted according to patient's needs. Inspiratory time is set as a percentage and 33% is recommended as an initial setting. Frequency should be set to 5 Hz, which correlates to a respiratory rate of 300 breaths/min. The main determinant of oxygenation during HFOV is the mPaw, and this is generally initiated at approximately 5 cm H₂O greater than the mPaw noted during conventional ventilation or equal to that of APRV. For severely hypoxemic patients, a recruitment maneuver of 40 cm H₂O for approximately 40 seconds can be considered. The Fio₂ should be set to 1 and then tapered using pulse oximetry to maintain SpO₂ greater than or equal to 88%.

The main determinants of Paco₂ removal are the pressure amplitude of oscillation (ΔP) and the frequency (Hz) setting. Increasing the ΔP and

decreasing the frequency reduces the delivered tidal volume and allows Paco₂ to rise. The ΔP is usually started at either a value where the chest vibrates down to their midthigh or a value of 20 to 30 cm H₂O above what the patient's Paco₂ was on conventional ventilation. For example, if the Paco₂ is 60 mm Hg, the ΔP is initiated at 80 cm H₂O. After approximately 30 minutes of HFOV, a repeat blood gas should be analyzed and the power setting should be titrated based on the desired Paco₂ level. The chest wall needs to be vibrating; if not, the power setting has to be increased.

TROUBLESHOOTING

On all patients placed on HFOV, it is crucial that oxygen is flowing to the patient. By convention, in the United States oxygen tubing and cylinders are color-coded green. Pressurized air is color-coded yellow, and contains only 20.9% oxygen, the same as room air. Most HFOV ventilators display the amplitude and frequency. While an unexplained rise in amplitude can suggest that the endotracheal tube is becoming obstructed, a sudden decrease in amplitude can suggest pneumothorax. Examining the ventilator tubing can sometimes reveal secretions or hemoptysis. When examining the patient, a decrease in the patient's chest wiggle can suggest pneumothorax, and a prompt chest x-ray should be performed. Although suctioning and bronchoscopy can cause derecruitment, they can be very important in managing the patient on HFOV. Care should be taken to minimize the duration of suctioning and bronchoscopy, and recruitment maneuvers might be considered following any interruption in HFOV.

Routine measures such as obtaining chest x-rays and performing physical examinations are not contraindicated while the patient is on HFOV. Temporarily stopping the piston allows for auscultation of the patient's heart, but stoppage should be minimized. Patients can be moved for imaging studies without stopping HFOV. Daily nursing care remains unaffected. Measures to ensure adequate sedation such as a Bispectral Index Sensor (BIS) monitor should be in place if an infusion of neuromuscular blocking agent is being used as well as routine train-of-four monitoring to minimize the side effects of neuromuscular blockade.

COMPLICATIONS OF HFOV

Complications that may occur during HFOV include hypotension, pneumothorax, and endotracheal tube obstruction. Hypotension occurs occasionally shortly following the switch to HFOV or as mPaw is increased and usually responds to intravenous fluid boluses. A pneumothorax during HFOV may be difficult to detect because of the background noise of the ventilator and the diffuse transmission of airway sounds. However, the loss of chest wiggle that usually occurs on the affected side is an important physical clue to the possibility of a pneumothorax. Obstruction of the endotracheal tube should be considered when there is an abrupt rise in Paco_2 during HFOV in an otherwise stable patient. In this circumstance, a suction catheter should be passed immediately to ensure patency of the endotracheal tube; occasionally, bronchoscopy may be required to visually inspect the airway.

WEANING FROM HFOV

Weaning attempts from HFOV usually commence when the patient responds with improved oxygenation and is able to maintain a SpO_2 greater than 90% on a Fio_2 of 0.4. When this occurs, the mPaw is gradually reduced by 2 to 3 cm H_2O every 4 to 6 hours as tolerated as alveolar derecruitment and desaturation may occur if the mPaw is decreased rapidly. As soon as a mPaw of 20 to 24 cm H_2O is achieved while maintaining an Fio_2 of 0.4, the patient can be switched back to a trail of conventional ventilation. The conventional ventilator is usually set to achieve a mPaw of 20 cm H_2O by using pressure control mode with peak pressure set to achieve a delivered tidal volume of 6 to 8 mL/kg of predicted body weight and inspiratory plateau pressure of less than 30 cm H_2O . An arterial blood gas is obtained 20 to 30 minutes after transfer to conventional ventilation to guide further ventilator adjustments.

RECENT STUDIES OF HFOV IN ADULTS

Two large multicenter trials compared HFOV with conventional ventilation in patients with moderate-to-severe ARDS. In the OSCILLATE (Oscillation for

ARDS Treated Early), the HFOV strategy with high mean airway pressures was associated with more deaths than the conventional ventilation strategy that used relatively aggressive high PEEP levels (47% vs. 35%) which led to premature termination of the trial. Hemodynamic compromise resulting from the elevated mean airway pressures was thought to be the mechanism accounting for the poor HFOV outcomes. In the OSCAR (High-Frequency Oscillation in ARDS) trial, there was no major difference in the outcome between the HFOV strategy and usual care with conventional mechanical ventilation. In both trials, there was a higher proportion of patients in the HFOV groups who received sedatives and muscle relaxants, which may have also contributed to the poorer outcomes.

Intracranial Pressure Monitoring

Nelson Moussazadeh, MD; Philip E. Stieg, PhD, MD
and Halinder S. Mangat, MD

KEY POINTS

- 1 By the “Monro-Kellie doctrine,” increase in volume of intracranial contents causes increase in intracranial pressure (ICP) once compensatory mechanisms are exhausted.
- 2 Intraventricular catheters (IVCs) are the most common mode of direct ICP measurement and remain the “gold standard.” Intraparenchymal probes may also be used via a transcranial placement device, commonly referred to as a “bolt.”
- 3 Traumatic brain injury (TBI) guidelines provide guidance when to place an ICP measurement device. Placement must be performed by a trained neurosurgeon.
- 4 Cranial landmarks are used to guide device placement most commonly at “Kocher point.”
- 5 Infection is the most important risk of IVCs; therefore, they must be removed when pressure measurement or cerebrospinal fluid (CSF) diversion is no longer required. Intraparenchymal probes carry a significantly lower risk of infection.

OVERVIEW

ICP monitoring is a mainstay of modern neurocritical care, with a range of devices serving different clinical needs. It is central to the management of severe TBI with suspected intracranial hypertension. In addition, ICP measurement and treatment may also be undertaken in other instances of brain injury associated with intracranial hypertension such as acute subarachnoid hemorrhage, malignant stroke, and meningitis.

The Monro-Kellie hypothesis explains the centrality of ICP to the neurologically ill patient. The rigid cranium limits the volume of its contents; any expansion of the brain, blood, or CSF volume (or addition of orthotopic volume, eg, from neoplasm, abscess, or via inflammation), results an initial

compensatory buffering by reduction in CSF and blood volume. If the increase in volume exceeds compensatory mechanisms, elevation in ICP occurs. Pressure elevation presages a volume reduction in tissues in order of compliance and proximity to outlets with large pressure-gradient interfaces. Cerebral herniation including uncal, transtentorial, central, and tonsillar herniation often result in brain stem and vascular compression, respiratory suppression, and irreversible neurologic injury, making malignant intracranial hypertension highly morbid ([Figure 101–1](#)).

IVCs remain the gold standard for the measurement of ICP. The procedure of placing an IVC is commonly referred to as ventriculostomy and when combined with a closed drainage system,

FIGURE 101–1 Schematic drawing of brain herniation patterns. 1. Subfalcine herniation. The cingulate gyrus shifts across midline under the falx cerebri. 2. Uncal herniation. The uncus (medial temporal lobe gyrus) shifts medially and compresses the midbrain and cerebral peduncle. 3. Central transtentorial herniation. The diencephalon and midbrain shift caudally through the tentorial incisura. 4. Tonsillar herniation. (Reproduced with permission from Wilkins RH, Rengachary SS: *Neurosurgery*, 2nd ed. New York: McGraw Hill; 1996.)

as an external ventricular drain (EVD). The latter combines ICP monitoring with CSF diversion ([Figure 101–2](#)). More recently the “transcranial bolt” has also been used as an access to place intraparenchymal probes for direct and continuous measure of ICP ([Figure 101–3](#)).

Each technique has distinct advantages and limitations; these notably include the ability to both diagnose and treat intracranial hypertension with an EVD, while posing the occasional technical challenge of cannulating the ventricle and imposing the need for closure to drainage for accurate monitoring. Whereas all monitors furnish instantaneous ICP and allow for derivation of cerebral perfusion pressure (difference between mean arterial pressure [MAP] and ICP), intraparenchymal probes placed using bolts have the added advantage of furnishing continuous data allowing for assessment of trends including ominous Lundberg wave patterns (eg, so-called plateau/A-wave) ([Figure 101–4A,B](#)). Bolts

equipped with requisite probes can also measure interstitial brain tissue oxygenation partial pressure (P_{btO_2}), cerebral blood flow, temperature, seizures via intracortical electroencephalography, and brain metabolism via online cerebral microdialysis. When selecting monitoring modalities, the neurointensivist and neurosurgeon should note that TBI and mass lesions may induce deranged CSF flow and pressure gradients resulting in disparate regional parenchymal versus ventricular ICP as well as transient compartmental ICP gradients.

INDICATIONS

Outside of severe TBI, guidelines are not well established for ICP monitoring and its use varies considerably from center to center. ICP monitoring is considered in cases with concern for acute intracranial hypertension resulting from a variety of pathologies causing generalized edema (eg, in the setting of trauma, ischemia anoxia, acute liver failure, diabetic ketoacidosis, venous hypertension, meningitis), mass lesions (traumatic hematoma/contusion, tumor), and hydrocephalus (communicating from, eg, subarachnoid hemorrhage as the most common indication or noncommunicating from a variety of causes). ICP is also commonly monitored in drowning or near-drowning in children. Noncorrectable coagulopathy or antiplatelet use is a contraindication to EVD placement (in addition to scalp infection and intracranial abscess). However, when offered despite this as part of lifesaving maneuvers, particular caution must be exercised during placement.

EVIDENCE FOR ICP MONITORING

ICP monitoring has been best studied in the setting of severe TBI, and is the mainstay in goal-directed treatment. According to the Brain Trauma Foundation guidelines on the basis of Level II evidence, ICP monitoring is indicated for all salvageable severe TBI patients (GCS 3–8 after cardiopulmonary resuscitation) in the setting of an abnormal head computed tomography (CT) (with hematoma, contusion, swelling, herniation, or compressed basal cisterns).

FIGURE 101–3 An intraparenchymal ICP monitor from Integra Life Sciences. (Permission granted by Integra LifeSciences Corporation, Plainsboro, New Jersey, USA.)

On the basis of Level III data, invasive ICP monitoring is recommended for patients with severe TBI and a normal CT with 2 or more of age greater than 40, unilateral/bilateral motor posturing, or systolic blood pressure less than 90 mm Hg.

There has been some recent debate regarding the use of ICP monitoring. A study by Chesnut et al, demonstrated that therapy based on ICP monitoring versus serial brain CT imaging had similar outcome benefit. However, this study has several criticisms, the most important being the delay in arrival of patients to the hospital and delay in ICP monitor insertion. Prehospital delay, hypoxia, and

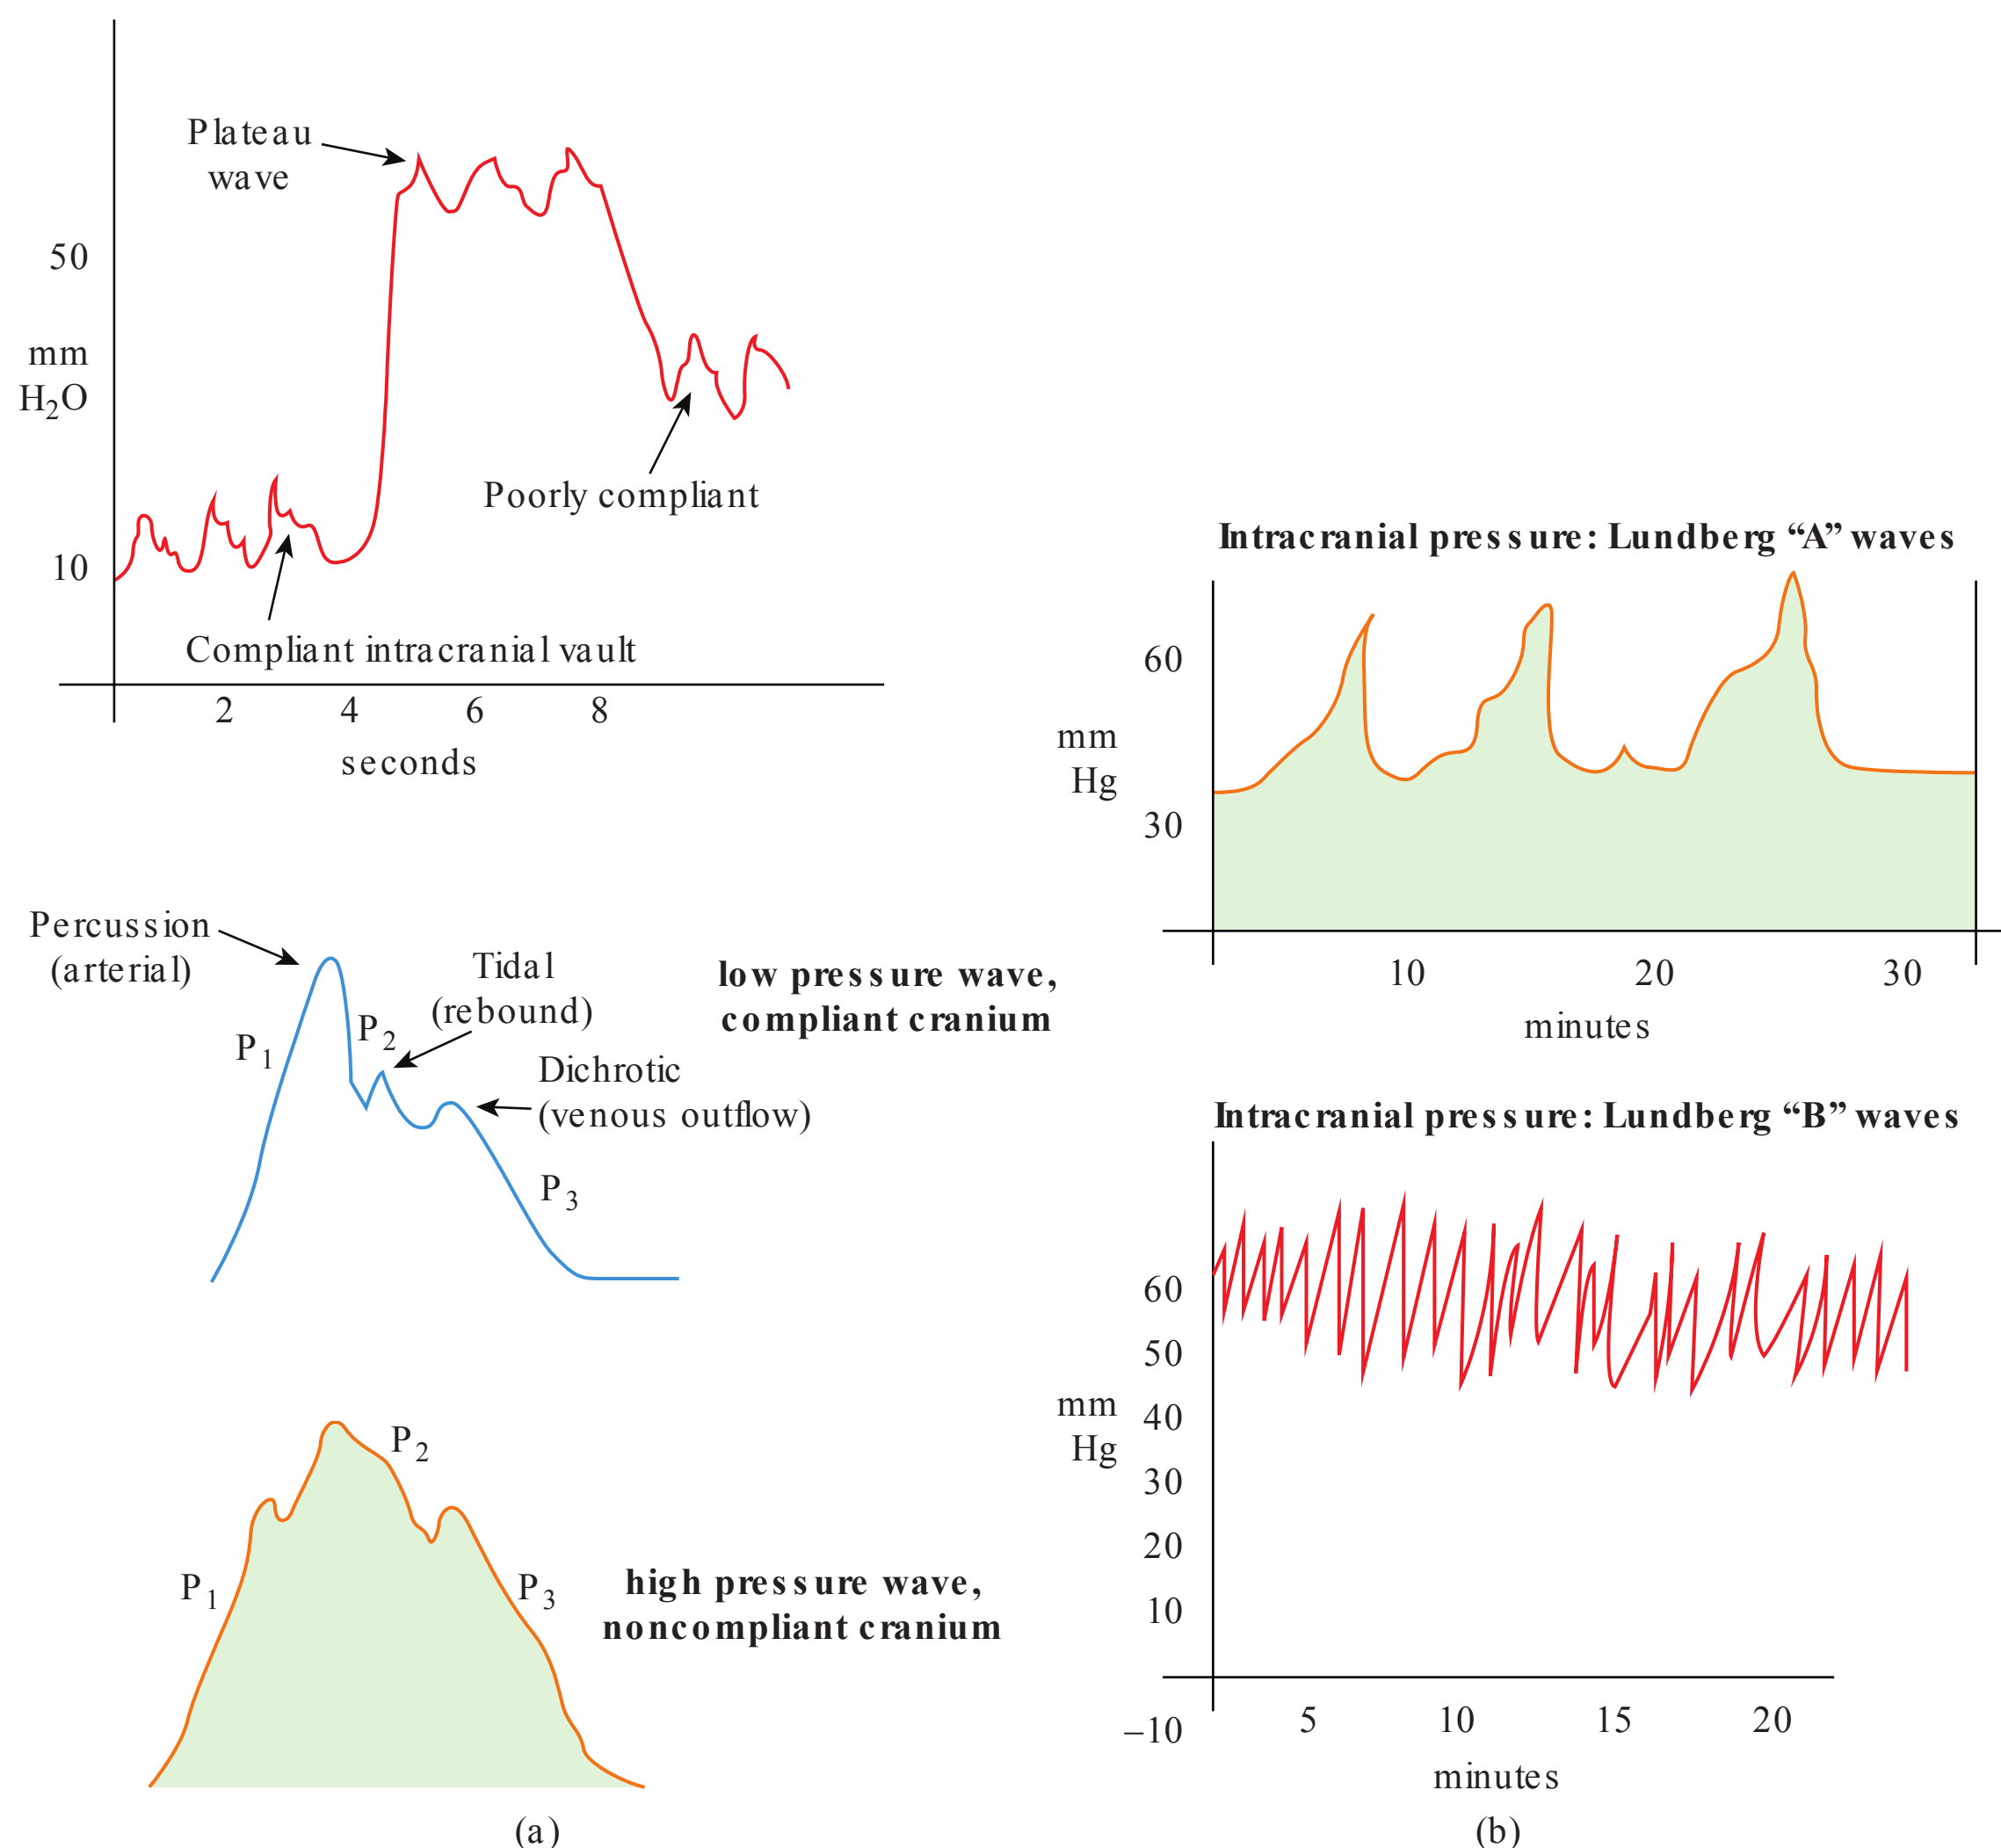

FIGURE 101–4A,B ICP waveforms. In the poorly compliant cranium, elevated rebound (P₂) pressures dominate waveform derangement, ultimately leading to transient plateau or Lundberg A-wave hypertension, which CSF and intracranial blood content reduction becomes progressively less (Reproduced with permission from Frontera JA: *Decision Making in Neurocritical Care*. New York: Thieme; 2009.)

hypotension have been shown to contribute to worse outcomes in severe TBI patients, and this is an important confounder in the above study. Therefore, the neurosurgical and neurocritical care communities remain circumspect about the significance of these results. Moreover, it has been shown that patients without measurement of ICP have higher mortality and patients who respond to treatment of elevated ICP have improved outcome.

VENTRICULOSTOMY PLACEMENT WITH ICP MONITORING

Ventriculostomy placement and bolt placement can be performed in the operating theater or at the bedside in the emergency room or the intensive care unit (ICU). These procedures should only be performed by qualified and accredited neurosurgeons.

The right frontal approach to cannulation of the lateral ventricle is the neurosurgical workhorse given relative ease of placement in supine patients and avoidance of the nondominant hemisphere; however, this may be modified according to individual circumstances.

In the most typical approach, Kocher point serves as a landmark for a typical safe trajectory. Kocher point lies 10 cm posterior to the glabella and 3 cm lateral to midline and is at the midpupillary line and anterior to the coronal suture. This allows for a nondominant high frontal corticectomy avoiding the superior sagittal sinus medially and precentral gyrus posteriorly.

The patient is positioned supine with head end of the bed elevated with creation of ample working corridors; this is particularly important with intubated patients within constrained ICU rooms. Imaging should be reviewed and displayed. The patient's head should be shaved, cleaned, and the incision site marked using landmarks described earlier.

A procedure time-out should be performed with surgical and nursing staff confirming conformation to standard procedures and availability of necessary equipment. Antibiotics should be administered within 30 minutes of skin incision time, and analgesia/sedation should be used judiciously.

After sterilization and draping the field, skin including tunneling and tack-down sites and the subperiosteal compartment are infiltrated with local anesthetic. An incision is made at Kocher point, anteromedial to posterolateral allowing for incorporation into any future incision, for example, frontotemporal craniotomy. Pericranium is scraped away with the scalpel handle and a self-retaining retractor is placed. Hemostasis should be obtained; while occasional brisk scalp bleeding may pose a challenge without cautery or the full menu of operating room equipment, local pressure, clamps, and suture are usually adequate. The head is firmly held from below the sterile drapes via mandibular grasp by an assistant, and a burr hole is created using a twist drill or an electric drill. A trocar is utilized to create a durotomy and to generate a tunnel for the ventricular catheter. Meticulous hemostasis is ensured to avoid clot formation at catheter inlet at the time of insertion. Bedside burr holes do not allow for

visualization and avoidance of sulci or use of pial cautery, however, in the operating room setting both should be performed.

For a frontal, for example, Kocher point approach, the catheter should be oriented orthogonally to the calvarial surface (the Ghajar Guide may be used to assist in this); as this may frequently be difficult to assess within the confines of a limited incision, the frontal horn and foramen of Monro are typically estimated with a trajectory toward the intersection of a sagittal line from the medical canthus and a coronal line from the external auditory meatus. The ventricular catheter should be passed to a depth of approximately 5 cm from the external calvarial table, with the final 1 cm of that length passed without the rigid catheter stylet, which is removed upon recognition of a trans-ependymal “pop” to avoid blunt vascular or parenchymal injury. Opening pressure should be noted. Should CSF not spontaneously flow, gentle syringe aspiration of any air lock may solve the problem.

Excessive attempts at catheter replacement should be avoided with a low threshold to obtain CT imaging to ensure no shifts in underlying anatomic structures. CT guidance may be used as an adjunct to ventriculostomy placement in difficult cases; neuro-navigation is also an option intraoperatively. The free end of the ventricular catheter is subcutaneously tunneled using a trocar available in the placement kit and is then connected to the closed collecting system. The incision is closed, a nonocclusive purse-string suture is placed at the skin exit site, and the catheter is tacked down at several points on the scalp to prevent accidental dislodgement. With a head elevation of 30°, the external auditory meatus lies in approximately the same horizontal plane as the foramen of Monro, allowing its use as a surface landmark for calibrating “zero” isotension. Drainage is continued at a level or rate appropriate to the patient's clinical circumstance.

INTRAPARENCHYMAL ICP MONITOR PLACEMENT

The approach to bolt placement is similar to ventriculostomy placement; the bolt is screwed into place following twist-drill hole creation (ensuring a drill

bit of diameter compatible with the available bolt is used). Durotomy is performed, the bolt's sheath is placed, and probes are placed to a suitable depth after requisite calibration/zeroing per the manufacturer's specifications; skin closure is performed around the device margins with meticulous prevention of CSF egress. Many probes allow for tunneling without the use of a bolt (including for intraoperative, postcraniectomy use) for which one should consult the manufacturer's instructions.

DEVICE USE AND MONITORING

CT imaging may be obtained to verify the device placement particularly in the setting of challenging placement or unreliable data or CSF output. ICP monitors are left in place for several days with data monitored continuously, or hourly with EVDs. The routine use of perioperative or prolonged prophylactic systemic antibiotics following ICP monitor introduction remains controversial, with disparate usage patterns. Though ICU-bound comatose patients are at elevated risk for surgical site infection including ventriculitis or cerebritis (see the section on Complications), the literature remains divided with regard to infection rates while potentially creating the risk of multidrug-resistant infections.

Similarly, routine CSF surveillance from EVDs for ventriculitis has been advocated or employed by some centers, though its use remains controversial given the potential for introduction of pathogens upon each instance of instrumenting the system. Prophylactic catheter exchange for infection prevention is not advocated on the basis of studies including one randomized trial performing routine exchange on 103 patients. Others have demonstrated a procedural noninfectious complication rate of 5.6% for EVD placement itself, which likely outweighs any benefit from infection reduction.

COMPLICATIONS AND TROUBLESHOOTING

The primary complications associated with ICP monitor placement are infection, hemorrhage, and malfunction. Ventriculostomy-related infection has

been reported most commonly around 10% of drains placed (2%-25%), or 7.5 to 32 infections per 1000 drain-days, though reported rates depend on the definition used (ie, surveillance data, including the Centers for Disease Control and Prevention [CDC] definition of health care–associated meningitis, are frequently blinded to clinical diagnosis, bacterial culture growth, and treatment ramifications). Associated clinical ventriculomeningitis (a diagnosis made on the basis of CSF cellular and metabolic profile, culture data and clinical parameters including fever, peripheral leukocytosis, and findings of meningismus) is a significant cause of morbidity.

Risk factors for ventriculostomy-related infection include duration of catheterization, catheter irrigation/sampling or replacement, neurosurgical operation, systemic infection, CSF leak, and intraventricular or subarachnoid hemorrhage. Responsible microorganisms most commonly include skin flora (eg, *Staphylococcus aureus* and *epidermidis*, streptococci, and *Propionibacterium acnes*), and gram-negative bacteria including *Pseudomonas* and *Enterobacteriaceae*. Evidence suggests reduced infection risk with minocycline or clindamycin plus rifampin-impregnated catheters (1.3% vs 9.4% infection and 17.9% vs 36.7% colonization rates), potentially with silver-impregnated ones, and with institution of ICU-based placement bundles and hygiene interventions.

Parenchymal pressure monitors may be associated with a seemingly lower infection rate, though this may be influenced by sampling bias given the ease of CSF access for ventriculostomy surveillance and with few studies culturing device tips in all patients or CSF in all patients. However, retrospective series generally describe clinical infection rates of less than 5% (and mostly < 2%, with higher colonization rates) and either noninferiority or reduced infection risk versus EVD.

While the majority of studies evaluating hemorrhage following invasive ICP device placement do not report radiographic hematoma volume or clinical significance, surgical evacuation of ICP monitor-related hematomas is reported on the order of 0.5% to 3.8%, with one pediatric report describing a 2.7-fold hemorrhage risk reduction with parenchymal monitors versus EVD.

ICP monitors are also subject to technical malfunction. All ICP monitors may provide inaccurate

data; in the case of parenchymal sensors this is most often due to insidious zero-drift, which may require replacement (see the section Device Use and Monitoring), or to filament kinking. Zero-drift, occurring on the order of up to 2 mm Hg/8 h in parenchymal monitors (the Integra Camino system is specified to drift up to 2 mm Hg in the first 24 hours and 1 mm Hg/d over the following 5 days), is less of an issue in EVDs as ventriculostomy pressure transducers can be recalibrated to atmospheric pressure. In one large series, some 38% of parenchymal monitors required replacement for drift (Shapiro, $n = 244$). Unlike fiberoptic transducers, ventricular ones can be recalibrated, and rezeroing should be performed each time the reading is in question and when the patient or drain height is altered.

EVDs are additionally susceptible to compromise of CSF drainage. Poor drainage with clinically consistent ICP data (including with a waveform varying appropriately with respiration and head position) may be due to ICP normalization (which can be ruled in via drain-lowering). Alternatively, this may be due to occlusion by blood or brain/choroidal debris, which can be assessed with visual inspection of EVD tubing and instillation of saline in the distal direction via access ports using sterile technique. Drains also commonly fail due to collapsed lateral ventricle (or ventricles, depending on the degree of compartmentalization) or intraventricular occlusion; CT imaging with particular emphasis on ventricular size/configuration and catheter placement aids in prompt diagnosis and serves as a new baseline prior to replacement should this be required; a nonfunctioning EVD should be promptly removed—regardless of intent to replace—to minimize the risk of infection.

REMOVAL

ICP monitors are removed at the bedside, with the entry point sutured to prevent CSF egress. Removal is dependent on the clinical scenario and the modality of the monitor. For ventricular catheters, necessity is frequently dictated more by the therapeutic need for CSF diversion; in these cases CSF challenge (via drain elevation or clamping) with clinical/radiographic follow-up is performed prior to drain removal.

Lumbar Puncture

Mai O. Colvin, MD; Ariel L. Shiloh, MD and
Lewis A. Eisen, MD

KEY POINTS

- 1 Lumbar puncture (LP) is essential for the diagnosis of two treatable but potentially fatal conditions, central nervous system (CNS) infection and subarachnoid hemorrhage (SAH) with a negative computed tomography (CT) scan.
- 2 LP can also be helpful in the differential diagnosis of other conditions including CNS malignancy, pseudotumor cerebri, and demyelinating diseases.
- 3 Contraindications to LP include skin or soft tissue infection at the puncture site, acute spinal cord or head trauma, uncorrected severe coagulopathy, and brain shift secondary to a space-occupying lesion (SOL) or diffuse cerebral edema.
- 4 Ultrasound-guided LPs reduce the risk of a failed or traumatic procedure, the number of needle insertions, and redirections compared to those performed without imaging.
- 5 Complications from LP include brain herniation, headache, infection, spinal hematoma, and neurologic compromise.

INTRODUCTION

Percutaneous needle LP was first introduced by Quincke in 1891.¹ Since then, LP has become a fundamental method to access cerebrospinal fluid (CSF) in a variety of clinical settings. In the field of critical care, LP is often used to obtain CSF for analysis and to measure the opening pressure of the subarachnoid space. With the advancement of other diagnostic modalities, especially neuroimaging procedures such as CT scans and magnetic resonance imaging (MRI), the numbers of definite indications for LP have been reduced in recent years. However, analysis of CSF remains essential to the diagnosis of two potentially fatal but treatable conditions, which are CNS infections and SAH in patients with a negative CT scan. CSF analysis should always be correlated with history, physical examination findings,

and other diagnostic tests. LP allows clinicians to access CSF in a relatively safe manner in the absence of significant contraindications, although on rare occasions harmful or even serious complications may result. This chapter will review the indications, contraindications, technique, and complications of performing LP in adults.

GENERAL INDICATIONS

The primary indication for LP is to diagnose or exclude bacterial, viral, fungal, and parasitic infections of the CNS. LP is also an indispensable step in the exclusion of SAH when there is a strong clinical suspicion of SAH and brain imaging is nondiagnostic. In addition, CSF analysis and CSF pressure provide clinically valuable information in the diagnoses

of many other noninfectious neurologic conditions such as CNS malignancies, pseudotumor cerebri, and demyelinating diseases including multiple sclerosis and Guillain-Barré syndrome.

CNS Infection

Meningitis refers to inflammation of the meninges and could be either infectious or noninfectious. Noninfectious causes of meningitis will not be discussed in this chapter. From 2003 to 2007, the United States had an estimated 4100 cases, including 500 deaths, of bacterial meningitis per year.² The annual incidence has declined significantly since the introduction of *Haemophilus influenzae* type b (Hib) and pneumococcal conjugate vaccines. Despite these vaccines, bacterial meningitis continues to be a serious health threat, as both the morbidity and mortality remain high. The two most common pathogens of bacterial meningitis in adults are *Streptococcus pneumoniae* and *Neisseria meningitidis*. Patients with acute bacterial meningitis commonly present with one or more of the following: fever, changes in level of consciousness, nausea or vomiting, headache, and meningeal signs. Thorough physical examinations are certainly important, but the clinical signs and symptoms may be subtle and nonspecific, and should not be used in isolation to rule out potentially life-threatening disease.

Given the high mortality and morbidity of this condition, CSF analysis is often required to diagnose or rule out CNS infection. CSF analysis is the only definitive way to establish the diagnosis and determine the causative pathogen. Therefore, when bacterial meningitis is suspected, LP should be obtained as soon as possible. Early diagnosis with prompt administration of appropriate antibiotics is crucial when managing meningitis. Ideally LP should occur before administration of antibiotics, but it should not delay the antibiotic therapy. While there are contraindications to LP, the decision to forgoing LP should not be undertaken lightly given the seriousness of this condition.

The term encephalitis refers to inflammation of brain parenchyma, most commonly caused by a virus. Viral encephalitis is often characterized by an altered level of consciousness, focal neurologic

deficits, seizures, as well as neuropsychiatric symptoms such as psychosis, personality changes, and hallucinations. Clinical manifestations vary depending on the pathogen because different pathogens may affect different areas of the brain. Herpes simplex virus (HSV) 1 is the most common diagnosed pathogen of sporadic viral encephalitis in the western world. In the absence of acyclovir, the mortality for this encephalitis was greater than 70%, and even with acyclovir the 6-month mortality remains high at 14% to 28%.³⁻⁶ Survivors often suffer from serious neurologic sequelae. Other viruses that cause acute encephalitis include other herpes viruses, rabies virus, arboviruses, enteroviruses, and human immunodeficiency virus (HIV). As with bacterial meningitis, when viral encephalitis is suspected, LP should be performed as soon as possible. Polymerase chain reaction (PCR) can detect HSV DNA in CSF rapidly and reliably with sensitivity similar to that of a brain biopsy.⁷ Brain imaging such as MRI or CT is often obtained before or after LP to support the diagnosis. When there is high suspicion for HSV encephalitis, initiation of acyclovir treatment should not be delayed. Delays, particularly beyond 48 hours, are associated with poor outcomes.^{6,8}

A patient's travel history, geographic location, recreational habits, and arthropod or animal exposure may suggest more unusual pathogens. If a CNS infection is suspected in such patients, CSF analysis should be obtained. In addition, immunocompromised patients may not present with classical signs and symptoms of CNS infections. Therefore, CSF analysis should be obtained when CNS infection is suspected in these patients.

Subarachnoid Hemorrhage

SAH refers to extravasation of blood into the subarachnoid space between the arachnoid membrane and the pia. Although SAH is most commonly caused by trauma, approximately 85% of nontraumatic SAH cases are due to a ruptured cerebral aneurysm.⁹ The incidence of spontaneous aneurysmal SAH is approximated to be 27,000 to 30,000 annually in the United States.^{10,11} The clinical hallmark of aneurysmal SAH is a sudden, unusually severe headache classically described as the "worst headache of my life." Headache onset is instantaneous,

usually within seconds. Additional associated features include a period of unresponsiveness, changes in level of consciousness, nausea or vomiting, pre-retinal subhyaloid hemorrhages, and localized neurologic signs. Nuchal rigidity and low back pain are also commonly seen in patients with SAH, however, these usually take hours to develop after the hemorrhage. If SAH is suspected, noncontrast head CT should be obtained first. Extravasated blood appears hyperdense on CT imaging. The sensitivity of head CT for detecting SAH is highest in the first 6 hours after SAH and declines over time. CT performed in neurologically intact patients has a sensitivity of 93% if the CT is performed within 24 hours of headache onset. The sensitivity declines over time to 58% on day 5.^{12,13} Even if the CT is performed within 12 hours after the bleed, about 2% of patients with SAH could have false negatives.¹⁴ Delayed diagnosis of SAH leads to delays in treatment and consequently results in worse overall patient outcomes.^{15,16} Therefore, LP should be performed in cases when SAH is suspected despite nondiagnostic CT. LP should not be performed if the CT is diagnostic for SAH or if possible contraindications to LP, such as obstructive hydrocephalus or an intracranial lesion causing mass effect are present. The classic CSF findings of SAH are elevated CSF pressure and xanthochromia, which represents hemoglobin degradation products. Xanthochromia is present when an LP is conducted 12 hours after the onset of bleeding and usually persists for 2 weeks.¹⁷ Although xanthochromia may be confirmed visually, spectrophotometry is a more sensitive method to differentiate xanthochromia and traumatic blood. Xanthochromia may not be apparent if LP is performed early in the disease process, because it takes approximately 4 hours to develop. Angiography should be performed and prompt neurosurgical consult should be requested once the diagnosis of SAH is made.

THERAPEUTICS

LP is both a diagnostic and a therapeutic procedure. LP may be used to access the intrathecal space for drainage of CSF as a treatment for elevated intracranial pressure (ICP), or for injection of contrast dye during neuroimaging studies such as myelogram. LP facilitates the intrathecal administration

of medications such as chemotherapy or spinal anesthesia.

CONTRAINDICATIONS

Contraindications to LP include skin or soft tissue infection at the puncture site, acute spinal cord or head trauma, uncorrected severe coagulopathy, and brain shift secondary to a SOL or diffuse cerebral edema. The term “raised ICP” is sometimes used as a contraindication to LP; however, elevated ICP itself does not necessarily incur the risk of herniation after LP, and therefore the term “brain shift” is preferred. Brain shift may end in herniation, and CT should be obtained prior to performing LP in those who are at a higher risk of developing herniation. Determining which adult patients should undergo CT before LP remains somewhat controversial. Physicians should make an attempt to select patients for CT on the basis of clinical findings rather than obtaining routine CT before LP in all patients.^{18,19}

Patients with a high likelihood of having intracranial pathology should be evaluated with a CT prior to LP. These include, but are not limited to, an immunocompromised state, history of CNS disease, new-onset seizures, papilledema, abnormal level of consciousness, or focal neurologic deficit.²⁰⁻²² CT features that are suggestive of brain shift and unequal pressures between intracranial compartments include obliteration of the ventricles, effacement of sulci, suprachiasmatic, or basilar cisterns, lateral shift of midline structures, and brain herniation.^{18,23-25} In addition to these signs, evidence of epidural abscess, noncommunicating hydrocephalus, and large posterior fossa masses preclude an LP.

Other contraindications include coagulopathy. There are no absolute cutoff values that determine when to forgo LP. The decision for emergent LP in such patients should be decided on a case-by-case basis. If time permits and it is clinically feasible, coagulopathy should be corrected before performing LP. In general, an international normalized ratio (INR) of less than 1.4, partial thromboplastin time (PTT) below 50, and a platelet count above 50,000/mm³ are considered safe parameters. Aberrations can often be corrected with fresh frozen plasma (FFP) and/or platelet transfusions.

PROCEDURE

Anatomy and Physiology

In the average adult, the skull encloses a total volume of 1475 mL, which includes brain parenchyma (~80%), blood (~10%), and CSF (~10%).²⁶ CSF is produced at a rate of 20 mL/h, for a total of 500 mL/d, by the choroid plexus. CSF is reabsorbed across the arachnoid villi of the superior sagittal sinuses, which act as one-way valves into the venous circulation. Based on the Monro-Kellie hypothesis, the sum of the volumes of brain, CSF, and intracranial blood remains constant. This means that an increase in one will result in a decrease in one or both of the remaining two.²⁷

CSF pressure depends on age, body posture, and clinical conditions. The normal CSF pressure in healthy adults in the horizontal position is normally 7 to 15 mm Hg.²⁸ The spinal cord normally ends at the inferior border of L1 or the superior border of L2. The needle should be inserted into L3/L4 or L4/L5 interspinous spaces. A direct line connecting the two superior iliac crests intersects the midline at the fourth lumbar vertebral body (Figure 102–1) and this allows the clinician to identify L3/L4 and L4/L5 interspinous spaces.

FIGURE 102–1 Anatomy of lumbar spine.

Preparation

Prior to performing an LP, explain the risks and benefits of the procedure to the patient and obtain an informed consent. The operator should wash their hands thoroughly and conduct a time-out at the bedside before starting the procedure. The standard prepackaged LP tray (Figure 102–2) typically includes antiseptic swab sticks, a sterile drape, 1% lidocaine solution, a syringe, needles for anesthetic (27 and 22 gauge), a spinal needle with stylet, a manometer, extension tubing, a 3-way stopcock, four collection tubes, gauze, and bandage. The operator will also need sterile gloves of the appropriate size and a face mask. Before starting the procedure, place the tray where the operator can access it without difficulty. A standard-point Quincke cutting spinal needle is most commonly supplied with the kit, but some physicians prefer to use atraumatic (noncutting) needles such as a Sprotte needle or a Whitacre needle to minimize the risk of post-LP headache (PLPH), also known as post-dural puncture headache (PDPH).

An LP can be performed with the patient in either lateral decubitus or sitting in the upright position. If opening pressure needs to be measured, it is better to position the patient in the lateral decubitus position because it allows for a more accurate measurement. The patient should lie on one side, pull the knees up to the chest, and flex the head toward the knees as much as possible. Placing a pillow under the head helps keep the head in line with the vertebral axis. Ensure that the top shoulder and hip are positioned directly above their bottom counterparts. If LP will be performed while the patient is sitting in the upright position, the patient needs to sit on the side of the bed. The patient should hunch over with the head faced down on a pillow atop a steady bedside table. The arching back will widen the intervertebral spaces. A stool can be used to support the patient's feet as hip flexion in the sitting position optimizes interspinous space width.²⁹ After positioning the patient, palpate the superior iliac crests again and identify the L3/L4 or L4/L5 interspace. A visual target for the needle insertion site can be made by a skin marker or by making an indentation with gentle pressure using the hub end of a needle sheath or cap of a pen.

FIGURE 102–2 Prepackaged lumbar puncture tray.

Technique

Clean the patient's back with povidone-iodine. It should be applied in a circular motion while starting at the L3/L4 interspace and moving outward with each motion. Place a sterile drape with an opening over the puncture site on the patient and frame the workspace. Place another sterile drape between the patient's hip and the bed. In adults, LP is normally performed under local anesthesia using 1% lidocaine. Sedation may be necessary to facilitate the procedure for anxious or combative patients. The local anesthesia is injected subcutaneously using a 27-gauge needle, making a wheal. A longer 22-gauge needle is then used to anesthetize the deeper subcutaneous tissues. Aspirate after each advancement of the needle to make sure that the needle is not in a blood vessel. As anesthesia is taking effect, assemble the manometer with a 3-way stopcock and prepare the CSF collection tubes.

A 22-gauge spinal needle is most commonly used in adults. Hold the needle between both the thumbs and index fingers, insert a spinal needle with a stylet in the midline and within the median plane. Staying in the median plane will help avoid damage to the nerve roots. Orient the needle rostrally at a 15° angle as if aiming toward the umbilicus. The bevel of the needle should be parallel to the long axis of the spine, as this will minimize trauma to the

dural fibers, which run parallel to the spinal axis. The needle is advanced through the skin, fat, supraspinous ligament, interspinous ligament, ligamentum flavum, epidural space, dura, arachnoid, until it reaches the subarachnoid space ([Figure 102–3](#)). Continue advancing the needle with the stylet in place until resistance is felt. A “pop” or reduction in resistance is often felt as the needle passes through ligamentum flavum. Remove the stylet to allow for release of CSF. If no CSF is seen, reinsert the stylet, advance the needle slightly further, and reassess. If bone is encountered, reassess the patient's position and bony landmarks, and ensure the needle is midline. Withdraw the needle into subcutaneous tissue, and reinsert at a slightly modified angle, assessing for the intravertebral space.

Upon confirming the return of CSF, quickly attach a 3-way stopcock to the needle hub using the extension tubing. Ensure to keep the “zero” mark of the manometer at the level of the spinal needle. If the patient is in the lateral decubitus position, ask the patient to relax by slowly extending the neck and legs. Turn the stopcock to allow CSF to flow up the manometer. Opening pressure is measured once the CSF column has leveled out in the manometer. Record the opening pressure and drain the CSF in the manometer into CSF collection tube 1. After removing the manometer, CSF is then serially

FIGURE 102–3 Midsagittal section of the spinal column with a lumbar puncture needle in place.

collected in sequential tubes. Typically a total of 8 to 15 mL of CSF is removed during a routine LP. More than 15 mL may be removed when special studies are required, such as mycobacteria cultures or cytology. If the opening pressure is elevated, keep the manometer on so that a closing pressure can be measured. When completed, replace the stylet into the needle hub and withdraw the needle. Once the needle is removed, place gauze over the LP site and cover with a bandage. Bed rest after LP is frequently recommended, however, it does not prevent the onset of PDPH regardless of the duration of rest, or the body or head positions of the patient.³⁰ Similarly, additional fluid intake does not seem to have a preventative effect on the onset of headaches.³⁰

Imaging Guidance

Bony landmarks may be difficult to palpate in obese patients as well as patients with generalized edema or scoliosis. LP with imaging guidance may be performed using fluoroscopy or ultrasound. Fluoroscopy-guided LP is performed under real-time continuous x-ray imaging. Fluoroscopy improves success rate, however, it may not be ideal in some situations because it requires a radiologist to

perform the procedure, use of radiation, and transportation of potentially critically ill patients.

Imaging guidance may also be provided with ultrasound, which is noninvasive and readily available at the bedside. It is commonly used by critical care physicians for diagnostic evaluation and procedural assistance. In patients with poorly palpable spinal landmarks, ultrasound successfully identified relevant structures in 76% of cases.³¹ Ultrasound-guided LPs also reduce the risk of a failed or traumatic procedure, the number of needle insertions, and redirections compared to those performed without imaging.³²

As the interspaces are small, direct ultrasound guidance can be technically challenging. We will describe a “mark-and-go” technique. An ultrasound-guided LP can be performed with the patient in either lateral decubitus or sitting in the upright position. A linear (high-frequency) probe works well for most patients, allowing for visualization of relatively superficial structures. A curvilinear (low-frequency) probe may be required for patients where deeper visualization is required. In an ultrasound-guided lumbar spinal imaging, the transverse and the longitudinal views are used. The transverse view is obtained by placing the probe perpendicular to

the spinal column at the level of the iliac crests. This view is used to determine a midline by identifying the spinous processes. The spinous process appears as a small crescent-shaped hyperechoic (bright) structure with associated posterior hypoechoic (dark) acoustic shadow (Figure 102–4A). Once the spinous process is identified, slide the probe to center the spinous process on the screen. Mark the midline at the midpoint of the probe, both above and below the transducer. Connect these two marks, and this line represents the anatomic midline of the spine. The longitudinal view is acquired next and is used to determine the spinal interspace. This view is obtained by placing the probe parallel to the spinal column. Starting at the superior border of natal cleft, slide the probe in a cephalad direction, while keeping it in the midline, to identify the sacrum and then the spinous processes. The sacrum appears as a continuous hyperechoic band while the spinous process appears as individual hyperechoic crescent-shaped structures (Figure 102–4B). The area between the sacrum and the lowest lumbar spinous process is the L5/S1 intervertebral space. Slide the probe in the cephalad direction, along the spine, to identify L4/L5 and L3/L4 interspinous space. The interspinous

space appears as a hypoechoic gray interspace between the two hyperechoic convexities. The ligamentum flavum appears at the base between the 2 vertebrae. Use the depth indicator to measure the distance between the skin and the ligamentum flavum. This approximates the needle length required to enter the subarachnoid space. Once the L4/L5 interspinous space is identified, center this interspinous space on the screen and mark the midpoint of the probe on both sides of the transducer. Move the probe and connect the two lines. The intersection of this line and the previously identified midline represents the optimal needle insertion site. It is important that patients maintain their body position throughout the ultrasound imaging and the LP so that the relationship between the labeled surface marks and the underlying structures is not altered. Cleanse the skin and perform the remainder of the procedure in the usual fashion as described previously.

COMPLICATIONS

PDPH is one of the most common complications following LP, and the incidence of PDPH varies from 1% to 70%.³³ PDPH is thought to be caused by CSF

FIGURE 102–4 **A.** Transverse ultrasound view of lumbar spine. Crescent-shaped white line (arrow) represents the spinous process. Shadow is cast by the spinous process and this identifies the midline of the spine. **B.** Longitudinal ultrasound view of lumbar spine. Crescent-shaped white lines (arrows) represent the spinous processes. The gap between the white lines represents the interspinous space.

leakage into the paraspinal spaces, which decreases the CSF pressure, and results in traction of the meninges and stretching of the pain-sensitive intracerebral veins. Headaches usually start within 24 to 48 hours after the procedure and resolve spontaneously within a few days. PDPH could be mild or disabling, usually exacerbated by an upright position, and relieved in the supine position. The use of smaller-gauge needles and atraumatic needles, stylet reinsertion before withdrawing, and parallel orientation of the bevel to the dural fibers have all been reported to reduce the incidence of PDPH.³⁴⁻³⁹ Despite common belief, bed rest and hydration post-LP do not reduce the incidence of PDPH.³⁰ Most PDPH can be managed by supportive care alone. Epidural blood patch is considered an effective treatment for persistent PDPH associated with a continued CSF leak.⁴⁰ Another relatively common complication of LP is back pain, which occurs in about 35% of patients and also resolves spontaneously after several days.⁴¹ Some patients may feel transient electric shock-like pain or dysesthesias during the procedure. The pain is usually transient, but permanent motor and sensory loss can result in very rare cases.⁴¹

The most serious complication of LP is brain herniation. Removal of CSF via LP usually results in a mild, transient reduction of lumbar CSF pressure that is rapidly communicated throughout the subarachnoid space. In the presence of brain shift, there is a relative pressure gradient with downward displacement of the brain stem and cerebrum. LP will increase this pressure gradient and potentially precipitate brain herniation. Determination of LP as the cause of brain herniation is difficult, and the exact incidence is unknown. Patients with a history of CNS disease, new-onset seizures within 1 week of presentation, papilledema, abnormal level of consciousness, focal neurologic deficit, as well as immunocompromised patients should undergo CT prior to LP.²⁰⁻²²

Subarachnoid space infection is a rare complication of LP. Most cases of postdural puncture meningitis are thought to be caused by contamination of the puncture site from the patient's skin flora and aerosolized bacteria from the operator's mouth.⁴² The risk of infection can be minimized by proper sterile techniques including hand washing and the use of a face mask.

A small amount of bleeding is relatively common but serious bleeding that results in spinal cord

compromise is very rare in the absence of a bleeding risk. If patients experience prolonged back pain or neurologic symptoms such as numbness, weakness, and incontinence after LP, they should be evaluated with a MRI for possible spinal hematoma. Other unlikely complications of LP include extraspinal hematoma, cervical spinal cord infarction, cortical blindness, intraspinal epidermoid tumor, and intervertebral disc herniation.^{23,43}

LUMBAR CSF DRAINAGE

A lumbar drain is used for external drainage of CSF, monitoring of CSF flow, and evaluation of ICP. Temporary externalized lumbar catheters are usually used as a treatment of CSF leaks, pressure monitoring, and drainage trials of patients with suspected normal pressure hydrocephalus. More permanent internalized lumboperitoneal shunts are used as the treatment of communicating hydrocephalus or idiopathic intracranial hypertension. Lumbar CSF drainage is also used as a spinal cord protective strategy in thoracic aortic aneurysm repair for patients at high risk of spinal cord ischemic injury.⁴⁴ Catheter placement is performed in a similar manner as a standard LP described previously. Instead of a 22-gauge spinal needle, a 14-gauge Tuohy needle is used for the lumbar drain placement. First, approximately 5 mL of sterile saline is injected into a plastic case surrounding the catheter guidewire to lubricate the guidewire. This facilitates threading the guidewire through the catheter. The guidewire is inserted into the open end of the catheter and set it aside. Prepare the area using sterile techniques and local anesthetics as previously described. Appropriate insertion of a Tuohy needle at the L3/4 interspace is confirmed by CSF return. Once the needle is in the subarachnoid space, rotate the needle 90° so that the bevel of the needle points in the cephalad direction. While holding the hub of the needle, the lumbar drain catheter is threaded over the guidewire through the needle. The catheter should advance smoothly. Advance the catheter to approximately the 15-cm mark (3-5 cm in the spinal space is sufficient), and remove the needle over the catheter. Once the needle is removed, carefully remove the guidewire. Thread the catheter tip onto the connector, attach the strain relief device, and snap the

connector closed to prevent contamination. Attach a sterile syringe to the connector, aspirate CSF, and confirm correct catheter placement. Secure the catheter to the patient's skin using a sterile dressing. The catheter is then attached to a sterile external lumbar drainage system. CSF is allowed to drain when the lumbar pressure exceeds a previously set threshold. Complications are similar to routine LP and include bleeding, infection, CSF leaks, nerve root irritation, and supratentorial subdural hematoma secondary to CSF overdrainage.

Temporary Pacemaker Insertion and Management of CV Implantable Electrical Devices in the ICU

Michael J. Grushko, MD and Jay N. Gross, MD

KEY POINTS

- 1 Bradyarrhythmias occur commonly in the intensive care unit (ICU), and most events do not necessitate temporary pacing.
- 2 Transient bradycardia often occurs in the setting of enhanced vagal tone or other reversible causes.
- 3 Temporary pacing should be considered when symptoms or hemodynamic compromise develops secondary to the bradyarrhythmia.
- 4 Transvenous temporary pacing in the ICU setting generally requires intracardiac electrogram (EGM) guidance.
- 5 Reliable temporary pacing requires adequate sensing and pacing thresholds, stable position of the lead, and secure connections of the pacing system.
- 6 Permanently implanted pacemakers and implantable cardioverter-defibrillators (ICDs) generally function well in the standard programmed settings, and apparent “anomalous behavior” may be the result of acute rhythm change or electrolyte abnormalities, rather than device malfunction.

TEMPORARY PACEMAKERS IN THE ICU SETTING

Bradyarrhythmias occur commonly in the ICU, and most events do not necessitate temporary pacing. Transient bradycardia often occurs in the setting of enhanced vagal tone due to tracheal irritation, suction, or intubation; abdominal distention; or severe vomiting. Reversible causes such as severe electrolyte or acid-base imbalances should be corrected first whenever possible, as this may obviate the need for pacing or enhance the likelihood that a temporary

lead will function appropriately when placed. Isolated sinus pauses, transient extended pauses in atrial fibrillation (AF), and nocturnal bradycardia in patients with obstructive sleep apnea are all common, and generally do not require temporary pacing. Pacing is considered when patients are having symptoms or have developed hemodynamic compromise thought to be secondary to a bradyarrhythmia, or if a rhythm is detected that is associated with a high risk of subsequent malignant bradyarrhythmia ([Table 103–1](#)). Recognizing circumstances that portend risk, for example, anterior wall or inferior

TABLE 103–1 Indications for temporary cardiac pacing (based on ACC/AHA guidelines).

Bradycardia associated with acute myocardial infarction <ul style="list-style-type: none">• Asystole• Sinus bradycardia with symptoms or hypotension not responsive to atropine, typically with inferior infarction• High-grade AVblock (second-degree type II AVB, high-degree AVB, or complete heart block) and/or new bundle branch (especially LBBB) or bifascicular block in patients with anterior/lateral MI with/without hemodynamic insult or syncope• Ventricular arrhythmia due to bradycardia
Bradycardia not associated with myocardial infarction <ul style="list-style-type: none">• Asystole• Second-degree type II AVB, high-degree AVB, or complete heart block with hemodynamic insult or syncope• Severe sinus node dysfunction with recurrent symptomatic long pauses, sinus arrest, or tachy-brady syndrome• Ventricular arrhythmia due to bradycardia
Support for procedures that may develop bradycardia <ul style="list-style-type: none">• General anesthesia in the setting of 2nd- or 3rd-degree AVblock, bifascicular block with a 1st-degree AVblock, intermittent AVblock• Cardiac surgery such as ventricular septal defect closure, ostium primum atrial septal defect repair
Overdrive suppression of tachyarrhythmias <ul style="list-style-type: none">• Ventricular tachycardia• Supraventricular tachycardia

wall myocardial infarction (MI), or preexisting infra-Hisian conduction disease, will help identify patients at high risk for need of temporary pacing.

Transcutaneous Pacing

There are multiple methods for temporary cardiac pacing, including transcutaneous, transvenous, and even transesophageal pacing. In the event of sustained hemodynamic compromise and/or ventricular asystole due to bradyarrhythmia, the most prompt and easiest pacing method is transcutaneous pacing. Current day external defibrillators allow for transcutaneous pacing via the defibrillation pads (Figure 103–1). One should ensure that the pads are applied to dry and intact skin. Ideally, the pads should be positioned in a relative anterior-posterior (AP) location, with the anterior pad placed to the left of the sternum near the point of maximal impulse, and the

posterior pad to the left of the spine and just beneath the scapula. The external generator is set to “pacer” and the rate set based on the acute need. The output is ramped up until reliable capture is obtained, which is usually greater than 40 mA. Due to saturation of the electrocardiogram (ECG) signal from the pacing artifact, myocardial capture may not be clearly evident on the telemetry or ECG. The peripheral pulse can be checked to verify consistent capture. External pacing, despite appropriate technique and multiple adequate pad orientations, achieves consistent capture in only a small majority of patients at best. In addition, it is quite painful to the conscious patient. Hence, it should only be used as a temporizing measure in anticipation of urgent transvenous pacing unless capture is reliable, the patient is deeply sedated or unconscious, and/or when temporary pacing is required for a brief period of time.

Temporary Transvenous Pacing

Like all interventions, the benefits of a temporary transvenous pacemaker (TVP) must be weighed against its risks. Insertion of a temporary pacemaker puts patients at risk for complications related to central venous access, such as bleeding, pneumothorax (level of risk depending on venous access site), thrombosis, line-related sepsis, and cardiac tamponade. Additionally, an unstable temporary pacemaker lead or malfunctioning system has the potential to induce malignant ventricular tachyarrhythmias. Individuals who insert temporary pacemakers should be specifically trained in this area and this procedure should not be equated with other procedures that solely require obtaining central venous access.

Temporary pacemaker leads are most commonly placed via the internal jugular (IJ) or subclavian veins, but when needed, can be placed through the femoral, brachial, or even external jugular veins. When performed at bedside, the right IJ (best with ultrasound guidance) or left subclavian veins are most commonly used as they offer the most direct routes for the shaped balloon-tipped catheters. When fluoroscopy is available (either via portable C-arm or in the interventional laboratory), any of the earlier access sites can be used. In some institutions, the left subclavian is avoided so that this access site is kept available for potential permanent device implantation. Needless to say, strict sterile technique must be adhered to as a pacing wire

FIGURE 103–1 A typical external defibrillator and transcutaneous pacemaker.

is delivered into the endocardium, which places the patient at risk for bacteremia or endocarditis.

There are various types of temporary pacing leads commercially available. Balloon-tipped leads designed to enhance advancement to the right ventricle are probably the fastest, most accessible, and generally do not require fluoroscopy. These catheters are generally placed via 6-Fr sheaths. Standard multipole electrophysiology (EP) catheters (5 or 6 Fr) or active fixation leads that provide for increased stability can also be used but require fluoroscopy ([Figure 103–2](#)). In rare circumstances, when there is a need for very extended temporary pacing, individuals who implant permanent devices have inserted a permanent active fixation lead and connected them to an externalized permanent pacemaker device until the time for permanent implantation.

Methods of Placement

Lead placement can be performed via electrogram (EGM) or fluoroscopic guidance or both. The most practical way to insert a pacing wire is via EGM guidance. The patient is connected to a 12-lead ECG machine, with standard placement of the 4-limb leads (at least). A 12-lead ECG confirming the indication can be obtained ([Figure 103–3A](#)). Once the temporary lead is placed into the circulation, the “distal” end

of the pacing lead (marked [–]) is passed to an assistant who connects the electrode to the V1 ECG clip. When connected in this manner, the “V1 lead” on the ECG actually displays the local unipolar intracardiac EGM at the tip of the pacing lead. Of note, care must be taken to cover this connection as this part of the pacemaker wire is no longer sterile. As one advances, the EGM pattern changes from a predominant atrial to a mixed atrial-ventricular signal at the level of the tricuspid valve, and finally when the valve is crossed, a large ventricular EGM is demonstrable. When good contact with the ventricular wall is made, a large localized ST elevation pattern referred to as the “current of injury” is typically seen ([Figure 103–3B](#)). The balloon is deflated at this point to allow the lead tip to oppose itself completely to the ventricular myocardium. The most reliable site for temporary pacing is the right ventricular apex. When the lead is positioned in the right ventricular (RV) apex, a paced QRS with a left bundle branch block (LBBB), inferior axis pattern will be present ([Figure 103–3C](#)). Typically, the RV position is reached between 35 and 45 cm, and if the markers on the lead indicate that significantly more lead is intravascular, it is likely that a large loop is present, which may promote lead instability. When using fluoroscopy, visual guidance makes placement of the lead to the RV apex easier. The position can be confirmed

(a)

(b)

FIGURE 103–2 Various examples of temporary transvenous pacing leads. **A.** It shows a standard balloon-tipped catheter with its distal connections. **B.** It shows 2 examples of multipolar-tipped electrophysiology (EP) catheters that can be placed via fluoroscopy.

by AP, right anterior oblique (RAO), and left anterior oblique (LAO) views.

Once the lead is placed in position with a good current of injury, careful assessment of pacing function is required. A normally functioning temporary pacemaker should have a low pacing threshold (typically 1 mA or less) and be capable of sensing spontaneous ventricular activity (preferably 5 mV signals or larger). If there is no underlying rhythm, or if the patient's spontaneous rate is less than the minimal programmable rate of the temporary pacemaker, the sensing threshold cannot be measured.

Once lead stability and functionality is established, suturing the lead at the insertion site in a highly secure manner is critical, as even a minimal displacement of a perfectly placed lead may result in a totally nonfunctioning pacing system. Most operators choose to leave the sheath in place, especially if needed for central venous access (as a sidearm is usually present). In addition, many choose to place a sterile sleeve that is integrated with the introducer around the pacemaker wire, so as to allow for some degree of lead manipulation if a sudden need arises.

Note that the EGM-guided approach is practical only when there is spontaneous ventricular electrical activity. In rare circumstances when there is absolutely no ventricular activity, and fluoroscopy is not immediately available, the only practical option is to advance the lead blindly while pacing in the hope that the lead is advanced to a stable site in the RV and ventricular capture is achieved.

Pacemaker Generators

There are numerous types of temporary pacemaker generators. When a temporary transvenous lead is placed, it is typically connected to a single-chamber generator, though in certain circumstances a temporary transvenous atrial wire can also be placed creating a dual-chamber system. In the cardiothoracic surgical areas, patients may have temporary epicardial wires connected to single- or dual-chamber temporary pulse generators (Figure 103–4). Programming capabilities of these devices vary widely depending on the model type, but all allow for adjustments of pacing rates, outputs, and sensitivities. Most devices also have a capability to deliver rapid antitachycardia

(a)

(b)

FIGURE 103–3 **A.** Electrocardiogram (ECG) with sinus rhythm, complete heart block with a very slow narrow complex escape rhythm. **B.** Lead VI attached to the temporary distal port displaying a myocardial current of injury, indicating good opposition with the myocardial endocardium. **C.** ECG shows ventricular pacing in a left bundle branch block (LBBB) pattern with negative QRS complexes in the inferior leads and positive QRS complexes in I, L, and augmented voltage right arm (aVR), consistent with right ventricular (RV) apical pacing.

(c)

FIGURE 103–3 (Continued)

FIGURE 103–4 Typical single- and dual-chamber temporary pacemaker generators.

FIGURE 103–5 Chest x-ray (CXR) showing right ventricular (RV) apical lead placement.

pacing, though such activities require the experience of a cardiologist or electrophysiologist.

A chest x-ray should be obtained soon after lead placement to rule out pneumothorax and establish initial radiographic location ([Figure 103–5](#)). Should unexplained hypotension or tachycardia ensue any time after placement, a transthoracic echo should be obtained to look for pericardial effusion and/or tamponade from a possible RV perforation. The insertion site should be monitored for bleeding/hematoma. Most importantly, the TVP should be checked at least once daily for both capture threshold and sensitivity, and also after any major movements or transfers. If any changes in device function are noted, a repeat chest x-ray (CXR) should be obtained for evaluation of lead position and a careful check of all connections should be made.

PERMANENT PACEMAKERS IN THE ICU SETTING

Even in the critical care setting, permanent pacemakers usually function normally and special modifications of programmed settings are very infrequently required. Fortunately, most complex mechanical and electrical devices in the critical care unit do not impact on pacemaker function. On occasion, attempts to increase cardiac output by pacing at more rapid rates are pursued, but this usually proves ineffective, as the higher pacing rate is often associated with a concomitant fall in stroke

volume. Patients, who develop severe electrolyte or acid-base disturbances, may be at risk for developing pacemaker malfunction. In such circumstances, programming the device to higher pacing outputs and more sensitive settings may offset, at least temporarily, some of these pacing abnormalities.

A basic understanding of pacemaker codes and modes is essential for interpreting pacing patterns seen on ECGs and telemetry. It is important to appreciate that the pacing pattern manifested is a function of both the patient's underlying rhythm and the programmed parameters of the pacemaker. Thus, the absence of any pacemaker activity during regular rhythms most often represents totally normal pacemaker function, and should not trigger any immediate concerns. In order to determine definitively whether function is normal, it is necessary to know the programmed settings of the device. Suspected discrepancies between the programmed settings and pacemaker function should trigger cardiology consultation.

Special Considerations

Cardioversion—In patients with pacemakers or ICDs who are to undergo urgent or planned cardioversion in the ICU setting via external pads, the delivery of direct current energy poses a small risk to both the integrity of the pulse generator and to the lead tip-myocardial interface. The preferred manner is to place the defibrillator pads in an AP orientation near the midline and not overlying the device. In addition, if the device is an ICD, cardiology consultation can be requested to evaluate if cardioversion via the implanted device is appropriate.

Newly implanted cardiac devices—If a hemodynamic monitoring catheter needs to be placed in a patient who has undergone pacemaker or ICD implantation in the previous 6 months, it poses a potential risk for dislodgement. Fluoroscopic guidance is preferred in this setting so as to decrease the risk of unintended lead displacement.

Rate modulation—Many pacemakers are programmed with the rate modulation feature activated. This refers to the ability

of the pacemaker to detect the need for an increased heart rate based on the information provided by specialized sensors. The 2 most common forms of rate modulation sensors and associated algorithms are piezoelectric crystal-based accelerometers (ie, equate movement with exertion) or calculated minute ventilation, which is based on transthoracic impedance changes. Infrequently, excessive shaking of the patient or high tidal volume–assisted ventilation may trigger inappropriately elevated pacing rates based on these sensors. In this uncommon circumstance, the rate modulation parameter should be programmed to off.

ICDS IN THE ICU SETTING

Most of the comments described in the pacing section are equally relevant to implantable ICDs, which have analogous pacing capabilities. There are additional considerations that should be kept in mind when dealing with a patient with an active ICD in the ICU setting.

Perhaps the most important consideration is that critically ill patients are frequently tachycardic, either as a physiologic response to their underlying circumstances or resulting from the pharmacologic agents that are being used to support their hemodynamics. This increases the possibility that the ICD patient may receive inappropriate ICD therapies if the heart rate exceeds the detection rate threshold of the device. While many devices have algorithms programmed to try to distinguish ventricular tachycardia (VT) from supraventricular tachycardia (SVT), AF, and sinus tachycardia, none is perfect. The best way to avoid inappropriate shocks is to assure that the tachycardia detection rate is above the patient's heart rate. Since settings vary widely between patients, it is valuable to know the programmed parameters of these devices, so as to avoid the possibility of inappropriate ICD therapies. On occasion, temporary reprogramming to allow for delivery of antitachycardia pacing therapies under the guidance of an electrophysiologist may facilitate minimally invasive and better-controlled treatment of arrhythmias in the critical care setting.

Paracentesis

Claude Killu, MD and Mark Ault, MD

KEY POINTS

- 1 Paracentesis is a relatively safe procedure that can be performed in either the inpatient or outpatient setting.
- 2 Diagnostic paracentesis should be performed on any patient with newly diagnosed ascites or any patient with known ascites that has a change in clinical status.
- 3 Therapeutic “total paracentesis,” the removal of all of the ascites with albumin replacement, is a safe technique for the treatment of symptomatic ascites.
- 4 Coagulation testing need not be performed and correction of coagulation abnormalities prior to paracentesis is unnecessary.
- 5 A-2 probe ultrasound technique (low-frequency probe to find an optimal fluid pocket and high-frequency probe to evaluate the abdominal wall for vessels) should be used in all cases.

DEFINITION

Abdominal paracentesis is a procedure in which fluid is removed from the peritoneal cavity with a needle or cannula in patients with ascites. It is a relatively quick and safe procedure and can be done with a minimal amount of equipment as an outpatient procedure or at the bedside for inpatients. Now routinely used as an adjunct to paracentesis, point-of-care ultrasound is a simple procedure that confirms the presence of ascites. Proper analysis of fluid is invaluable in determining the etiology of ascites. The procedure can be done by any trained physician, surgeon, or a midlevel provider. At our institution we have a dedicated team of proceduralists and intensivists experienced in performing paracentesis using exclusively ultrasound guidance.

INDICATIONS

The procedure can be done for therapeutic, diagnostic, or both purposes.

Diagnostic: The procedure helps diagnose.

- The cause of a new-onset ascites or the status of preexisting ascites in patients who are admitted to the hospital for any reason. This is particularly important if there is evidence of infection, hepatic encephalopathy, fever, leukocytosis hypotension, and acute kidney injury.¹
- Spontaneous bacterial peritonitis where detection at an early stage and expedient initiation of antibiotics can lower mortality. Therefore, the procedure must be performed

promptly in virtually all circumstances where a patient with known or newly discovered ascites sustains any change in clinical status. Delays that may occur due to lack of an experienced operator, unfounded concerns for the presence of coagulopathy, or unnecessary administration of blood products prior to paracentesis should be avoided. Analysis of the ascitic fluid may allow not only assessment of the likelihood of spontaneous bacterial peritonitis (SBP) but, with proper collection, identification of a specific microorganism and susceptibility testing to antibiotics guiding treatment in 90% of cases.

- Secondary peritonitis when free fluid is present in peritoneal cavity from rupture or perforation of an abdominal organ. The total protein may be a key differentiating factor in this situation as it is generally low in SBP but may be normal or elevated in secondary causes.
- Malignancy-related ascites (not to be confused with peritoneal carcinomatosis) may be seen with several tumors, including malignancies of the ovary, pancreas, colon, breast, lung, and liver. In addition, the presence of chylous ascites may indicate lymphoma as the cause of the ascites.
- Hemoperitoneum related to trauma, postprocedural or spontaneous intraperitoneal hemorrhage.

Therapeutic: The procedure is usually performed to relieve intra-abdominal pressure causing symptoms of dyspnea, fatigue, early satiety, and/or abdominal discomfort. The amount of fluid a patient can tolerate and the rate of accumulation is highly variable between patients, but will generally establish a predictable pattern in any given patient. Symptoms can be relieved by removal of as little as 1 to 2 L of fluid in a small individual.

CONTRAINDICATION

In general, the diagnostic value of paracentesis outweighs the risks in virtually all circumstances. One of the most frequent concerns in the cirrhotic patient is the potential for bleeding due to coagulopathy and

the risks this may pose, yet this concern is largely unfounded. When tested the majority of cirrhotic patients with ascites will be found to have some degree of coagulopathy, but this should preclude paracentesis only in severe cases of disseminated intravascular coagulopathy with overt bleeding or clinically evident primary fibrinolysis. Bleeding from a paracentesis puncture is rare and when it occurs is generally due to injury to a vascular structure which is consistent with the fact that these patients usually have normal coagulation function despite abnormal test results such as the prothrombin time (PT)/international normalized ratio (INR), activated partial thromboplastin time (aPTT), or platelet count. This is partly due to the fact that there is deficiency of both anticoagulants and procoagulants. In fact liver disease can lead to either a hypocoagulable state or a hypercoagulable state. The relative balance or imbalance of these factors is not reflected in conventional tests of coagulation. Clinical evaluation for overt bleeding tends to be a more valuable determinant of bleeding risk than coagulation testing. The inappropriate practice of transfusion of fresh frozen plasma (FFP) and/or platelets' blood product to reverse the coagulopathy before paracentesis is therefore unnecessary and must be discouraged. Routine administration of blood products exposes the patient to a risk of infection and fluid overload and is costly; furthermore, there are no available data to support a threshold or a cutoff value for coagulation parameters beyond which paracentesis should be avoided. It has been shown that approximately 100 to 200 units of FFP would need to be administered prior to paracentesis to prevent transfusion of 2 units of red cells making this practice impractical at best. Grabau and colleagues reported no bleeding complications in series of 1100 patients who underwent large-volume paracenteses without pre- or postprocedure transfusions required despite INRs as high as 8.7 and platelet counts as low as 19,000/mL highlighting the lack of benefit of "corrective" blood product administration in virtually all instances.²

COMPLICATIONS

Paracentesis is a safe procedure with a major complication rate of less than 1 in 1000 procedures. Deaths caused by paracentesis are rare but do

occur and require meticulous attention to technique. Major complications include procedurally related intraperitoneal bleeding, bowel perforation, and injury to internal organs. The last 2 complications have been virtually eliminated by the adjunctive use of ultrasound. However, until recently hemoperitonium remained a potentially tragic and unpredictable complication. Recently, this occurrence has largely been attributed to the presence of both normal and abnormal vascular structures buried in the abdominal wall that are generally not palpable, visible, or seen by routine fluid localization with a low-frequency abdominal ultrasound probe. By using in addition, a high-frequency linear probe to specifically evaluate the abdominal wall for the presence and location of these vessels, they may be identified and subsequently avoided (Figures 104–1A, B, and C). In our experience ultrasound assessment both for the optimal location of the fluid and the presence of abdominal wall vessels has nearly eliminated the risk of postprocedural hemoperitonium and is now considered standard of practice at our institution.³

Minor complications are relatively infrequent occurring in 2% to 5% of cases and may include abdominal wall hematoma, leakage from the paracentesis site, the need for more than one attempt to obtain fluid, excessive pain during the procedure, and the inability to completely drain the abdominal cavity. While abdominal wall or rectus sheath hematoma may be extensive, in general these complications can be managed with local measures. Of note, we also track operator injury in the form of needle stick or fluid contact contamination as a complication to emphasize the need for sharp safety and procedural hygiene to our operators.

PRECAUTIONS

Aseptic technique is required when performing this procedure though the need for wide sterile barriers is unnecessary. Caution should be taken especially in patients with massive bowel distension or ileus and in patients with scars indicative of prior abdominal surgeries. Ultrasound should be used in all cases and is invaluable in avoiding these potential anatomic pitfalls. Ultrasound, while essential to the overall safety of the procedure carries its own

(a)

potential hazards if not applied appropriately. While the learning curve is relatively steep for this application, appropriate training is required to avoid interpretive errors.

PREPARATION AND TECHNIQUE

Patient Positioning

The procedure is usually done with the patient in supine position and the head of the bed flat or slightly elevated. It may be helpful to have the patient tilt slightly to the side of where the entry is planned to allow for pooling and fluid shift.

Sites of Needle Entry and Anatomy

The patient is tilted slightly to the side to allow for fluid shift. The entire abdominal cavity must be scanned with ultrasound using a low-frequency phase array or curvilinear probe to determine the area of “maximum echogenicity” representing the most favorable pocket of fluid. The potential site of entry is then evaluated using a high-frequency linear

probe to identify a site within this region devoid of abnormal vasculature. The optimal site of entry is marked on the abdominal wall with an indelible marker (Figures 104–2A, B, and C).

PREPARATION AND EQUIPMENT

An informed consent must be obtained and a formal time-out performed to verify procedure and patient identifier. The following supplies and equipment are needed (Table 104–1):

- Spring-tipped paracentesis drainage kit (Figures 104–3A and B)
- Sterile gloves
- Collection canisters
- Chaux

TABLE 104–1 Supplies.

- Safe-T-Centesis catheter drainage tray
- 8-Fr catheter drainage device
- Filter needle 19 gauge
- Needle, 25 gauge x 1.5 in
- 10-mL syringe
- 60-mL syringe
- Scalpel
- Universal drainage set
- Collection bag
- ChloroPrep 3-mL applicator
- Drainage tubes
- Gauze pads
- Lidocaine 1% 5 mL
- Fenestrated drape
- Towel
- Bandage

The use of sterile gown, hair cover, or face mask is not required. But the overlying skin is to be prepped in the usual sterile fashion and sterile gloves are used with sterile barriers to create the appropriate sterile field.

PARACENTESIS NEEDLE CHOICE

For local anesthesia the preferred needle is 1.5-in 22- or 25-gauge. In obese patients, a 3.5-in 22-gauge “spinal” needle can be used for diagnostic paracentesis.

Using nonsterile gloves first the skin is sterilized with chlorhexidine. Sterile gloves are then used. If the original X mark has been erased during site preparation, a new mark can be placed with a sterile

pen. A sterile drape with a round hole in the middle is placed over the prepped skin and another sterile drape is placed on the side next to the patient to create a wider area. The needle with the syringe to administer lidocaine is inserted intradermally to create a skin wheel. Then the same needle is advanced ideally to the peritoneum providing anesthesia along the needle track. Once the needle enters the peritoneal cavity, fluid is aspirated but this may not be accomplished in obese patients and should not preclude proceeding with the procedure if adequate ultrasound landmarks have been established. At this point the needle is withdrawn and a small skin nick is to be made with a #11 size scalpel at the exact site of needle entry. Attention should be paid to avoid an unnecessarily large skin nick as this will lead to postprocedural leakage and issues with hemostasis. A 6- or 8-Fr catheter over a blunt spring-tipped trocar is then introduced through the skin incision into the peritoneal space with a return of fluid aspirate. When the trocar is at the level of the peritoneum it is helpful to ask the patient to take a deep breath. This tightens the peritoneum and provides countertraction to the trocar making entry into the peritoneal space more comfortable with less rebound. A click of the spring-tip catheter will be appreciated indicating passage of the needle tip past the peritoneum membrane into the peritoneal space. The metal trocar is then held in place and the soft catheter is advanced into the cavity ([Figure 104–4A–D](#)). Samples are collected sterilely with the specimens for cell count and chemistries are placed in the clear tubes provided.

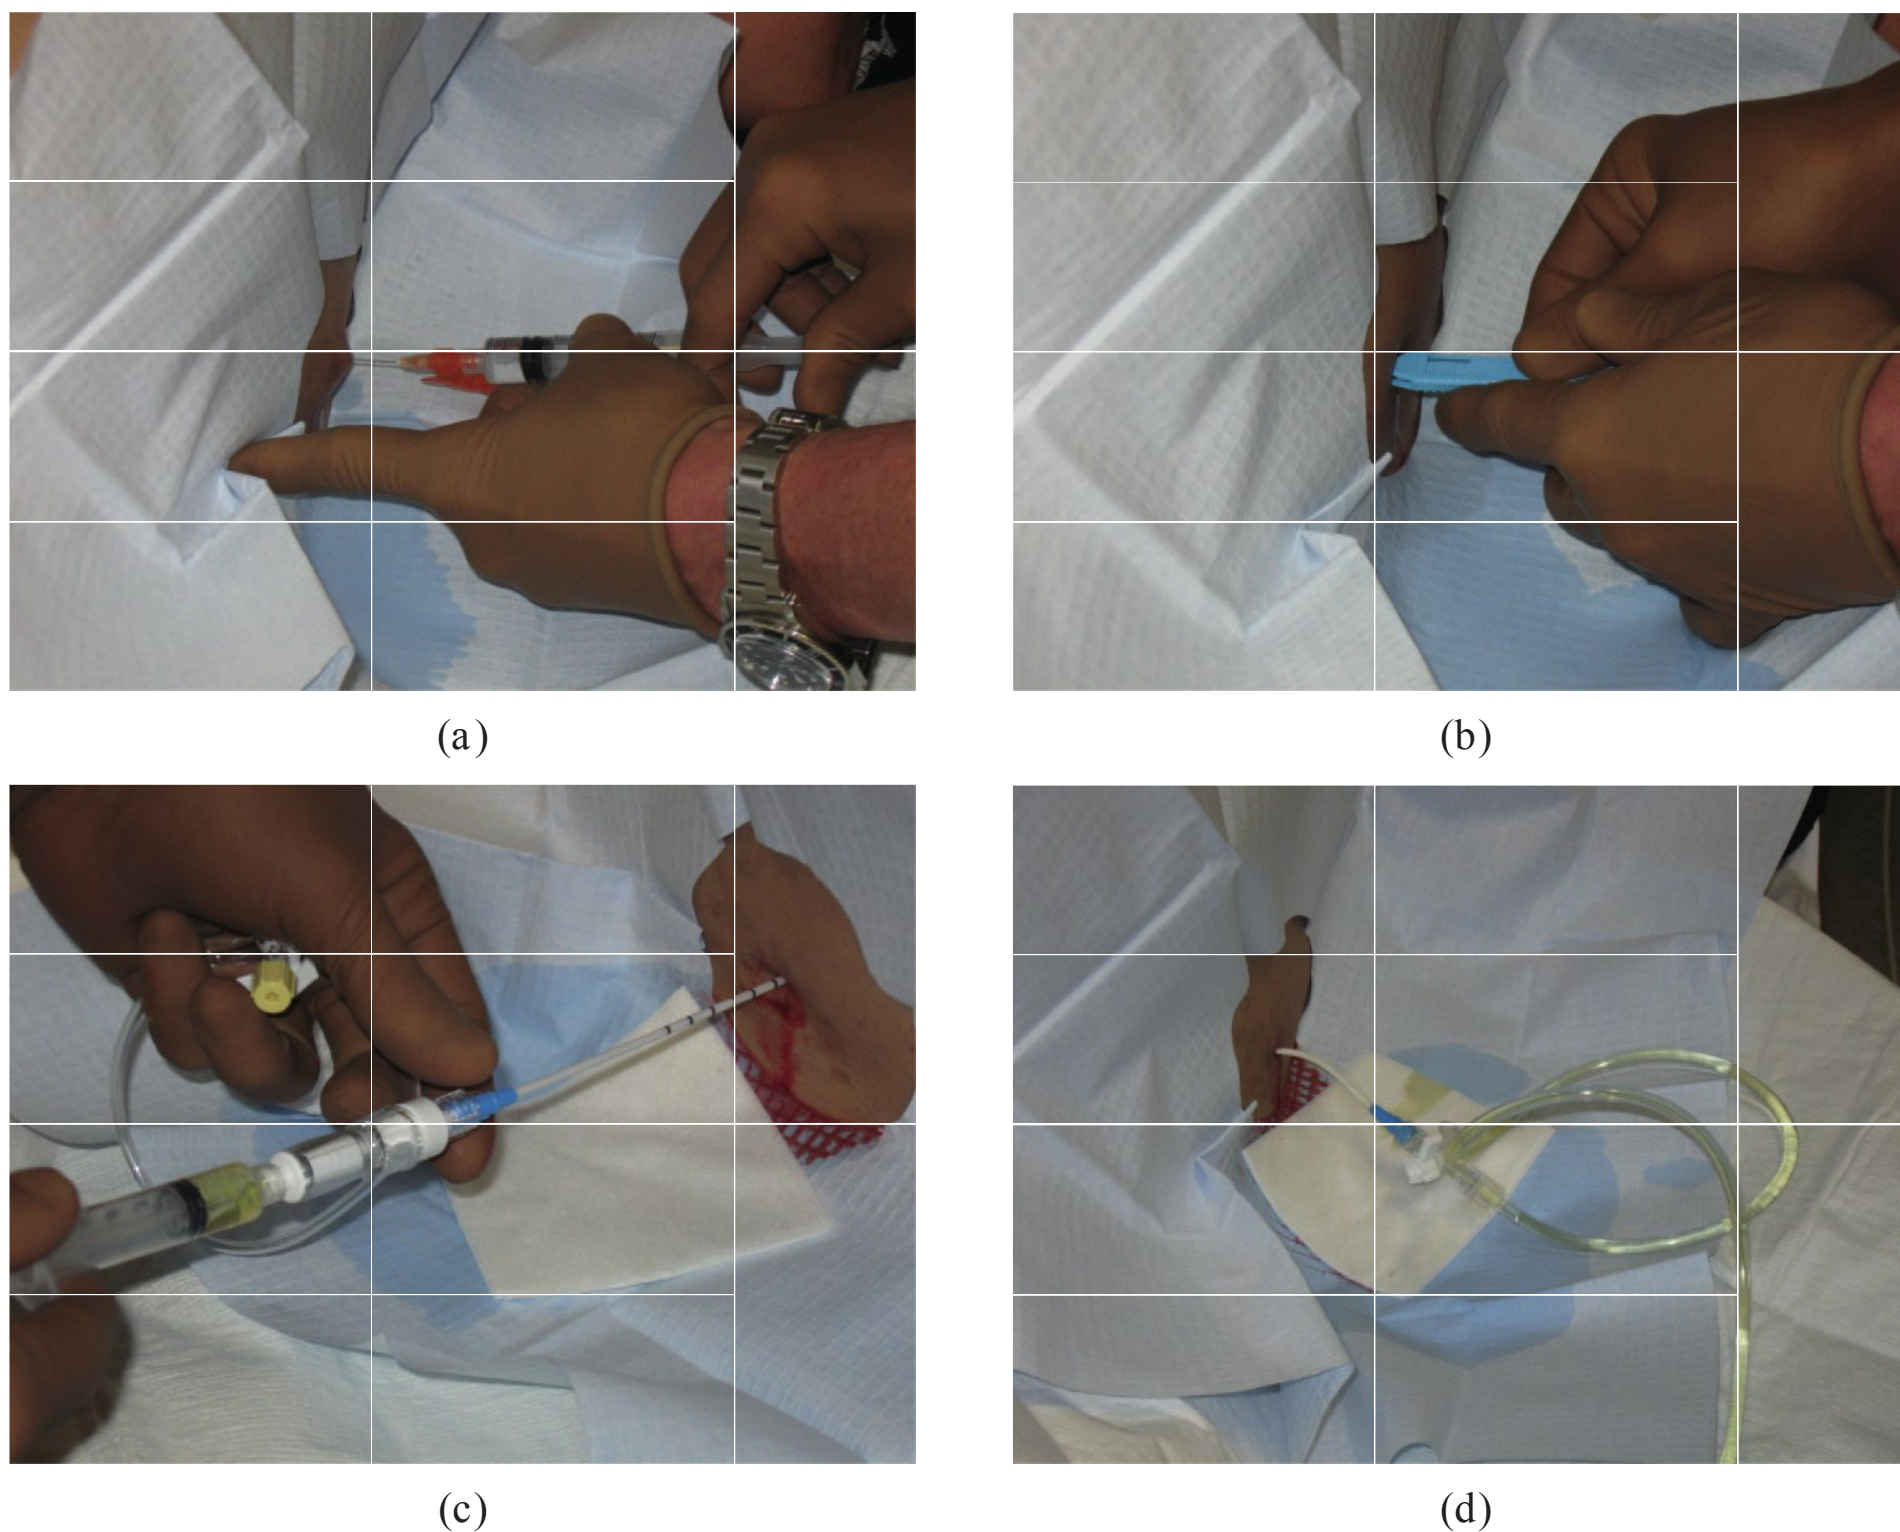

FIGURE 104–4 **A.** Needle with the syringe to administer lidocaine is inserted intradermally; the same needle is advanced ideally to the peritoneum. **B.** The needle is withdrawn and a small skin nick is to be made with a #11 size scalpel at the exact site of needle entry. **C.** A 6- or 8-Fr catheter over a blunt spring-tipped trocar is introduced through the skin incision into the peritoneal space with a return of fluid aspirate. **D.** The metal trocar is then held in place and the soft catheter is advanced into the cavity.

Cultures are obtained by inoculating culture bottles directly and if cytology is needed the entire canister is sent to the laboratory to be concentrated. The catheter is then connected to a negative suction bottle or vacuum suction system (Figure 104–5A and B).

As drainage ensues, the bowel and the surrounding omentum may block the flow of the ascitic fluid. Residual ascites may be verified and occasionally the catheter tip itself can then be visualized by placing the ultrasound probe directly adjacent to the catheter insertion site. The stopcock can be opened to release the suction that may have occurred at the catheter tip and the catheter can then be pulled back a few centimeters until flow is restored. In persistent cases it may be worth trying to reposition the patient by further tilting him/her slightly toward the draining site in an attempt to shift the fluid toward the catheter before withdrawing the catheter completely.

When ultrasound examination shows no further fluid to be drained, the 3-way stopcock is turned toward the patient and the catheter is gently pulled out. A sterile gauze and adhesive dressing is applied at the site.

Occasionally, we have noticed a leak from the insertion site after removal of the draining catheter. This, if unrecognized is not serious, but invariably is distressing to the patient and may cause local chemical cellulitis. To address this potential problem, we have been applying a high-viscosity tissue adhesive (Octylseal) or a skin adhesive (Dermabond) to help prevent leakage. This has effectively replaced our prior practice of suturing the puncture site with less skin irritation and no need for suture removal. Multiple references describe the practice of “Z-tracking” to prevent leakage. We have not found this to be an effective option in most patients.

FREQUENCY OF PARACENTESIS AND VOLUME REMOVAL

Removal of 5 L of ascitic fluid in a single session is defined as large-volume paracentesis (LVP) and is considered safe without the need to replace colloids⁴ and it used to be considered the safe practical limit to relieve symptoms while preventing hepatorenal

syndrome. More recent studies however document the safety of “total paracentesis” where all of the fluid is removed and albumin replacement is given. Standard albumin replacement is performed with 25% albumin administered as 6 to 8 g/L of ascites removed. Occasionally a larger dose of albumin (10 g/L removed) may be given in the setting of baseline renal insufficiency, hypoalbuminemia, or significant edema/anasarca. Additional albumin may also be given postprocedure in the setting of hypotension related to volume shifts. The largest-volume removal reported is 42 L. We have removed 38.8 L without incident.⁵

In our experience, we routinely schedule patients with recurrent ascites refractory to diuretics to return to the clinic at regular intervals that will vary per patient but in general a pattern will be established after 1 to 2 visits. We aim to see them before their ascites interferes with their ability to eat or to exercise in order to prevent muscle breakdown. This has the additional benefit of preventing unwanted emergency department visits for symptom relief and an opportunity for dietary reinforcement.

ANALYSIS OF PERITONEAL FLUID

Clarity and color of the fluid should be noted. The clarity or opacity of the fluid depends largely on the presence and the amount of the neutrophil count or the presence of lipids. The amount of protein, bile, and bilirubin present will determine color. A “benign” fluid sample that has low protein and neutrophil count less than $250/\text{mm}^3$ is usually transparent and slightly yellow-tinged. The presence of bloody or serosanguinous fluid should be noted. A traumatic tap gives a bloody fluid that would clot easily in a nonanticoagulant-containing tube, while a blood-tinged nontraumatic ascitic fluid due to other reasons will not clot. Examples where bloody ascitic fluid may be expected are patients with hepatocellular carcinoma, trauma, and postsurgical and occasionally in peritoneal carcinomatosis. A milky or chylous fluid indicates a high triglyceride concentration and can be seen in advanced stage lymphomas. Bilirubin-stained ascitic fluid occurs in the setting of significant jaundice and appears tea-colored or

dark brown. Bile-stained ascites appears greenish and is seen in patients with a bile leak and in patients with hemorrhagic or necrotic pancreatitis.

Only a limited number of diagnostic tests need to be ordered to “profile” the nature of the ascites. A cell count, total protein, and albumin are generally sufficient in most cases and need not be repeated with each paracentesis. The most important test in the symptomatic patient is the cell count and only a few milliliters are needed for evaluation. It is usually agreed that in uncomplicated cirrhosis, the white blood cell (WBC) count will be less than 500/mm³ and the absolute polymorphonuclear neutrophil (PMN) count should be less than 250/mm³. A PMN count of greater than 250/mm³ is considered presumptive evidence of SBP pending culture results but it is important to note that 10% of cases of culture-proven SBP may occur with a PMN count of less than this value. A bloody or serosanguinous ascitic fluid is more difficult to interpret however; using a correction factor subtracting one PMN for each 250 red blood cells (RBCs) may be useful in some scenarios.

Other basic diagnostic tests include Gram stain and culture (aerobic and anaerobic), albumin, total protein, and cytology. More specific tests for diagnosis are triglyceride level in chylous ascites, red blood cell count in trauma and malignancy, bilirubin concentration in bowel perforation, and amylase in pancreatitis (Table 104–2), but need not be ordered routinely.

The serum-to-ascites albumin gradient (SAAG) helps to differentiate etiologies of ascites. The SAAG can be calculated by subtracting the ascitic fluid albumin value from the serum albumin, both measured on the same day. SAAG above 1.1 g/dL suggests the presence of portal hypertension. Etiologies

SAAG, serum-to-ascites albumin gradient.

of ascites that are associated with portal hypertension include cirrhosis, congestive heart failure, portal vein thrombosis, and Budd-Chiari syndrome. SAAG less than 1.1 g/dL indicates absence of portal hypertension. Examples of causes of ascites without portal hypertension are nephrotic syndrome, peritoneal tuberculosis, and carcinomatosis (Table 104–3). In addition to the ascitic fluid albumin, a total **ascites protein** may be used to assess the risk of SBP with an increased risk associated with levels less than 1 g/dL. It is felt that this level predisposes to SBP because it correlates with complement levels and opsonic activity.

ALBUMIN USE

The use of colloids after a LVP has been debated, but it is generally agreed that paracenteses of 5 L or less would not routinely require albumin replacement. The usual formulation of albumin given in the United States is 25% solution. This provides less volume and less sodium load than the 5% solution. The term postparacentesis circulatory dysfunction (PCD) refers to a state of increased plasma renin activity as a marker of active hypovolemia following LVP and may be responsible for more avid fluid retention and more rapid reaccumulation of ascites. Whether albumin solution administration after LVP has value to correct hypovolemia and improve survival and whether this depends on the amount of fluid removed has been looked at in one study of 105 patients who underwent LVP. These patients were allocated to receive albumin (10 g/L of fluid removed) or no albumin. Those patients who did not receive albumin had an increase in plasma renin activity, developed hemodynamic instability, worsening renal function and hyponatremia.⁶ Additionally, albumin replacement has been posited

to mitigate fluid extravasation leading to anasarca, and to improve pharmacokinetics of protein-bound medications though data are limited. As noted earlier it is our practice to routinely replace albumin based on volume removed and conditions related to hypovolemia and low oncotic pressure.

In conclusion, paracentesis is a relatively commonly performed procedure that is clearly in the purview of the internist in a variety of settings. It can provide invaluable diagnostic information and significant symptomatic relief. As a benchmark, individuals performing this procedure should maintain records of their procedural activity and be able to document major complication rates approaching 1/1000 procedures. Additionally, it is imperative that the operator be familiar with ultrasound characteristics of the patient with ascites and that ultrasound be used for guidance in all cases.

Percutaneous Tracheostomy

Robert Lee, MD and Mohit Chawla, MD, FCCP

INTRODUCTION

Tracheostomy is defined as creating an artificial airway passage through the neck directly into the trachea. Percutaneous tracheostomy or percutaneous dilatational tracheostomy (PDT) refers to the method of performing tracheostomy using the modified Seldinger (over wire) and dilatational technique. The development of the PDT technique was a natural progression in the era of the rise of minimally invasive approaches. There are, however, notable differences between PDT versus a surgical tracheostomy (ST), in terms of risks and benefits, which will be further discussed in detail. PDT has received wide acceptance by many clinicians, and is now being routinely performed by intensivists, interventional pulmonologists, and surgeons in many countries. It is crucial for those managing patients with tracheostomies to be familiar with PDT in order to provide the best care possible.

HISTORY

Tracheostomy is considered one of the oldest procedures dating back to 3600 BC. The earliest written descriptions are found in Rigveda, a sacred Hindu book, and Babylonian Talmud circa 2000 BC. Percutaneous tracheostomy dates back to 1955, when Sheldon et al used a cutting trocar to place a tracheostomy tube.¹ However, due to the sharp trocar, many deaths occurred. This technique was modified in 1969 when Toye and Weinstein introduced a single tapered dilator with a recessed cutting blade over wire.² It was not until 1985, however, when wide acceptance of the percutaneous approach resulted from Ciaglia's new technique of serial dilations over wire in 24 patients.³ Following this, other techniques came on the horizon including Rapitrach (1989), Griggs (1990), Fantoni, and PercuTwist, which will

be discussed further below. Ciaglia's original multi-dilator method also underwent further refinement leading the Ciaglia Blue Rhino one step dilation technique in 1999, which is undoubtedly considered the most popular approach at this time.⁴

INDICATIONS AND CONTRAINDICATIONS

Indications for PDT are the same as the indications for tracheostomy; however, patient selection is especially important for PDT to minimize potential complications. Unlike ST, the trachea is not directly visualized prior to insertion of the tube during PDT. Only minimal blunt dissection is performed during PDT with rare use of cautery, and therefore, unexpected bleeding can occur during or immediately following the dilatation step.

According to the American Academy of Otolaryngology and Head and Neck Surgery, suggested indications for tracheostomy include the following⁵:

1. Upper airway obstruction
2. Prolonged or expected prolonged intubation
3. Inability of patient to manage secretions (aspiration or excessive bronchopulmonary secretions)
4. Facilitation of ventilation support
5. Inability to intubate
6. Adjunct to manage head and neck surgery
7. Adjunct to manage significant head and neck trauma

In addition, tracheostomy appears to improve the work of breathing and respiratory mechanics.⁶⁻⁸ In comparison to ST, PDT is an elective procedure typically performed in the intensive care unit (ICU)

setting in patients who are already intubated and hemodynamically stable. PDT as an emergent airway management, although possible, is controversial and not universally recommended.⁹

Contraindication for PDT is mostly related to increased risk of bleeding. Although significant bleeding is not common, when it occurs it can be difficult to control.^{10,11}

TECHNIQUES

Although several variations in techniques exist for PDT, the basic premise is the same: the trachea is punctured using a hollow needle, guidewire is advanced into the airway, then over the wire, dilatation and eventual placement of the tracheostomy tube is performed. The Fantoni technique is one of the few exceptions that deviates from this basic principle. Bronchoscopic guidance may or may not be used during the procedure depending on the operator's expertise and/or preference.

Ciaglia Blue Rhino Single Dilator

This technique is by far the most widely accepted and practiced approach. When initially introduced by Ciaglia in 1985, multiple separate dilators were used prior to a tracheostomy tube insertion. This multidilation step was consolidated into one single dilator technique in 1999, which simplified the insertion process and reduced the insertion time.^{3,4}

Once the entry site is identified by palpation, an incision is made. After minimal dissection, the needle is inserted into the trachea. Bronchoscopic guidance is helpful but not mandatory. Once the wire is inserted into the airway, dilation is made using a punch dilator followed by the single tapered dilator with the subsequent insertion of the tracheostomy tube (Figure 105–1).

Ciaglia Blue Dolphin

This method was designed to prevent significant force exerted from anterior to posterior direction during the single dilator method, which can lead to tracheal ring fracture.¹² Also, an attempt was made to further simplify the tracheostomy insertion by having the dilator and tracheostomy tube loader

FIGURE 105–1 A Local anesthesia (lidocaine and epinephrine mixture) is given at the site of entry.

FIGURE 105–1 B Incision is made either horizontally or vertically over trachea.

FIGURE 105–1 C Minimal blunt dissection is performed (this is considered as an optional step).

FIGURE 105-1D Bronchoscope light is used to withdraw the endotracheal (ET) tube proximal to the entry point.

FIGURE 105-1G Dilator is passed over the wire.

FIGURE 105-1E Introducer needle is inserted into the trachea under direct bronchoscopic visualization.

connected together. Over the wire, the dilator balloon is inflated causing more radial force rather than the anterior to posterior force. The balloon is then deflated with the advancement of the tracheostomy tube, which is loaded onto the same device connected to the balloon. Therefore, the dilator does not have to be removed first, prior to passing the tracheostomy tube loader over the wire.

Griggs

The Griggs technique uses Griggs forceps, which has grooves to slide over the wire. Using the Griggs forceps, the trachea is dilated and a tracheostomy tube is placed.¹³

FIGURE 105-1F Wire is passed through the introducer needle.

FIGURE 105-1H Tracheostomy tube is passed into the trachea.

Fantoni

The Fantoni technique, also known as retrograde percutaneous translaryngeal tracheostomy, is radically different from other techniques in which the tracheostomy tube is placed from the endoluminal site toward the skin. Once the wire is passed into the trachea percutaneously, it is moved retrograde toward the larynx and attached to a special soft tracheostomy tube. Then the wire is pulled out toward the skin until the tracheostomy tube comes out of the skin. The trachea portion of the tracheostomy tube then needs to be redirected toward the main carina using a rigid bronchoscope.¹⁴

Percutwist

The Percutwist technique was introduced in 2002, which uses rotational force during dilation using a screw-like dilator that is twisted into the trachea over the wire. The main advantage would be potentially minimizing the chance of tracheal ring fracture, which can occur with techniques using traditional anterior-posterior directional force for dilation.¹⁵

EVIDENCE

A number of studies comparing PDT to ST have been published. The first meta-analysis published in 1999 by Dulguerov et al, a surgical group in Switzerland, showed increased perioperative complication rate with PDT compared to ST.¹⁶ Of note, ST was divided into older (1960-1985) versus newer (1986-1996) period on the basis of the improved surgical techniques. The difference of perioperative complications between PDT and newer ST period was significant (10% vs 3%). However, this study was widely criticized for including both the observational and randomized trials, and not separating different PDT techniques as different PDT techniques have showed different safety profiles.

The second meta-analysis soon followed in 2000 by Freeman et al in response to the first meta-analysis. This included only prospective randomized trials with the Ciaglia dilatational technique versus ST.¹⁷ Odds ratio (OR) for all operative complications did not show any difference (OR 0.73), but stomal infection (OR 0.02), operative bleeding (OR 0.15), postoperative bleeding (OR 0.39), and

all postoperative complications (OR 0.15) seem to favor PDT over surgical tracheostomy. However, the weight of evidence was questioned due to the limited number of patients and studies included in the meta-analysis. There were 5 trials included with a total number of patients being 236 (115 in PDT arm and 121 in ST arm).

The third meta-analysis was published in 2006 by Delaney et al that included 14 randomized trials comparing PDT to ST in critically ill patients, a total of 1212 patients. Pooled estimate of OR did not show any difference between PDT and ST in significant bleeding or mortality. The only significant finding was reduced overall wound infection in PDT of 2.3% compared to 10.7% in ST.¹⁸ The benefit of PDT over ST in surgical site infection was again demonstrated in a trauma population by Park et al in 2013, showing 7% versus 3.4% that was statistically significant with a P value of 0.04.¹⁹

As of now, the evidence suggests that PDT has a lower wound infection rate compared to ST, but other complication rates including bleeding and mortality seem comparable.¹⁷⁻²⁰ Of note, there are other benefits to PDT over ST, which include consumption of less operating room cost and staff resource, less overall cost, and less time it takes to perform the procedure from the time the decision is made to proceed with tracheostomy, given more flexibility in scheduling (28.4 hours compared to 100.4 hours).¹⁷ Because there is no need to transport the patient to the operating room with PDT, it may potentially reduce morbidity associated with the intrahospital transport of critically ill patients.²¹

SPECIAL CONSIDERATION

Bronchoscopic Guidance

It appears intuitive that bronchoscopic guidance would make the PDT procedure safer since it would allow visualization of the needle entry into the airway and prevent posterior wall puncture. Kost et al suggested in his 500 PDT experience that continuous bronchoscopic guidance led to a low complication rate with no incidence of pneumothorax, pneumomediastinum, or paratracheal placement.²² However, a study published by Dennis et al in 2013,

demonstrated a low complication rate in 3162 patients without the use of bronchoscopy, arguing against mandating bronchoscopic guidance for PDT (complication rate of major airway complications and deaths were 0.38% and 0.16%, respectively).²³ The operator's experience is likely a large contributing factor since Kost et al demonstrated a decline in complication rate once the operator performs over 30 PDTs.²² The decrease in the complication rate occurred even with the percentage of obese and difficult airway patients increasing after the initial 30 patients, suggesting increased comfort level and competency of the operator.

Early Versus Late Tracheostomy

The median tracheostomy timing in United States was reported to be 9 days with interquartile range of 5 to 14 days.²⁴ The definition of early tracheostomy varied based on the study (ranging from 1 to 8 days). Some of the prior retrospective studies suggested the potential benefits of ICU length of stay and duration of mechanical ventilation. However, 3 main randomized trials showed no such benefits. The only benefit of early tracheostomy seems to be potentially using less sedation, meanwhile showing no evidence in reducing ventilator-associated pneumonia, length of ICU stay, or mortality.^{25,26}

Ultrasound Guidance

Ever increasing popularity of using ultrasound has made its way into PDT. By using linear array high-frequency probe, the neck can be examined prior to tracheostomy to reveal aberrant blood vessels in the path of the needle. In obese patients with difficult anatomy, real-time guidance can be used. There is 1 randomized trial that showed an increased success rate of first time puncture when real-time ultrasound is used compared to the traditional landmark method.²⁷⁻²⁹ However, no statistically significant finding was noted in complication rate. Additionally, a number of feasibility and case series studies showing the potential benefits of the ultrasound guidance especially in obese patients.³⁰ Given the unlikelihood of any adverse effect posed by using the real-time ultrasound, it is possible that this will benefit a subgroup of patients with difficult neck anatomy.²⁷⁻²⁹

Operator-Dependent Outcome

One study examined safety and efficiency of PDT performed by physicians trained in either interventional pulmonology or surgery at a tertiary referral center. Of note, all interventional pulmonologists have critical care medicine training background. Almost all procedures were done within 48 hours with no differences in complication rate.³¹

Specific PDT-Related Complications and Death

A specific type of tracheal stenosis was reported termed "corkscrew stenosis" in 11 patients who underwent PDT, which occurred as a result of tracheal ring fracture. Mean time to occur was 13 months (range 1.5-24 months) with 7 requiring tracheal resection.³² Methods to prevent tracheal ring fracture may be needed to prevent long-term complications like this.

Fatalities that result from PDT arose predominantly from damage to vessels and subsequent bleeding either intraoperatively or up to 22 days after the procedure. Identified factors that led to vessel damage include low placement of tracheostomy below the eighth tracheal ring, prior neck surgery, and radiation therapy. Two fatality cases occurred from loss of airway during the procedure.^{10,11}

CONCLUSION

Percutaneous dilatational tracheostomy is a minimally invasive method of placing a tracheostomy tube in intubated patients. It is performed at bedside in the ICU, which reduces cost and resources usually required for a surgical procedure performed in the operating room. It can be safely performed by nonsurgical physicians including interventional pulmonologists and intensivists. Adequate training for the proceduralists, and proper patient selection are crucial in minimizing complications and better outcomes.

Pericardiocentesis

Martin E. Goldman, MD

KEY POINTS

- 1 Pericardial effusions that compress the cardiac chambers can cause cardiac tamponade.
- 2 Cardiac tamponade requires thorough clinical and echocardiographic imaging to determine whether emergency pericardiocentesis is needed.
- 3 Echocardiographic guidance of pericardiocentesis has increased the safety margin by indirect confirmation of needle placement and fluid drainage.

INTRODUCTION

The pericardium is a protective double-lined sac that surrounds the heart. The function of the pericardium is to reduce the friction between the heart and surrounding mediastinal structures and also to provide a barrier against spread of infection and malignancies to the heart. Though most cardiac conditions affect the 4 chambers of the heart, its blood supply and/or the conduction system, the surrounding pericardium plays an important role in normal cardiac physiology and disease.

Under certain pathologic conditions, pericardial disease can lead to palpitations, hypotension, and acute cardiac decompensation.¹ Patients presenting with pericardial tamponade accompanied by impending hemodynamic collapse require emergency pericardiocentesis. (An excellent video presentation by Fitch et al in the *N Engl J Med*. should be viewed in conjunction with this review.)²

NORMAL ANATOMY AND FUNCTION

The normal pericardium is a double-layered membrane that encases the heart and the origin of the great cardiac vessels. The outer fibrous layer (the parietal pericardium) is attached to the surrounding mediastinal structures: the diaphragm, sternum, and costal cartilages; while the inner serous layer (the visceral pericardium) lies on the surface of the heart and is contiguous with the epicardium.³ The pericardial lining secretes 15 to 35 mL of serous pericardial fluid (an ultrafiltrate of plasma that contains proteins, electrolytes, and phospholipids) that lubricates the surfaces of the heart to minimize the friction for the contracting heart, and drains through the mediastinal and tracheobronchial lymph nodes.² Posteriorly, the pericardium stops at the base of the left atrium so that the posterior wall of the left atrium is not covered by the pericardial space.

FIGURE 106–1 Small pericardial effusion: parasternal long-axis view, transthoracic echocardiogram; long-axis view of small pericardial effusion. LV, left ventricle; PERI, pericardial effusion; PLEURAL, pleural effusion; RV, right ventricle.

With chronic pericardial fluid that accumulates gradually, pericardial compliance is able to increase to accommodate the slowly accumulating larger volumes. However, because the pericardium is a relatively stiff structure, intrapericardial pressure rises rapidly as intrapericardial volume becomes too large or the volume increases acutely, compressing the cardiac chambers, which could lead to pericardial tamponade.⁴

In suspected pericardial disease, transthoracic echocardiography (TTE) (including 2-dimensional (2D) TTE, M-mode echocardiography, pulse-wave Doppler, and inferior vena cava imaging, collectively 2D TTE) is the first-line imaging technique. 2D TTE can image the size, location, and relative pericardial volume and serve as a guide to therapeutic intervention (pericardiocentesis) (Figure 106–1).^{4,5}

PERICARDIAL EFFUSION

Pericardial effusion is the accumulation of greater than 50 mL pericardial fluid within its 2 layers, which can be due to numerous etiologies. Levy found the most common causes of large pericardial effusions were idiopathic (33%), iatrogenic (16%), malignancy (13%), following acute myocardial infarction (MI) (9%), renal failure (uremia, dialysis) (6%), and

collagen vascular disease (6%).⁶ Etiologies can vary with institution and referral populations. Pericarditis, a nonspecific inflammation of the pericardium, can be associated with inspiratory chest pain, worse lying than sitting, may be accompanied by a friction rub that may be lost if the effusion is large and may be associated with palpitations and atrial or ventricular arrhythmias.

Pericardial effusion is recognized by echocardiography as an echo-free space between the visceral and the parietal pericardial linings posteriorly in the parasternal long-axis and short-axis views (see Figure 106–1). With M-mode and 2D TTE, a semiquantitative estimate of the pericardial effusion volume can be made by the size and extent of the anterior and posterior echo-free space (if not loculated).⁷ A pericardial effusion limited posteriorly, less than 1 cm, is usually less than 250-mL volume (ie, small); greater than 1 cm effusion posteriorly is around 250 to 500 mL (small-moderate); a circumferential, posterior and anterior 1 cm echo-free space is approximately 500 mL (moderate); and if the circumferential echo-free space is greater than 1 cm there is more than 500 mL of effusion (large) (Figure 106–2). A large effusion accompanied by

FIGURE 106–2 Large pericardial effusion: parasternal long-axis view. Ant, anterior pericardial effusion; LV, left ventricle; Post, posterior pericardial effusion; RV, right ventricle.

swinging of the heart, may indicate pericardial tamponade and more than 1 L of fluid. Estimation of the fluid volume is relative to cardiac size, which may depend on cardiac chamber enlargement and patient's body surface area. The physiologic consequences of pericardial effusion depend on the effusion volume, rate of fluid accumulation, presence of ventricular hypertrophy, pulmonary hypertension, and the presence or absence of cardiac compression. With increase in effusion size, the fluid extends laterally and once it exceeds 250 to 300 mL, it can appear anteriorly while the patient is in the supine position (Figures 106–2 to 106–5).

Pericardial effusions are usually transudates, seen on 2D TTE as a black nonechogenic (anechoic) space. However, infected or bloody fluid can appear as a hazy-gray rather than clear fluid and should suggest an abnormal exudative content. If not loculated, the pericardial effusion fluid around the heart is dynamic, and shifts with systole and diastole as the heart beats. This is to be distinguished by masses in the pericardial space or postoperative hematomas, which are usually relatively noncompressible.

FIGURE 106–3 Pericardial effusion: parasternal short-axis view. Ant Peri Eff, anterior pericardial effusion; LV, left ventricle; POST PERI EFF, posterior pericardial effusion; RV, right ventricle.

FIGURE 106–4 Pericardial effusion: apical view of large circumferential pericardial effusion. *, pericardial effusion; LV, left ventricle; RV, right ventricle.

Loculated effusions may occur postoperatively in cardiothoracic surgery or due to exudates or inflammatory states following recurrent pericarditis that can occur with infections, viral pericarditis, recurrent rheumatic pericarditis, or in renal disease

FIGURE 106–5 Pericardial effusion: subxiphoid view, large effusion anterior to right ventricle (RV) and posterior to left ventricle (LV). *, pericardial effusion.

(Figure 106–6). Loculated effusions are usually localized, and not circumferential, but may have hemodynamic significance by compression of chambers or vena cava or pulmonary veins. Hematomas appear as immobile, flat or protruding, echodense thickening, usually anteriorly, and may be traumatic or postoperative (common following cardiac surgery where the pericardial space may be violated, uncommon following thoracic or abdominal surgery).

Pericardial fluid should be differentiated from the normal pericardial fat pad that is usually seen anterior to the heart lying within the pericardial sac and has speckled, hyperechoic areas because it is reticulated with echodense fibrous tissue and fatty tissue. The fat pad tissue does not significantly compress with cardiac contraction as free fluid does.

Pleural effusions, which can be easily confused with pericardial effusions, can be distinguished by certain key features. On the parasternal long-axis

FIGURE 106–6 Pericardial effusion: apical view, with pericardial strands (arrows) breaching the pericardial effusion, creating potential loculated pockets. LV, left ventricle; RV, right ventricle.

view, the pericardial reflection usually stops at the atrial-ventricular groove posteriorly, where the left ventricular posterior wall meets the posterior mitral annulus and there is usually no pericardial reflection behind the posterior left atrium; therefore, fluid behind the left atrium and aorta usually represents a pleural effusion (see Figure 106–1). Frequently, atelectatic lung tissue can be seen in the pleural space as well. If there is both a pericardial and pleural effusion, it can be easier to differentiate the 2 spaces. The descending aorta usually lies behind the left atrium and also demarcates the end of the pericardial reflection on the posterior surface of the heart. Fluid, therefore, behind the descending aorta would represent pleural effusion, not pericardial. If the probe is placed far laterally around the chest, the presence of a pleural effusion can be confirmed.

Pericardial effusion can be differentiated from ascites, which can be potentially confusing when imaging from the subxiphoid position. Ascites is usually closer to the liver, separated from heart by the fibrous band of pericardium. With significant ascites, the falciform ligament can be seen as a linear band extending from the liver to the pericardium traversing the black nonechoic ascites.

PERICARDIAL OR CARDIAC TAMPONADE

When fluid accumulates slowly, the parietal pericardium can stretch to accommodate large volumes of fluid. However, if the development and accumulation of the effusion is very rapid or the volume exceeds the capacity of the pericardial space to stretch to contain the volume, increases in intrapericardial pressure begins to impact intracardiac pressure, elevation and equalization of diastolic intracardiac and pericardial pressures, decrease cardiac output, and exaggerated inspiratory decrease in systolic pressure (> 10 mm called pulsus paradox)^{4,5} (Figure 106–7).

Circumstances that can lead to pericardial tamponade include all those that cause pericardial effusions including uremic renal failure, hypothyroidism, coronary vessel perforation during percutaneous interventions in the catheterization laboratory, a bleed following cardiac surgery, rupture or dehiscence

FIGURE 106–7 Pericardial pressure. (Reproduced with permission from Hoit JP, Rhode EA, Kines H: Pericardial and ventricular pressure, *Circ Res* 1960 Nov 1;8(6):1171-1181.)

following valve surgery or aortic dissection, bleeding into the pericardium from a neoplasm, infection (viral, bacterial, fungal, tubercular), or a marked inflammatory response.¹ One study of 173 patients who underwent pericardiocentesis cited the etiologies as malignant (33%), acute or chronic pericarditis (26%), trauma (12%), uremia (6%), postpericardiotomy (5%), infection (5%), collagen vascular disease (3%), and radiation (2%).⁸

Tamponade following cardiac surgery may be due to bleeding from anticoagulants for prosthetic valves, delayed cessation of antiplatelet drugs, oozing from vascular or aortic anastomoses, or irritation from chest tubes. Loculated effusions may create regions of focal cardiac tamponade that may present with hypotension, but difficult to diagnose unless suspected, especially after cardiac surgery.

Clinically, patients with tamponade may have dyspnea, weakness, tachycardia, and hypotension. On anterior-posterior (AP) x-ray, a large cardiac silhouette, projecting a “water bottle-shaped” heart, in a patient with clear lung fields suggests the presence of a pericardial effusion with at least 250 mL of fluid. An electrocardiogram (ECG) may show signs of pericarditis with sinus tachycardia, and PR depression in leads 2, 3, and aVF. A valuable ECG sign indicative of potential cardiac tamponade is electrical alternans. Computed tomography (CT) and magnetic resonance imaging (MRI) scans

may show incidental large effusions suggestive of tamponade.^{5,9-11} If the patient is stable, hemodynamics in the catheterization laboratory will show equilibration of average diastolic pressure across the cardiac chambers produced by the extrinsic pericardial pressure and ventricular interdependence, an inspiratory increase on the right-sided pressures with a concomitant decrease on the left-sided filling pressures—pulsus paradoxus.

Echocardiography is the most expedient modality to diagnose pericardial effusion and confirm the presence of pericardial tamponade. Echocardiography demonstrates circumferential pericardial fluid and compressed cardiac chambers (Figures 106–8). Among echocardiographic signs, the most characteristic is the diastolic right atrial and right ventricular compression. Right atrial collapse may also be seen in patients with hypovolemia who do not have tamponade. With greater compression, the left atrium may also collapse, a more specific finding. The diastolic collapse of the right ventricle usually connotes large enough external pressure to impact stroke volume. Doppler of aortic or pulmonic systolic flow discloses marked respiratory variations: On inspiration, the right ventricle fills at the expense

FIGURE 106–8 Ventricular interdependence: 2D echo demonstrating indentation of left ventricular (LV) interventricular septum due to inspiratory increase in right ventricular (RV) pressures. * pericardial effusion

FIGURE 106–9 M-mode echocardiogram demonstrates large anterior pericardial effusion (*), with ventricular interdependence: the right ventricle enlarges with inspiration, while the left ventricle (identified by the mitral valve) becomes smaller and the opposite occurs with expiration.

of the left ventricle, seen as increased peak filling pulsed-wave Doppler velocity; both the ventricular and atrial septa move sharply leftward, reversing on expiration when the left ventricle fills at the expense of the right ventricle (Figure 106–9). A greater than 25% change in peak Doppler flow velocity obtained from the left ventricular outflow track or through the aortic valve, obtained by pulsed Doppler in the apical 4-chamber/5-chamber view or of the pulmonic valve, may connote pericardial tamponade (Figure 106–10). Pulsus paradoxus may also be seen with pulmonary embolism, chronic asthma, chronic obstructive pulmonary disease (COPD) and croup, but may be absent in low cardiac output states. The absence of any cardiac chamber collapse has greater than 90% negative predictive value for cardiac tamponade.¹²

Importantly, pericardial tamponade is a clinical diagnosis based on the presence of tachycardia and hypotension, which can be supported by echo/Doppler findings. Therefore, clinical suspicion of the presence of tamponade or the imminent development of tamponade is extremely important in prevention of acute cardiac collapse. Under certain circumstances, especially with hypertrophy of the left and/or right ventricle and pulmonary hypertension, which may be seen in hypertensive patients

FIGURE 106–10 Transaortic Doppler flow in the left ventricular outflow track, demonstrating higher velocity with expiration and lower with inspiration, creating pulsus paradoxus (arrows).

with chronic renal failure, who are prone to recurrent pericardial effusion, there may not be the typical findings of tamponade, because the ventricular hypertrophy limits the impact of the external compression on ventricle interdependence.

Management of Acute Cardiac Tamponade

Patients presenting with hypotension and tachycardia in which pericardial pressure from the volume of pericardial effusion causes cardiac compression have cardiac tamponade and require emergency pericardiocentesis that should be performed with echo guidance. The European Society of Cardiology's recent position statement on the triage of patients with potential cardiac tamponade proposed a stepwise scoring system to triage patients requiring

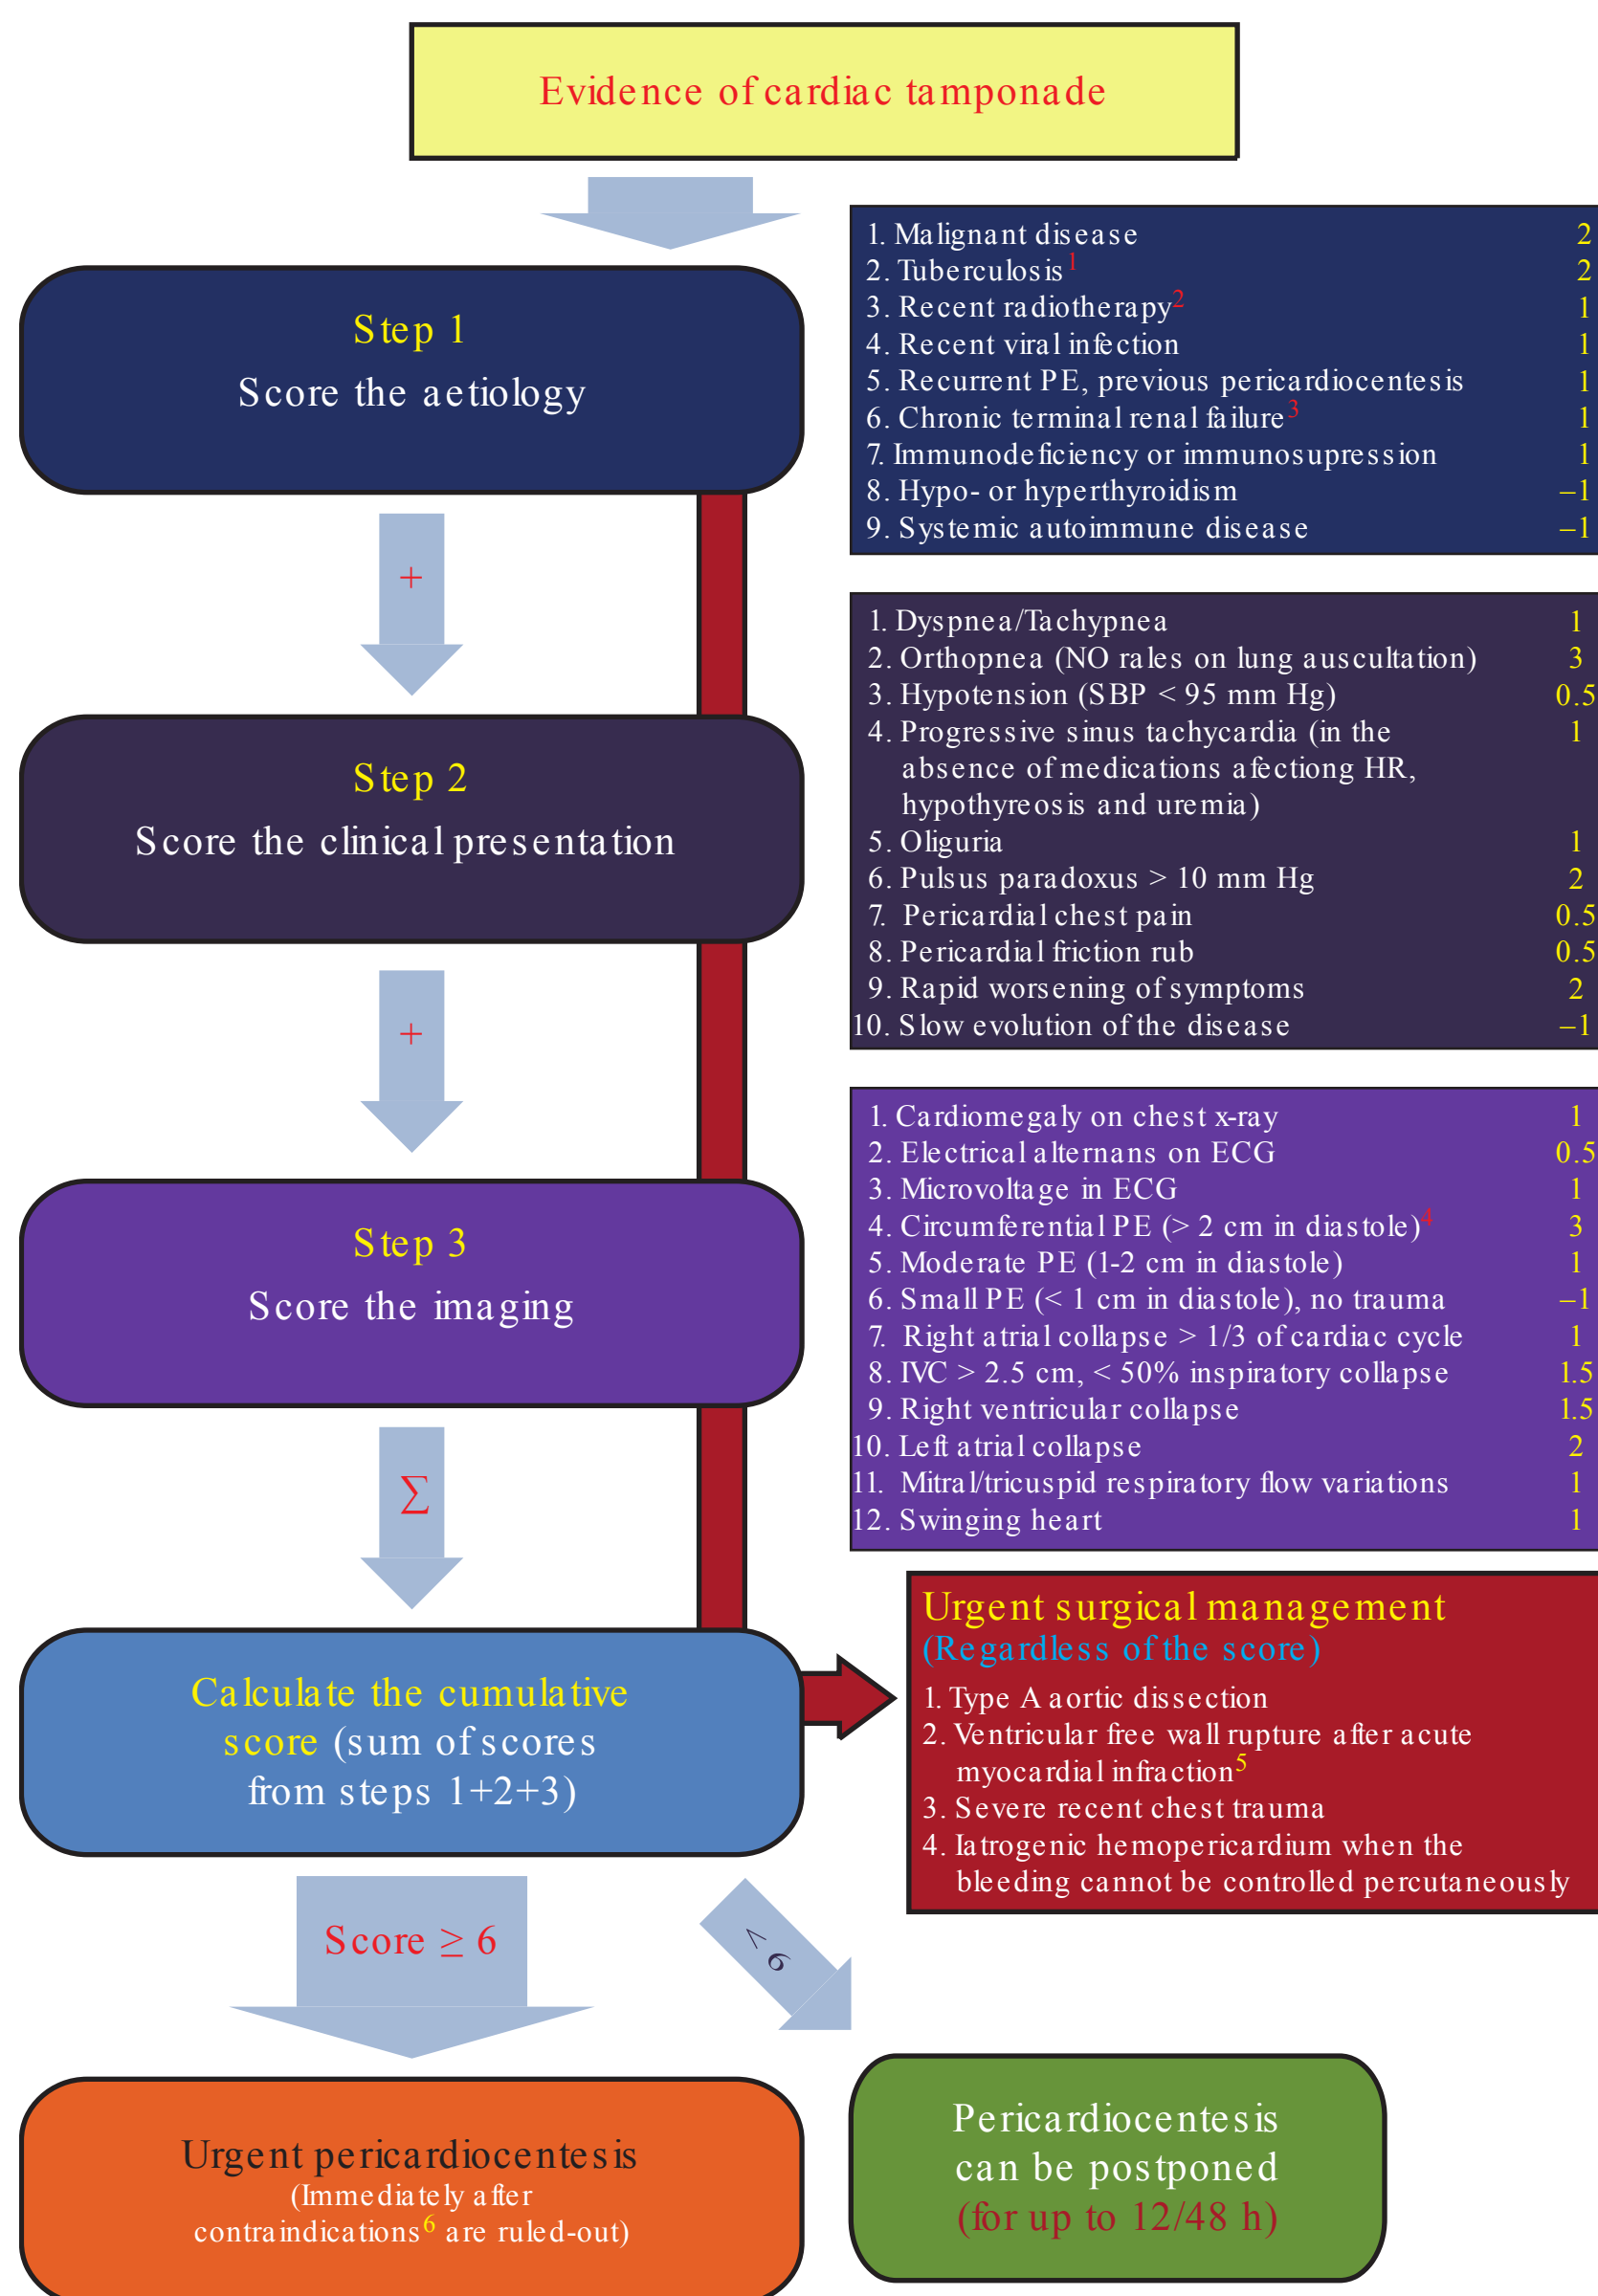

FIGURE 106–11 Triage strategy for urgent management of cardiac tamponade: European Society of Cardiology Working Group on Myocardial and Pericardial Diseases.¹⁴ (Reproduced with permission from Ristic AD, Imazio M, Adler Y, et al. Triage strategy for urgent management of cardiac tamponade: a position statement of the European Society of Cardiology Working Group on Myocardial and Pericardial Diseases, Eur Heart J 2014 Sep 7;35(34):2279-2284.)

pericardiocentesis.¹³ The paper incorporates etiology, clinical presentation, and imaging findings (with primary emphasis on echo findings) to determine whether urgent pericardiocentesis, surgical approach, or intervention can be delayed¹⁴ (Figure 106–11).

Pericardial drainage may be performed in the catheterization laboratory with hemodynamic measurement, with sterile technique in which both transthoracic echo and fluoroscopy can be utilized. However, sudden circulatory collapse may mandate

the use of pericardiocentesis with imaging where the patient presents, in the emergency ward, ICU, or in the regular ward bed. Surgical drainage may be required if drainage cannot be achieved by percutaneous needle, in the presence of an active intrapericardial bleed, cardiac trauma or laceration, or complicating aortic dissection.

Medical treatment of acute cardiac tamponade can briefly temporize, but even volume infusion may increase intracardiac volume and pressures, thus increasing pericardial pressure and interventricular dependence, exacerbating the hypotension. Mechanical ventilation with positive airway pressure should be avoided in patients with tamponade, because this decreases venous return and may potentiate hypotension.

Pericardiocentesis is the most expedient method to resolve the impending circulatory collapse.¹⁵ The immediate treatment of cardiac tamponade is drainage of the pericardial fluid by either needle pericardiocentesis or surgical pericardial window.

Relative contraindications include suspected effusion due to aortic dissection, traumatic hemo-pericardium, or myocardial rupture in which the pericardiocentesis may exacerbate the underlying condition that may be temporarily in equilibrium.

Anticoagulation or bleeding dyscrasias are relative contraindications, depending on the acuity of the situation and the severity of bleeding disorder.

PERICARDIOCENTESIS

Medical personnel should be gowned, gloved, and masked. Patients should be sterilely draped and have pulse oximetry, heart rate, and blood pressure continuous monitoring. Emergent intubation or sedation with short-acting hypnotics or anxiolytics may induce more pronounced decompensation.¹⁶

Materials needed which can be found in pre-packaged commercial sets usually include a 21-gauge needle attached to a 5-mL syringe for subcutaneous lidocaine (1%) injection, a scalpel for small skin incision, a 7- to 9-cm 16- to 18-gauge spinal needle or a sheath over the needle catheter, a J-tipped flexible guidewire, a dilator to slip over the guidewire, a 3-way stopcock, a pigtail catheter or dedicated catheter for centesis procedures, several half-filled 10-mL saline syringes, and syringes (20 and 50 mL) for aspiration. An alligator ECG lead can be attached to the needle to monitor for current of injury as the needle is forwarded and hits the epicardium and generates ST elevation (“current of injury”) (Table 106–1).

TABLE 106–1 Checklist for pericardiocentesis.

<ul style="list-style-type: none">• Lidocaine, 1%, with 10-mL syringe and 25-gauge needle.• Pericardiocentesis needle: 17-gauge, 12.5-cm (5-in) thin-walled steel needle (usually a spinal needle) for aspiration. It is possible to use 16-gauge and even 14-gauge needles with plastic outer cannulas.• Syringes: assorted sizes, including 50 mL (2), 30 mL (2), 10 mL (2), and 5 mL (1).• No. 11 scalpel blade, mounted.• Sterile conductive monitoring cable with alligator clamps at each end.• Three-way stopcock.• Silk suture (5-0) on a cutting needle.• Straight clamp and needle holder.• Needles: assorted sizes, including 25 gauge, 1.5 cm (0.59 in) (1); 22 gauge, 2.5 cm (1 in) (2); and 19 gauge, 4 cm (1.5 in) (5), for transferring specimens.• Drapes.• Sterile, capped, 15-mL specimen tubes (10).• Heparin, to lightly heparinize cytologic specimen tubes.• Specimen tubes, one purple-topped and three red-topped.• Clean-glass microscope slides.• Microhematocrit centrifuge tubes with occlusive sealant.• Ice bucket to hold cytologic specimens.• Sterile dressing for entry and exit sites.• Cardiopulmonary resuscitation (CPR) cart.

FIGURE 106–12 Potential sites to perform a pericardiocentesis. (Reproduced with permission from Reichman EF, Simon RR: *Emergency Medicine Procedures*, 2nd ed. New York: McGraw-Hill Education; 2013.)

Before draping and preparing the patient, ECHO imaging should confirm the presence of the effusion, whether the fluid is loculated, the presence of adhesions, the appropriate drainage window, and the approximate angle for needle insertion. Select a window in which the effusion can be clearly visualized, preferably all 4 cardiac chambers (**Figure 106–12**). The ECHO probe can either be placed in a long sterile plastic sheath with ultrasonic gel at the tip for the probe and used adjacent to the needle in the sterile field or ECHO imaging can also be done at the apex, remote from the needle insertion site at the subxiphoid window or image from the subxiphoid window if the apex window is deemed the safer approach. The echo probe can then be manipulated under the sterile drape, off the sterile field by an experienced echocardiographer physician or sonographer while the pericardiocentesis itself is performed by another experienced physician.

The subxiphoid approach, just underneath the left costal margin, is also the safest for pericardiocentesis performed without ECHO or fluoroscopic guidance, because it avoids the coronary arteries, internal mammary artery, and is extrapleural (**Figure 106–12**). The alternative apical approach for pericardiocentesis may be closer to the skin surface, but may carry a greater risk of cardiac and pulmonary complications unless the performer is experienced

with this approach. Using sterile technique, the skin should be prepared with a chlorhexidine-based solution and sterilely drape the chest and abdomen with an open window for the procedure location. While monitoring hemodynamically, administer enough anxiolytics and topical pain medicine so the patient is relatively immobile during the procedure to avoid complications such as arrhythmias and cardiac laceration during needle insertion. After topical anesthesia with lidocaine, a small, superficial puncture is made for the spinal needle insertion site with a scalpel blade. The long spinal needle (a 16- to 18-gauge sheathed needle can be used so the metal core can be withdrawn and aspiration injections can be done through the sheath) is slowly advanced at a 30° to 45° angle with its hub depressed so that the point is pointing toward the left shoulder just under the xiphisternum, from the subcostal window. The needle is then advanced slowly, until the piercing of the fibrous pericardium is felt while continuously aspirating (**Figure 106–13**). Normal pericardial fluid is clear and straw-colored. Aspiration of bloody fluid may be pericardial, pleural, or intracardiac. Once fluid is aspirated back, the sterile clamp can be placed at the skin surface securing the needle and avoiding accidental advancement. By either echo guidance technique, though the tip of the pericardiocentesis needle itself may not be seen, the presence of the needle in the pericardial space is confirmed by “contrast” echo

FIGURE 106–13 The subxiphoid approach. The needle is inserted at a 45° angle to the midsagittal plane (**A**) and at a 45° angle to the abdominal wall (**B**). (Reproduced with permission from Reichman EF, Simon RR: *Emergency Medicine Procedures*, 2nd ed. New York: McGraw-Hill Education; 2013.)

created by rapidly injecting either the aspirated fluid or sterile-agitated saline back into the space creates echogenic microbubbles within the pericardial space (Figure 106–14). The microbubbles are easily seen echo-flowing rapidly into the pericardial space, but move slowly in an exudate or bloody effusion. If the needle is not in the pericardial space, microbubbles may be seen injected into a cardiac chamber or may not be seen if injected into a pleural space. Visualizing the microbubbles in the right ventricle or another cardiac chamber requires removal of the needle and very careful monitoring for worsening tamponade if

the cardiac puncture site doesn't self-seal. Repeat the procedure until the needle position is confirmed by the microbubbles.

Once the needle is confirmed to be in appropriate position, a guidewire is then introduced through the needle and a dilator passed over the guidewire to manually drain with 20- or 50-mL syringes, with strict sterile control. Fluid drainage can be followed by ECHO to the point of minimal residual fluid. Because of the steep slope of the intrapericardial pressure-volume curve, aspirating a small volume (50 mL) may be enough to decompress the heart and recover blood pressure and slow the heart rate (Figure 106–7). The source and quality of fluid will determine if a drain should remain in place.

Bloody effusions from iatrogenic cardiac laceration or trauma may require surgical repair. For prolonged drainage, a guidewire passed through the sheath or needle will facilitate the introduction of a pigtail angiographic catheter. However, a drain may occlude, be an irritant, causing arrhythmias and is a potential source of infection. A follow-up TTE should be performed a few hours postpericardiocentesis to ascertain that no further accumulation has occurred.

Loculated effusions may present a problem because a single needle position may only remove fluid from one isolated pocket and those patients may require a pericardial window with lysis of adhesions in the pericardial space.

Pericardiocentesis is usually very safe using ECHO guidance with almost an immediate hemodynamic response of improved blood pressure and slowing of the heart rate.^{15,17,18}

Familiarity with the anatomic approaches and contiguous structures will ensure a better outcome.¹⁹ In a large series by the Mayo Clinic, ECHO-guided pericardiocentesis by experienced personnel was safe with a low incidence of minor complications (3.5%) or major complications (1.2%) such as requiring emergency surgery.²⁰ Cardiac laceration, atrial or ventricular arrhythmias, or vascular injury are very rare complications.

SUMMARY

Pericardial effusions are common, but when they accumulate rapidly or generate enough pressure to impair intracardiac filling, pericardial tamponade

can develop. Clinical suspicion, rapid recognition, and confirmation of tamponade by TTE followed by prompt echo-guided pericardiocentesis and drainage of the pericardial fluid can be lifesaving.

Pulmonary Artery Catheterization

Rafael Alba Yunen, MD and
John M. Oropello, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 There is a core of accurate and reliable hemodynamic information obtained from the pulmonary artery catheter (PAC) not readily available from any other single device.
- 2 The most reliable pressure measurements obtained from the PAC are continuous pulmonary artery systolic and diastolic pressures; the least reliable is the pulmonary artery occlusion (or “wedge”) pressure.
- 3 Holding rapid fluid infusions via the introducer and proximal PAC ports and turning off the inflation of sequential compression devices (SCDs) improves the accuracy of thermodilution cardiac output (CO).
- 4 SvO_2 does not correlate with CO in critically ill patients; increases in the $P[v-a]_{CO_2}$ gradient are inversely proportional to the CO.
- 5 Information from any hemodynamic monitor must be interpreted in the context of the clinical situation (eg, diagnoses, physical examination, laboratory, radiologic), the treatment goal, and the response to treatment.

The PAC, also called a right heart catheter or named after its creators a Swan-Ganz catheter, was introduced in 1970.¹ Made of flexible plastic (polyvinyl chloride) with an inflatable balloon at the tip, the PAC is directed at the bedside, without the need for fluoroscopy, via a central vein, using the flow of blood through the right heart, into the pulmonary artery, guided by pressure waveforms displayed on the bedside monitor. Harry Swan developed the concept of using a flotation device while observing sailboats and initially planned to use a sail-like device, but a balloon proved to be a safer interface within blood vessels and cardiac chambers. Norman Ganz developed the thermodilution CO capability of the PAC.

Use of the PAC peaked during the 1980s and 1990s, but usage has since trailed off due to its

invasive nature and subsequent randomized controlled studies demonstrating no outcome benefit (ie, reduced mortality, organ failure, length of stay, or costs).^{2,3} Despite this, there remains a core of accurate and reliable hemodynamic information, not readily available from any other single device, which can be obtained from the PAC.

The lack of demonstrable improvement in patient outcome when using the PAC is multifactorial. The main factors include reliance on inaccurate data (eg, pulmonary artery occlusion pressure [PAOP]) to guide management; the fact that the PAC is a monitoring technology, not a therapeutic technology; and that the critical illnesses the PAC is used to manage such as septic shock, acute respiratory distress syndrome (ARDS), and multiple organ failure are syndromes that have no specific treatment

and outcomes are not directly dependent on hemodynamic variables.

This chapter describes standard PAC anatomy, function, indications for insertion, insertion technique, complications, and obtaining reliable data while guiding bedside hemodynamic management.

PAC ANATOMY

A standard triple port VIP 7.5-Fr PAC is described herein. A double-lumen port PAC has identical components, other than lacking the additional infusion lumen.

The PAC insertion length ([Figure 107–1](#)) is 110 cm with an outside diameter of 2.3 mm (7.5 Fr). The catheter is yellow color and constructed of polyvinyl chloride extrusions. There are 3 main internal lumens ([Figure 107–2](#)): the **distal PA lumen** opens at the catheter tip, the **proximal injectate lumen** (also called the right atrial [RA] or central venous pressure [CVP] lumen) opens at 27 cm proximal to the catheter tip, and an **infusion lumen** opens adjacent to the proximal lumen, at 29 cm. In addition to the 3 main lumens, the tip of the catheter has a small 1.5-mL capacity latex balloon that can be inflated (11-mm diameter) and deflated (7-mm diameter) via an **inflation lumen**. A 3-mL “blood gas” syringe, modified to withdraw a maximum of 1.5 mL of air is connected to the inflation lumen. The inflation lumen has a lock that can prevent unintentional

FIGURE 107–1 Standard triple port VIP 7.5-Fr PAC (Edwards Lifesciences, Irvine, CA). The markings indicate the following PAC lengths: each thin band = 10 cm, each thick band = 50 cm, for example, 1 thick + 1 thin band = 60 cm.

FIGURE 107–2 Close up of PAC ports: yellow tubing (distal PA), blue tubing (proximal injectate), white tubing (proximal infusion), and red tubing (balloon inflation port). The red cap is covering the connection to the thermistor.

balloon inflation or air embolism in the event that both the syringe becomes disconnected and the balloon has a defect ([Figure 107–3A and B](#)). The thermistor is located about 4 cm proximal to the PAC tip. At the proximal end of the catheter, a thermistor connector, protected by a red removable cap allows connection to an electrical cable that transmits core body temperature information from the thermistor to the monitor ([Figure 107–4](#)).

The introducer kit (see later under PAC Insertion) includes a catheter sheath that is placed over the PAC prior to insertion to allow sterile manipulation of PAC depth after insertion. Some introducers can lock the PAC to prevent migration, in those that do not, a piece of tape is provided to secure the proximal end of the catheter sheath to the PAC that helps resist PAC migration.

PAC FUNCTION

The functional components of the PAC are outlined in [Table 107–1](#). Direct parameters obtained from the PAC are outlined in [Table 107–2](#).

Pressure Data

Pressure information derived from the PAC includes CVP, right ventricular (RV) systolic pressure, RV diastolic pressure, PA systolic and PA diastolic pressure and the PAOP (also called the pulmonary capillary

FIGURE 107–3 **A.** Inflation port connected to modified blood gas syringe. Note the red markings are in line indicating that the inflation port is open. **B.** The red markings are displaced indicating that the inflation port is locked.

wedge pressure [PCWP] or pulmonary artery wedge pressure [PAWP]). CVP measurement does not require a PAC, only a central venous catheter.

Before the PAC was developed, CVP was recommended as a simple measure of intravascular volume and RV filling or preload. Ventricular preload is the ventricular end-diastolic volume. Either absolute CVP or changes in CVP were proposed to differentiate decreased, normal, or increased intravascular volume or RV preload. However, there is no correlation between CVP and blood volume or cardiac preload in critically ill patients or normal volunteers.^{4,6}

CVP does not reflect left ventricular end-diastolic pressure (LVEDP) and the major reason

the PAC was designed was to provide information about left heart function. The PAC was proposed to provide information about the function of the left ventricle (LV) by occluding a segment of the

TABLE 107–1 PAC: functional components.

Component	Function
110-cm length	This length allows passage from the femoral vein to the PA if the neck veins are not accessible
Distal PA lumen	Used to monitor pressure waveforms during PAC insertion and continuous PAP after insertion; PAOP during balloon inflation; true mixed venous blood gas sampling
Proximal RA lumen	CVP/RAP monitoring, fluid bolus for thermodilution CO, infusions
Proximal infusion port (VIP)	Additional infusion port; can perform the functions of the proximal RA lumen port if the RA port becomes occluded
Balloon	Filled via the inflation port during insertion to protect the endocardium from the PAC tip and carry the PAC forward through the right heart; inflated after PAC placement in the PA to determine proper positioning of the PAC; when inflated may provide PAOP
Thermistor	4 cm proximal to the tip; monitors core body temperature; senses temperature change used for thermodilution CO

FIGURE 107–4 Red cap removed from the thermistor connection.

CO, cardiac output; CVP, central venous pressure; PA, pulmonary artery; PAC, pulmonary artery catheter; PAOP, pulmonary artery occlusion pressure; RA, right atrial; RAP, right atrial pressure.

TABLE 107–2 PAC: direct measurements.

Direct Data	Accuracy	Comments	Additional Information
CVP/RAP (normal: < 8 mm Hg)	Accurately reflects central venous pressure which is equal to right atrial pressure; RAP = RVEDP in the absence of TR; both CVP and RAP are inaccurate determinants of intravascular volume or RV preload.	This parameter should not be used for hemodynamic clinical decision making.	This parameter does not require a PAC and may be obtained via a central venous catheter. In the PAC the proximal infusion port will be usually located in the SVC, but may also be located within RA or less commonly within the introducer catheter.
RV pressures (systolic/diastolic) 15-30/0-8 mm Hg (normal)	Accurately reflects RV pressures.	Noted during PAC insertion; RV pressures are not present after the distal tip passes into the pulmonary artery.	RV systolic pressure is normally equal to the PA systolic pressure; RV diastolic pressure is normally equal to the mean right atrial pressure.
Pulmonary artery pressures (systolic/diastolic) 15-30/4-12 mm Hg; mean: ≤ 20 mm Hg (normal)	Accurately reflects continuous PA pressures; more accurate than PAP estimated by echocardiography.	Continuously displayed and monitored from the distal port once PAC is in final position in the pulmonary artery.	The true left ventricular end-diastolic pressure is less than the PAD pressure.
PAOP < 12 mm Hg (normal)	The pressure obtained after the PAC balloon is inflated when the tip of the PAC is in the PA. Highly inaccurate, does not reflect LVEDP, LV preload, or intravascular volume.	The most inaccurate parameter derived from the PAC. Interpretation errors, physiologic/pathologic limitations.	The main purpose of balloon inflation should not be to determine a PAOP per se, but to determine that the PAC tip is not located too distally in the PA.
Hemodynamic waveforms	a, c, v waves in RAP tracing; a, v waves in PAOP tracing.	Waveforms are difficult to visualize with standard ICU monitoring equipment.	Waves may be absent in pathologic conditions, eg, large v waves absent with atrial enlargement.
Core body temperature (CBT)	Most accurate measure of CBT.	Measured by a thermistor 4 cm proximal to the PAC tip.	PAC thermistor readings are altered by rapid fluid infusions and sequential compression/decompression devices leading to errors in CO measurement.
Thermodilution cardiac output 3-7 L/min (normal)	Considered the practical “gold standard” for CO measurement; inaccurate in certain situations.	Right heart thermodilution is an indicator dilution method. Under ideal conditions accuracy is within 10%-20% of true CO.	Average 3 measurements; do not measure during rapid fluid infusions, SCD inflation, inaccurate in the presence of tricuspid regurgitation.
True mixed venous blood gases	Most accurate representation of global venous blood; central venous blood gases may sample SVC or IVC blood preferentially and do not reflect true mixed venous blood.	Represent “true” mixed venous blood as the blood is drawn distal to the right ventricle, after the mixing of SVC and IVC blood.	S _{vo₂} must be interpreted relative to hemoglobin and CO; P _{vco₂} is a more accurate indicator of flow than S _{vo₂} .

CO, cardiac output; CVP, central venous pressure; ICU, intensive care unit; IVC, inferior vena cava; LV, left ventricular; LVEDP, left ventricular end-diastolic pressure; PA, pulmonary artery; PAC, pulmonary artery catheter; PAD, pulmonary artery diastolic; PAOP, pulmonary artery occlusion pressure; PAP, pulmonary artery pressure; P_{vco₂}, mixed venous carbon dioxide; RA, right atrial; RAP, right atrial pressure; RV, right ventricular; RVEDP, right ventricular end-diastolic pressure; SCD, sequential compression device; S_{vo₂}, hemoglobin saturation of mixed venous blood; SVC, superior vena cava; TR, tricuspid regurgitation.

pulmonary artery via the balloon at the PAC tip, creating a no-flow situation in the vessel, thus the pressure at the PAC tip, the PAOP, would be equal to the pulmonary capillary pressure, pulmonary venous pressure, left atrial pressure, and the LVEDP. In both published research and at the bedside, the PAOP often became equated with LV preload. However, subsequent radionuclide and echocardiography studies have shown that the PAOP does not correlate with LV preload or intravascular volume.^{7,8} Pressures do not correlate with volume due to alterations in cardiac compliance induced by positive pressure ventilation, positive end-expiratory pressure (PEEP), intra-abdominal pressure, pulmonary vascular disease, cardiac hypertrophy, ischemia, inopressors, and that the heart functions as a suction pump, that is, diastole is active and can create negative pressures within the chambers.⁹ In fact the PAOP may not even reflect the LVEDP due to pathophysiologic factors (eg, mitral valve disease, pulmonary parenchymal and vascular disease) or that PAOP is a very difficult parameter to measure accurately.^{8,10} It has also been demonstrated that in stable patients on mechanical ventilation, the PAOP can vary as much as 7 mm Hg in 40% of patients.¹¹

The acronym “PCWP” perhaps best describes its role in hemodynamic monitoring: **P**arameter that **C**ommonly gives **W**rong information about the **P**atient. The most reliable pressure measurements provided by the PAC are the PA artery systolic and PA diastolic pressures.

Cardiac Output

PAC CO measurement utilizes the indicator-dilution principle using a thermal load as the indicator, called right heart thermodilution. The thermistor located near the tip of the PAC continuously monitors core body temperature in the PA. There is also an external temperature probe measuring the injectate temperature. To obtain a CO measurement, a thermal load (commonly 10 mL of room temperature fluid [saline or D₅W]) is injected rapidly via the proximal (CVP) infusion port and cools the blood as it travels through the right heart, into the PA and as this cooled blood (indicator) passes the thermistor, the temperature change over time is recorded. The monitor displays the curve of temperature over time and the area under the curve is inversely proportional

to the rate of blood flow in the pulmonary artery. These data are converted by the monitor into the CO in liters per minute using the Stewart-Hamilton equation:

$$CO = V_i(T_B - T_i)K_1K_2/\int \Delta T_B(t)dt$$

Where, V_i is the injectate volume, T_B is the blood temperature, T_i is the injectate temperature, K_1 is the injectate density factor, K_2 is a computation constant accounting for the catheter dead space and the heat exchange during transit, and $\int \Delta T_B(t)dt$ is the area under the time-temperature curve.

A single CO measurement is approximately within 30% of the actual CO. When the average of the 3 closest CO measurements are made, accuracy is within 10% to 20% of the actual CO.¹² Average at least 3 similar measurements, for example, within 10% to 15% of the median value discarding those outside this range.¹³

Right heart thermodilution CO is considered the practical gold standard for CO measurement, but there are conditions that can affect the accuracy of thermodilution CO. These include the following:

1. Tricuspid regurgitation (TR). Either falsely low (commonly) or falsely high CO as the regurgitant flow causes changes in the temperature curve due to recirculation or loss of indicator. Echocardiography can assess for TR. If there is significant TR another CO method must be used to determine the CO.
2. Rapid infusion of intravenous (IV) fluids via the introducer port and proximal infusion or VIP port can reduce the thermistor temperature leading to a smaller temperature change and a falsely low CO.
3. Intermittent SCD. Not in use at the time the PAC was introduced, but very common today, SCD—used to reduce the incidence of deep venous thrombosis (DVT)—increase the flow of relatively colder blood from the lower extremities when they inflate. If thermodilution CO is performed during inflation of the SCD, the thermistor (reading a lower temperature) will sense a smaller temperature change leading to a falsely low CO determination.¹⁴

4. Injectate volume. If less than the expected (eg, 10 mL) injectate volume is injected, a falsely high CO will occur due to a more rapid than expected temperature change.
5. Respiratory variation can change the temperature of PA blood and alter the CO.
6. Intracardiac left-to-right shunts, for example, ventricular septal defect (VSD).
7. The wrong CO computation constant setting in the monitor. The injectate temperature range and the PAC model determine the computation constant.

Thus holding rapid fluid infusion via the introducer, proximal infusion port, and VIP port of the PAC for at least 30 seconds, turning off the inflation of SCD, and timing the start of injection to the same point of the respiratory cycle, for example, end expiration, improves the accuracy of thermodilution CO. Room temperature injectate is used since ice-cooled injectate does not increase the accuracy¹³ and is more burdensome. However, in the setting of hypothermia (low T_b ie, 29°C-30°C) ice-cooled injectate should be used to improve the accuracy by increasing the temperature difference between blood and injectate.

Hemodynamic Waveforms

Hemodynamic waveforms from the PAC consist of “a,” “c,” and “v” waves in the right atrial pressure (RAP) tracing and “a” and “v” waves in the PAOP tracing (Figure 107–5). The “a” wave due to atrial contraction occurs after the P wave of the electrocardiogram (ECG). The “c” wave in the RAP waveform is caused by tricuspid valve closure, the “c”

wave caused by mitral valve closure is too small to be reflected across the pulmonary vascular bed, and hence the “c” wave is absent from the PAOP waveform. The “v” wave is caused by filling of the atria against a closed atrioventricular valve during ventricular contraction occurs after the ECG T wave. The downslope after an “a” wave is called the “x” descent and similarly for the “v” wave is called the “y” descent (not labeled in Figure 107–5).

Large (cannon) “a” waves may be seen with atrioventricular dissociation. Large “v” waves may be seen with TR or mitral valve regurgitation (MR), decreased ventricular compliance or (in the RAP waveform) with a VSD. Enlarged “v” waves may be absent in TR or MR if the right or left atrium is enlarged. An echocardiogram is more specific and sensitive for the detection of TR and MR. In cardiac tamponade early diastolic compression can lead to a prominent “x” descent. In constrictive pericarditis, late diastolic limitation of ventricular expansion can lead to a prominent “y” descent. However in practice, echocardiography is more sensitive and specific for diagnosis if these conditions are suspected.

In reports about hemodynamic waveforms in patients with these and other cardiac disorders, the waveforms are usually obtained in the cardiac catheterization laboratory or coronary care unit setting using equipment that is more sensitive than that used in the general noncoronary intensive care unit (ICU) setting. It is notable that using standard PACs and recording systems in the general ICU setting, no hemodynamic waveform components can be identified in 52% of PAOP tracings and 20% of RAP tracings.¹⁵ Increased monitor/recorder sensitivity can enhance the detection of waveform components.

FIGURE 107–5 Right atrial pressure tracing demonstrating “a,” “c,” and “v” waves relative to cardiac events on the ECG tracing.¹⁵ (Reproduced with permission from Oropello JM, Leibowitz AB, Gefroy V, et al: Hemodynamic Waveform Detection from Pulmonary Artery Catheters in the ICU, *J Intensive Care Med* 1999;14(1):46-51.)

Mixed Venous Blood Gas

Mixed venous oxygen and carbon dioxide levels provide further information about hemodynamics. The most accurate global venous blood gas, the mixed venous blood gas (MVBG), is obtained by drawing PA blood from the distal port of the PAC. The PA is distal to the mixing of superior vena cava (SVC), inferior vena cava (IVC) blood in the RV. The SVC carries blood returning from the head and upper extremities. Due to the relatively high cerebral metabolic rate of oxygen consumption, SVC oxygen levels are normally lower than in the IVC or mixed venous blood. Depending on tip location, a central line may preferentially sample SVC or IVC blood, thus central venous blood gases may differ from true MVBGs.

The normal mixed venous P_{O_2} (P_{vO_2}) is 40 mm Hg with a mixed venous hemoglobin-oxygen saturation (S_{vO_2}) of 75%; it is a mixture of venous return from the SVC and IVC. The normal SVC hemoglobin-oxygen saturation ($S_{SVC O_2}$) is 70% and the normal IVC hemoglobin-oxygen saturation ($S_{IVC O_2}$) is 80%. The other important component of the MVBG is the mixed venous carbon dioxide level (P_{vCO_2}), which normally is within 5 mm Hg higher than the arterial carbon dioxide level obtained on a simultaneous arterial blood gas (P_{aCO_2}).

Interpretation of S_{vO_2}

Low or decreased S_{vO_2} levels can result from decreased CO, increased oxygen consumption (vo_2), or anemia. A low S_{vO_2} value (eg, 40%) does not necessarily mean that the tissues are not getting enough oxygen or that the CO is decreased or inadequate. For example, if the CO is low and the tissues extract more oxygen per unit of blood flow, the S_{vO_2} will fall, but the tissues may be extracting enough oxygen to meet the metabolic needs. Anemia or increased vo_2 (fever, hypermetabolism) can reduce S_{vO_2} despite a normal or increased cardiac output.

High or increased S_{vO_2} levels can result from anatomic systemic left-to-right shunting (arteriovenous [AV] grafts, liver disease) or inability of the cells to utilize oxygen as is commonly seen in sepsis and liver dysfunction as part of the multiple organ failure syndrome—conditions that are the most common in critically ill patients in general medical and surgical ICUs.

Normal S_{vO_2} levels may not indicate that all is well. Normal S_{vO_2} may result from the mixing of venous blood returning from both high and low S_{vO_2} regions, as S_{vO_2} is a global measure.

From the above information, it should be no surprise that S_{vO_2} does not correlate with CO in critically ill patients. Further, looking at S_{vO_2} levels as an indicator of the adequacy of oxygen delivery is similar to looking at the amount of garbage your neighbor throws out to determine if they are getting enough food.

Attempts to increase CO to raise levels of oxygen delivery to arbitrary levels via inotropes or blood transfusions have failed to positively impact patient outcome and may be harmful particularly in older patients.¹⁶⁻¹⁸

S_{vO_2} levels should be interpreted with regard to hemoglobin level, CO, vo_2 and lactate level. Lactate levels correlate more closely with the adequacy of tissue oxygen than S_{vO_2} .

Oxygen Content, Delivery, and Consumption

The mixed venous oxygen can be used to calculate oxygen consumption (vo_2), which is the difference in AV oxygen content multiplied by the CO. [Table 107-3](#), contains the formulas for oxygen content (CO_2), delivery (DO_2), and consumption (vo_2).

Fick Cardiac Output

The blood flow to an organ (eg, CO) is equal to the AV difference in the concentration of a substance across the organ multiplied by the release or uptake of that substance by the organ. Using oxygen as the substance and the lung as the organ, CO is equal to the total body oxygen uptake (consumption) as measured by indirect calorimetry divided by the AV oxygen content difference. This is an alternative method to thermodilution indicator-dilution method. The accuracy of Fick-derived CO is limited by considerable inaccuracies in total body oxygen consumption measurement and shunting.

Intracardiac Left-to-Right Shunts

The oxygen levels in the right atrium (RA), RV, and PA are normally similar, for example, S_{vO_2} approximately 75%. An intracardiac left-to-right shunt, for example, VSD, results in step-up in venous oxygen moving from RA to RV to PA from oxygenated LV blood directly ejected into the RV and pulmonary circulation. This can be assessed by sampling blood

TABLE 107–3 PAC: derived data.

Parameter	Derived From PAC Value	Formula	Limitations
Stroke volume (SV)	CO	CO/HR	
Cardiac index (CI)	CO	CO/BSA	CO is more useful in individual patients. CI is used in research, eg, comparing group data; for individual patients the relationship between CO and BSA is nonlinear; BSA is estimated from height and body weight—this adds additional error to any CO error.
Systemic vascular resistance (SVR) 1100-1500 dynes/s/cm ⁻⁵ (normal)	CO, CVP	MAP - CVP × 80/CO (L/min)	SVR is not afterload—CVP used in the SVR calculation is not a determinant of LV afterload; a high SVR does not differentiate between intravascular volume depletion, primary LV dysfunction, or low LV due to a high SVR; it is better to note the CO and the arterial BP for analysis and decision making.
Pulmonary vascular resistance (PVR) 120-450 dynes/s/cm ⁻⁵ (normal)	PAP, PAOP, CO	MPAP - PAOP × 80/CO (L/min)	Utilizes the least accurate parameter (PAOP) derived from the PAC; it is better to note the CO and the PAP for analysis and decision making.
Left ventricular stroke work (LVSW) 60-80 g (normal)	CO, PAOP	SV × (MAP - PAOP) × 0.0136	Utilizes the least accurate parameter (PAOP) derived from the PAC; does not answer the question: is it good to do more work or less work? That depends on the clinical picture.
Arterial oxygen content (Ca _{o2}) 19-20 mL/dL (normal)	Not derived from PAC	Hb (g/dL) × 1.34 × SaO ₂ + Pa _{o2} × 0.0031	
Mixed venous oxygen content (C _{vo2}) 15 mL/dL (normal)	Distal port blood gas	Hb (g/dL) × 1.34 × S _{vo2} + P _{vo2} × 0.0031	
Oxygen delivery (D _{o2}) 900-1100 mL/min (normal)	CO	Arterial O ₂ content × CO (L/min) × 10	No clear target parameters affect outcome; some studies demonstrate worse outcomes with intentional increases in oxygen delivery.
Oxygen consumption (v _{o2}) 200-250 mL/min (normal)	S _{vo2} and CO	Arterial mixed venous O ₂ content × CO × 10 (Normal arterial–mixed venous O ₂ content difference = 3.5–5.5)	Consumption normally equals demand, but in critical illness, demand may be higher than consumption, this is usually reflected by increased lactate levels.

BSA, body surface area (m²); CO, cardiac output; CVP, central venous pressure; Hb, hemoglobin; HR, heart rate; LV, left ventricle; MAP, mean arterial pressure; MPAP, mean pulmonary artery pressure; PAOP, pulmonary artery occlusion pressure; PAP, pulmonary artery pressure; Pa_{o2}, arterial oxygen; P_{vo2}, venous oxygen; SaO₂, arterial oxygen saturation; S_{vo2}, hemoglobin saturation of mixed venous blood.

gases from the distal port of the PAC as it passes each level.

Interpretation of Pvco₂

Although S_{vo2} has garnered the most attention to date, Pvco₂ levels correlate more closely with blood flow and CO. A consistent finding is the dissociation between

venous and arterial Pco₂ (increased P[v-a]co₂ gradient) during reductions in blood flow, that is, decreased CO.¹⁹⁻²¹ The normal P[v-a]co₂ gradient is less than or equal to 5. The P[v-a]co₂ gradient is considered to be increased if it is greater than or equal to 7. Increases in the P[v-a]co₂ gradient are inversely proportional to the CO. However, an increased P[v-a]co₂ gradient

may also be due to an increased metabolic rate. Hypermetabolic rates are usually associated with a fever. An extreme example is malignant hyperthermia which is associated with very high fever and both a hyperdynamic and hypermetabolic state with increased CO and an increased $P[v-a]co_2$ gradient.

Derived Parameters

Parameters that are derived from PAC data are outlined in Table 107–3. It is important to understand that systemic vascular resistance (SVR) is not equivalent to LV afterload and the pulmonary vascular resistance (PVR) contains an unreliable parameter in its calculation—the PAOP. A more direct approach is to analyze the arterial blood pressures and the pulmonary artery pressure (PAP) in relation to the CO. See Table 107–3 for additional explanation.

INDICATIONS FOR PAC INSERTION

The decision to insert a PAC should be based on individual clinical assessment where frequent hemodynamic assessments using information obtained from the PAC may allow more effective hemodynamic management. Inability to transport a patient for further diagnostic testing (eg, computed tomography [CT] angiogram) or inadequate echocardiographic windows may influence these decisions as well. The clinical scenarios include the following:

1. Shock (nonhemorrhagic) or hemodynamic instability unresponsive to treatment and when cardiac output determination and trending is deemed valuable.
2. Pulmonary hypertension (PHTN) assessment, trending and treatment in diseases resulting in PHTN (eg, suspected or proven pulmonary embolism, primary or secondary forms of PHTN, severe ARDS).
3. Respiratory failure including severe hypoxemia of undetermined etiology.

PAC INSERTION

The PAC is not utilized as often as in the past. It is especially important to have a physician skilled in PAC insertion be present at the bedside during

the insertion when less experienced physicians are involved. The same is true for the nurses in having an experienced nurse skilled in PAC setup and monitoring be available and present.

1. **Introducer insertion.** The first step is obtaining venous access with a large-bore (8.5 Fr) introducer catheter (Figure 107–6). The right internal jugular or left subclavian veins are preferred as these are the least likely to result in kinking of the PAC compared to the left internal jugular or right subclavian vein sites. The femoral vein can be used if the neck veins are not accessible, but it can be more difficult to direct the PAC into proper position. As with any central venous access, the access site is prepared in sterile fashion with drapes covering the entire patient; venous cannulation, guidewire placement, and confirmation should be done under ultrasound guidance.

FIGURE 107–6 An 8.5-Fr introducer catheter in the process of insertion into the right jugular vein. The dilator (blue) and guidewire will be removed as the introducer is fully inserted.

2. Transducer preparation. The transducers are connected to the monitor via electrical cables and connected to tubing that will be attached to the proximal and distal PAC ports during insertion. Transducers are also connected to a saline flush apparatus.
3. PAC preparation. Before insertion of the PAC place the catheter sheath over the PAC and inflate the balloon with 1.5 mL of air via the modified blood gas syringe. Check for symmetric expansion of the balloon and for leaks (Figure 107–7).
 - a. Place stopcocks on PAC the distal and proximal ports and then isolate them by using a clamp to pinch the sterile sheets around the proximal catheter while retaining the balloon inflation syringe within the sterile field and hand off the ports to the assistant who connects the transducer tubing to the ports (Figure 107–8). A saline-filled syringe may be connected to the VIP port and that is also flushed. The VIP port is connected to IV fluid after PAC insertion.
 - b. The ports are then flushed. The flush should be cleared of any air bubbles. During flushing,

the flow out from the distal port should be brisk; if it only trickles, the pressure bag compressing the saline flush is not inflated properly and needs more inflation. The display is checked for waveforms created by shaking the PAC, noting that both the CVP and PAP waveform displays are moving. Place a sterile-gloved finger to occlude the distal port and the distal port waveform should rise on the monitor (Figure 107–9). If the waveforms are not seen, make sure the monitor is set up properly, check the transducer connections, and electrical cables that may need to be reconnected or changed. If the CVP waveform increases when the distal port is occluded, the transducer tubing or the electrical cables are reversed and need to be switched. If the waveforms are small check the scale—if it is set to arterial pressure ranges, for example, 0 to 120 or 0 to 160, the PAC waveforms will appear very small. The scale should be set to 0 to 30 or, if elevated PA pressures are expected or encountered, 0 to 60.

- c. Finally the bed should be leveled with the transducer at the midaxial level and the

FIGURE 107–7 Prior to insertion via the introducer, the PAC has been passed through the sheath and the balloon has been inflated, testing for air leaks or balloon asymmetry.

FIGURE 107–8 PAC ports have been handed off to the assistant while retaining the balloon inflation syringe within the sterile field.

transducer zeroed to atmosphere. Then with the PAC connected to the transducer, the distal port is positioned at the midaxillary line and the pressure reading on the monitor should be zero. If not, the level of the bed/transducer should be readjusted.

FIGURE 107–9 The PA pressure waveform is increasing when the tip of the PAC (distal PA lumen) is occluded with a gloved finger indicating that the port is properly connected.

4. PAC insertion. The ECG is closely observed for arrhythmias during PAC insertion (see 4a later). The PAC is initially inserted until the 15- to 20-cm mark is at the entry of the introducer; this places the balloon tip outside of the introducer, near the SVC or RA level with the nonpulsatile small-amplitude oscillations CVP or RAP waveform displayed on the distal port waveform ([Figure 107–10](#)). The normal CVP or RAP is 0 to 8 mm Hg. The balloon is then inflated with 1.5 mL of air and advanced quickly passing the tricuspid valve until the pulsatile RV pressure waveform is obtained, usually at 25 to 30 cm of PAC insertion. The normal systolic/diastolic RV pressure is 15 to 30 or 0 to 8 mm Hg. If the RV pressure waveform is not obtained after insertion to more than 40 cm, the balloon is deflated and the PAC is withdrawn and reinserted as earlier until the RV waveform is obtained. Once the RV pressure waveform is obtained, continue advancing the PAC until a step-up in the diastolic pressure is visible on the waveform, confirming passage across the pulmonic valve and placement into the proximal PA (see [Figure 107–10](#)). This usually occurs at

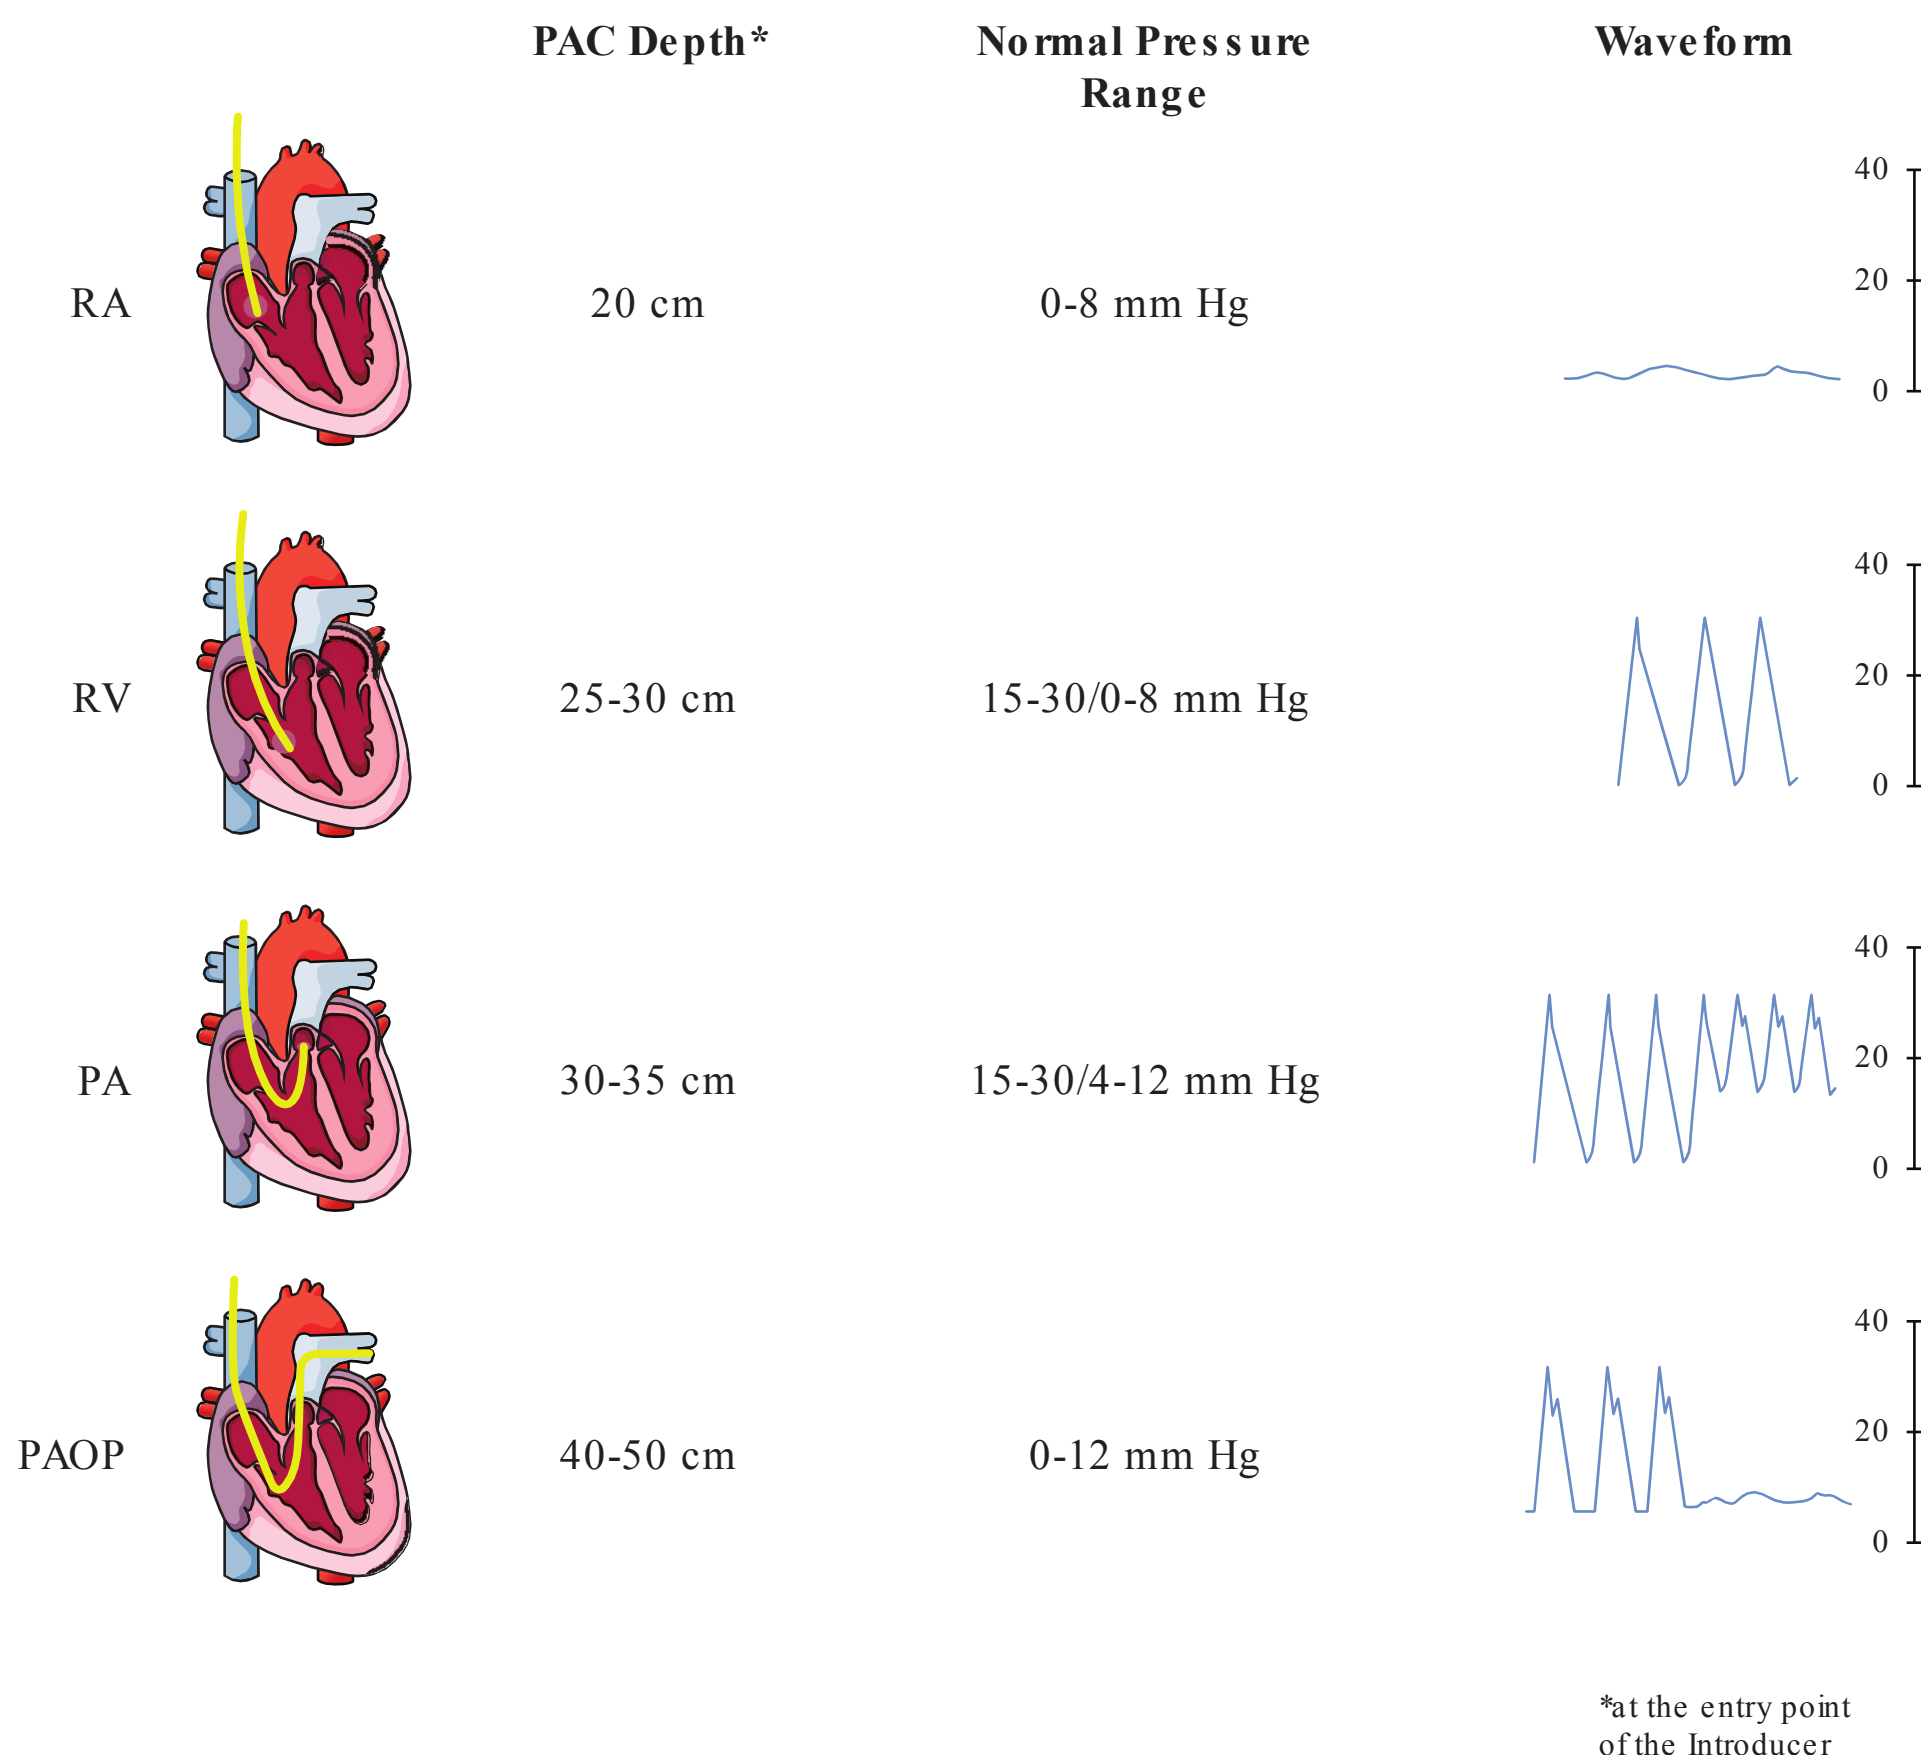

FIGURE 107–10 PAC insertion indicating average insertion length, normal pressures, and hemodynamic waveforms as the PAC is advanced into the PA. (Adapted from Servier Medical Art, Creative Commons Attribution 3.0 Unported License.)

35 to 40 cm of insertion, but can be longer, for example, 40 to 60 cm in tall patients and/or with cardiomegaly. A diastolic notch due to closure of the pulmonic valve may be visible. The normal PA systolic/diastolic pressure is 15 to 30/4 to 12 mm Hg. With further advancement of the PAC into the PA, the pulsatile waveform eventually disappears leaving a nonpulsatile waveform similar to the RAP. This is the PAOP, at the same pressure level as the pulmonary artery diastolic pressure (usually < 12 mm Hg). When the wedge pressure first becomes evident, the balloon at the tip of the catheter should be deflated (see point 5 later).

- a. Both atrial and ventricular arrhythmias can occur during passage of the PAC tip through the RA and RV to the PA.

Ventricular are more common. Although inflation of the balloon at the tip of the PAC protects the endocardium from tip irritation, arrhythmias can still occur. These arrhythmias usually resolve as the PAC tip passes into the PA. However, if arrhythmias do not immediately resolve with passage into the PA or if there is difficulty in passing the catheter into the PA, the PAC balloon should be deflated and the PAC immediately removed. Occasionally arrhythmias may persist even after the PAC is removed. After treatment of the arrhythmia, if PAC insertion was felt to be the cause, PAC reinsertion should not be done.

5. PAC placement. Once a PA tracing or PAOP is obtained, deflate the balloon and observe

the waveform. If the tracing is in the PA (PA waveform), then after balloon deflation, the PA waveform should remain. If a RV waveform results, the balloon should be reinflated; if the PA tracing is obtained then the PAC should be advanced 1 to 2 cm and the balloon deflated; repeat until a PA tracing remains after balloon deflation. If a PAOP waveform is obtained, deflate the balloon and observe for a PA tracing. If the PAC remains wedged, withdraw the PAC about 1 to 2 cm until a PA tracing is obtained.

6. PAC fine adjustment. To ensure that the PAC tip is not further out in the PA than necessary, observe the distal PAC waveform—it should be a PA waveform and not wedged (ie, without a PAOP waveform). If it is wedged, see 5 earlier. If a PA waveform is present, then inflate the balloon to 1 mL (it takes 1 mL to open the balloon, 1.5 mL to fully inflate)—if a PAOP waveform is seen, then deflate the balloon and withdraw about 1 to 2 cm and repeat until the balloon can be filled with the full 1.5 mL of air either without wedging (PA waveform remains)

or a PAOP waveform occurs—with the full 1.5 mL. This will ensure that the tip of the PAC is not too distal. Note that it is safer if the balloon takes the full 1.5 mL remaining in the PA without wedging. Recall that the PAOP is the least reliable number obtained from the PAC, so better to err on the side of a more proximal PAC tip location, as long as it is not in the RV.

7. PAC postinsertion. Once the PAC is in proper position with the balloon deflated and displaying a PA waveform via the distal port, the insertion depth at the entry point into the introducer should be noted (eg, 45 cm) and then documented in the procedure note. A chest x-ray (CXR) is obtained to view the course of the PAC and the tip position. Nearly 80% of the time the tip is in the right PA (Figure 107–11), about 20% of the time it is in the left PA. If the tip of the PA catheter is nearer the periphery of the lung, for example, beyond the midclavicular line, the PAC is likely overinserted and needs to be checked (see point 8). In smaller patients, the PAC may wedge at 40 to 42 cm and the PAC may

FIGURE 107–11 CXR after insertion of a PAC via the right internal jugular vein. The tip of the PAC is in the right PA.

need to be pulled back into the PA to less than or equal to 40 cm. If this occurs it should be appreciated that the CVP port will lie within the introducer, that is, if the CVP port is at 29 cm and the introducer length is 13 cm and the PAC is inserted to 40 cm (or less), both the VIP and CVP ports will lie within the introducer sheath. This may affect the accuracy of CO measurements.

8. Post-PAC insertion monitoring. The PA waveform should be repeatedly assessed by nursing and physician staff, to display a PA waveform and not the wedging (PAOP) or the RV. If a PAOP or an RV waveform is observed, check the insertion depth for migration and adjust the catheter as described in points 5 and 6 earlier. When a PAC is in place, if any atrial or ventricular arrhythmias occur, PAC tip migration should be ruled out as a possible cause by ensuring that the waveforms indicate proper position in the PA (see later).

PAC: SAFETY POINTS

The following are additional points essential to maximize safety when using the PAC.

1. The main principle of balloon deployment is that when **inserting (advancing)** the PAC, the **balloon** should always be **inflated**; when **pulling out (withdrawing)** the PAC, the **balloon** should always be **deflated**. (Except for when you are first inserting the PAC 15 to 20 cm through the introducer—obviously with the balloon deflated.)
2. Usually ventricular (but occasionally atrial) arrhythmias may result from PAC migration or occasionally only from the PAC itself passing through the right heart chambers. If arrhythmias are clearly due to migration and are readily terminated with proper PAC adjustment, then the PAC can remain; however, if they are felt to be due to the PAC, the PAC should be removed.
3. Right bundle branch block (RBBB) may rarely occur with insertion of the PAC. In the setting of left bundle branch block (LBBB) there is

the potential for complete heart block if RBBB occurs during PAC insertion. Therefore, in the presence of a LBBB it is prudent to have a transcutaneous pacemaker immediately accessible when inserting a PAC.

4. Care should be taken to note how much of the PAC has been inserted during PAC placement; no more than 40 cm of PAC should be inserted in attempting to advance the PAC into the RV; the PAC may be coiling in the RA and upon withdrawal, the PAC can wrap around the introducer and become knotted.
5. Multiple attempts at passing the PAC due to difficulty getting into the PA from the RV could result in cardiac perforation and tamponade. It is better to discontinue PAC insertion if things are difficult. Remember, the PAC is an invasive device that is diagnostic, not therapeutic.
6. PACs are heparin coated as this helps prevent thrombosis around the catheter. This bonding also has antimicrobial activity. Patients with heparin-induced thrombocytopenia (HIT) or a history of HIT, should not have a heparin-bonded PAC inserted. There are nonheparin-bonded PACs available for these patients.
7. The PAC balloon is made of latex. In patients with known severe (eg, anaphylactic reactions) latex allergies, a PAC insertion should be avoided unless a PAC with a nonlatex balloon is available via the manufacturer.

COMPLICATIONS

The PAC is an invasive monitor. A task force in 2003 reported the overall deaths due to the PAC to be between 0.02% and 1.5%.²² Complications can be divided into those resulting from the central venous access versus those resulting from the PAC itself. Complications of central venous access include bleeding, hematoma, arterial puncture, pneumothorax, arrhythmias (from guidewire insertion), air embolism, and hemothorax. Complications of PAC insertion include arrhythmias (greatest risk when the PAC tip is in the RV), RBBB, complete heart block, knotting of the catheter, valvular damage, cardiac perforation, and infection including catheter-related bloodstream infection and endocarditis.

Complications of PAC overinsertion or migration if prolonged and unrecognized, and exacerbated by balloon inflation, include pulmonary infarction and pulmonary artery rupture with hemoptysis and pseudoaneurysm formation.

Complications can be reduced by careful insertion technique, the use of ultrasound for venous access, and only using the PAC when the information is likely to be helpful and for limited time periods—as short as possible, for example, 1 to 3 days.

USING THE PAC TO GUIDE BEDSIDE HEMODYNAMIC MANAGEMENT

Information from any hemodynamic monitor must be interpreted in light of the clinical data (eg, physical examination, ventilator, laboratory, radiologic), the treatment goal and the response to treatment, both hemodynamic and clinical. Hemodynamic data derived from the PAC is not pathognomonic; it is always subject to interpretation.

In the past, Starling curves (the relationship between contractility vs heart muscle stretch) were generated using PAC data comparing stroke volume (SV) on the Y-axis to PAOP on the X-axis. The problem is that PAOP is not an accurate reflection of preload, that is, ventricular cavity dimension or stretch. Subsequent studies have revealed the lack of Starling curves using PAOP versus generating Starling curves using radionuclide or echocardiography-determined preload.^{5,23}

The major diagnostic assessments that can be made using PAC data include hyperdynamic circulation, hypodynamic circulation, and pulmonary hypertension. Trends in cardiac output, stroke volume, and PAPs can help to guide hemodynamic interventions.

When using the PAC it is important to use accurate and reliable information:

1. The transducers should be leveled at the midaxillary level and zeroed. No air bubbles should be present within the tubing.
2. The systolic and diastolic PA pressures (PAS and PAD) constitute the reliable pressure data obtained from the PAC. They are more accurate than echocardiography estimates of PA pressure.

The PA pressures are used to assess the presence and degree of PHTN and the changes in PA pressure that occur with changes in condition and treatment. The true LVEDP is less than the PAD with the gap between PAD and LVEDP increasing with PHTN.

3. If the PAC waveform goes from a clear RV tracing to suddenly damped and “wedged” appearing without seeing a PA waveform, suspect a proximal pulmonary embolism—the catheter tip may be lodging in a blood clot.
4. Do not use the CVP or PAOP; they do not reflect ventricular preload or intravascular volume better than flipping a coin.
5. Do not rely on CO measurements if there is evidence of significant TR.
6. Optimize the accuracy of CO measurement by holding rapid fluid infusions via the introducer or PAC for at least 30 seconds, turning off SCDs, and timing the start of injection to the same point of the respiratory cycle.
7. A high CO in the setting of an elevated lactate level rules out heart failure as the etiology and raises the suspicion for a local process, for example, mesenteric ischemia versus a systemic process, for example, septic shock–induced mitochondrial dysfunction. A high CO in the setting of pulmonary edema supports the diagnosis of ARDS rather than heart failure. (The PAOP should not be used to make this differentiation and has in fact been dropped from the current criteria for ARDS diagnosis.)
8. A very low CO on high-dose multiple inotropes should raise the suspicion of dynamic left ventricular outflow tract obstruction due to decreased preload and systemic anterior motion of the mitral valve into the left ventricular outflow tract. Despite an empty left ventricle, the PAOP is usually very high. An echocardiogram should be emergently done to rule this out. The treatment is fluid resuscitation, withdrawal of inotropes, and the use of pure noninotropic alpha agents (ie, phenylephrine) for hypotension.
9. When administering a fluid challenge, repeat the CO immediately after the challenge.

An increase of 15% or more in the SV (or CO if the heart rate [HR] has not increased) constitutes a response to fluid.

10. If removing fluid by diuretic or renal replacement therapy, decreases in the CO ($\geq 15\%$) may indicate the limits of fluid removal.
11. Repeat the CO and SV after starting an inotropic agent to assess the response.
12. Use both the mixed venous oxygen and carbon dioxide. Interpret the SvO_2 in terms of the hemoglobin (Hb) level and CO. An increased $P[v-a]CO_2$ gradient (> 7) may signify a low CO unless the patient is hypermetabolic. If the patient is afebrile or only has a low-grade fever, they are not hypermetabolic and the increased $P[v-a]CO_2$ gradient is a reflection of lower flow (CO).
13. Use echocardiography to supplement the PAC data that can be interpreted in the light of the direct preload and contractility information provided by echocardiography. Echocardiography can also determine if there is TR and if the CO is accurate.

MODIFIED PACs

We have discussed the standard PAC. Modified PACs include the following:

1. Continuous cardiac output PAC. Utilizes a heated coil to increase the temperature of the blood that then passes by a distally located thermistor-generating CO data without the need to inject a bolus of fluid. The CO is not actually continuous in the sense that it is updated every 2 to 3 minutes.
2. RV ejection fraction PAC. Estimates RV end-diastolic volume (preload) by measuring the decay in the thermodilution curve gated to the ECG R-R interval. It tends to overestimate the right ventricular end-diastolic volume (RVEDV). Also, accuracy diminishes with rapid or irregular heart rhythm.
3. Oximetric PAC. Modified with a fiberoptic bundle to measure continuous SvO_2 .

Despite the greater cost of modified PACs, significant clinical advantages over the standard PAC

have not been demonstrated. Finally there are also PACs modified with an RV port to allow simultaneous temporary cardiac pacing and PAC monitoring capability.

Thoracentesis

Satish Kalanjeri, MD and
Stephen M. Pastores, MD, FACP, FCCP, FCCM

KEY POINTS

- 1 Thoracentesis involves the removal of pleural fluid for diagnostic or therapeutic purposes.
- 2 The decision to perform thoracentesis should be based on clinical judgment and take into account the perceived safety and utility of the procedure for individual patients.
- 3 The use of ultrasound to localize the best site for pleural space access is strongly recommended to reduce complications particularly pneumothorax.
- 4 Caution should be exercised in patients with coagulopathy and those receiving mechanical ventilation.

INTRODUCTION

Pleural effusions occur in 8% to 60% of patients admitted to the intensive care unit (ICU).^{1,2} Although majority of these patients are in respiratory failure, pleural effusions may not be the primary cause of the respiratory compromise. This is because pleural effusions are mostly secondary to other conditions, such as pneumonia or malignancy. Often the cause of pleural effusion in ICU patients is presumptive based on the overall clinical picture. For these reasons, the decision to perform a diagnostic or therapeutic thoracentesis is often a judgment call. In a questionnaire-based study in France, only 15% of the intensivists routinely performed thoracentesis in ICU patients with pleural effusions, while 37% of the physicians felt routine thoracentesis would result in a specific diagnosis.³ Additionally, there are challenges unique to the ICU, such as mechanical ventilation, multiorgan failure, and coagulopathy. This chapter will address the causes of pleural effusions, technique of thoracentesis including sample

handling, special considerations in the ICU patient, and the complications of the procedure.

PHYSIOLOGIC EFFECTS OF THORACENTESIS IN THE ICU

In nonventilated patients, regardless of the volume drained, thoracentesis is thought to improve the functional residual capacity (FRC) and total lung capacity (TLC). However, there is no significant improvement in vital capacity (VC), arterial oxygenation, or an improvement in alveolar-arterial (A-a) gradient.⁴ In mechanically ventilated patients, the physiologic effects of thoracentesis include a decrease in pleural pressure and ventilator work, and a modest decrease in intrinsic positive end-expiratory pressure (PEEPi), but the A-a gradient, arterial oxygen tension (Pao₂), and lung compliance do not change significantly after drainage of the pleural effusion.⁵

CLINICAL IMPLICATIONS OF PLEURAL EFFUSIONS AND UTILITY OF THORACENTESIS IN THE ICU

Although pleural effusions are rarely the primary reason for respiratory failure in the ICU, because of their physiologic effects, effusions may contribute to the overall morbidity of ICU patients. In a study of 100 ICU patients by Matheson et al, patients with pleural effusions had longer lengths of ICU stay, and spent more days on mechanical ventilation compared to those without effusions.¹ The type of pleural effusion itself seems to have little difference in the clinical outcome. However, Park et al found that patients with transudative effusions needed vasopressor agents more frequently than those with exudative effusions,⁶ but there was no difference in terms of length of ICU stay or need for mechanical ventilation. To tap or not is often a question plaguing intensivists, unless faced with a large pleural effusion that automatically warrants a procedure. Fartoukh et al addressed this question in their prospective analysis of 82 thoracentesis procedures in ICU patients.⁷ As a result of thoracentesis nearly 10% of patients had an alternative diagnosis for the effusions, and 56% of patients had a change in their management. Such changes included administration of antibiotics, corticosteroids or chemotherapy, insertion of a chest tube, or referral to surgery. Seven patients developed a pneumothorax as a complication of the procedure; majority of the patients were on mechanical ventilation. A meta-analysis by Gollinger et al of pleural fluid drainage in mechanically ventilated patients indicated that thoracentesis resulted in improved oxygenation and lung mechanics, and contributed to change in management, but there was no change in the ICU length of stay or mortality.⁸

ETIOLOGY

Table 108–1 lists the common causes of pleural effusions in the ICU. Congestive heart failure (CHF) and atelectasis are the most common causes of pleural effusions, representing 35% and 22% of all effusions, respectively.¹ Other studies showed parapneumonic effusions (41%-50%) were more

TABLE 108–1 Common causes of pleural effusions in the ICU.

Pulmonary embolism
Hepatic hydrothorax
Hypoalbuminemia
Pancreatitis
Hemothorax
Uremia

common than CHF (17%-20%) as cause for the effusions.^{6,7} One of the reasons for this disparity is because the cause for effusions is often determined by pleural fluid analysis, and not all patients in the ICU undergo diagnostic studies for effusions. Thus, it is not surprising that these mostly single-center studies demonstrate varying incident rates for the etiologies of pleural effusions. However, there is agreement that the most common cause of a unilateral effusion is infection while CHF is the most frequent cause of bilateral effusions. Light criteria remain the gold standard in classifying effusions as transudates or exudates.⁹

EQUIPMENT AND TECHNIQUE

The first step in a successful and safe thoracentesis procedure is adequate preparation. This begins with confirming the indications for the procedure, review of relevant imaging, and ruling out contraindications. There are no absolute contraindications to the procedure. The relative contraindications are coagulopathy, use of antiplatelet agents and anticoagulants, chest wall cellulitis, and metastasis.

Although several algorithms are available to aid decision making for performing thoracentesis, we do not recommend a rigid approach to ICU patients.

FIGURE 108–1 Thoracentesis tray and drainage bag/bottle (Not to scale).

The decision to perform thoracentesis should be based on clinical judgment, and should take into account the perceived safety and utility of the procedure for individual patients. Informed written consent needs to be obtained from the patient or the health care proxy. Assembling the equipment and paraphernalia is the next step. There are several commercially available kits for thoracentesis that contain the essential equipment. One such kit is shown in [Figure 108–1](#). [Table 108–2](#) lists all the necessary equipment including those contained in readymade kits. It does not matter what type of kit is used for the procedure, since the basic principle of thoracentesis is to access the pleural space with a sharp metallic needle, and once in the pleural space, a flexible nonmetallic catheter is passed into the space either through the access needle or over it.

PROCEDURE

Patient positioning in the ICU can be a challenge. The ideal position for thoracentesis is for the patient to sit up at the edge of the bed leaning forward to rest arms and face on a table such that the back is

TABLE 108–2 Equipment for the procedure.

Portable ultrasound machine
Chlorhexidine 2%/povidone Iodine 1% solution or swabstick
Sterile gloves
Thoracentesis needle/catheter with a 3-way stopcock
16-gauge aspirating needle, 25- and 22-gauge injection needle
10-cc Luer lock syringe
60-cc Luer lock syringe
Scalpel
Collection bag w/ drain tube or evacuated containers
Specimen vials × 3
Sterile towel/drape with fenestration
Lidocaine 1% 5-mL ampule × 2
4 × 4 gauze sponge applicators
Adhesive dressing

accessible for the procedure (Figure 108–2). However, this may not be possible in many patients in the ICU due to mechanical ventilation or other reasons. Access from the infra-axillary area is another approach, with the patient in a semireclined position with the arm to the side (Figure 108–3). We strongly recommend the use of ultrasound to localize the best site for pleural space access. There is clear evidence about favorable safety outcomes and the utility of ultrasound-guided thoracentesis. Mayo et al observed a pneumothorax rate of only 1.3% in their prospective observational study of 211 mechanically ventilated patients (mean PEEP 6.8 cm of water and mean Pao_2/Fio_2 178) who underwent both diagnostic and therapeutic thoracentesis.¹⁰ After appropriate patient positioning, the phased array ultrasound

probe is placed on the chest wall to identify pleural effusion. The criteria for accurate diagnosis of pleural effusion on an ultrasound image are 3-fold—an anechoic/hypoechoic region that represents pleural effusion; identification of anatomic boundaries of this anechoic region: chest wall, diaphragm, and lung tissue that appears like a “fish tail”; and dynamic respiratory movement of the lung surface, diaphragm, or the fluid itself¹¹ (Figure 108–4). These ultrasound characteristics are meant to minimize the chances of injury to the lung and to prevent subdiaphragmatic insertion of the needle. Presence of debris and floaters (so-called plankton sign) within the anechoic/hypoechoic region are clues to exudative nature of the effusion. In ICUs where portable ultrasonography is unavailable, the classical method

FIGURE 108–2 Patient and needle position—posterior approach. (Memorial Sloan Kettering Cancer Center ©2014.)

FIGURE 108–3 Patient and needle position—lateral approach. (Memorial Sloan Kettering Cancer Center ©2014.)

of choosing a site that has maximum dullness to percussion (usually third-fifth intercostal space in the midaxillary line: “the triangle of safety,” or fifth-seventh intercostal space in the posterior scapular line) should be performed. It must be emphasized that this method is fraught with fallacies because a visual identification of effusion is not possible, and chest x-ray (CXR) and percussion findings may not necessarily represent effusion. The point of entry is identified and marked. The point of entry is always “above the rib,” that is, along the upper border of a rib in order to avoid neurovascular injury. The neurovascular bundle runs along the lower border of a rib.

The skin is cleaned with 2% chlorhexidine or 1% povidone iodine. If iodine solution is used, it must be allowed to dry on the skin in order to be most effective.¹² A sterile drape with fenestration is then placed over the skin. A 25-gauge needle is used to anesthetize the skin with 1% lidocaine at the intended point of entry. After the skin is anesthetized adequately, the deeper tissues including the pleura are instilled with the local anesthetic using a 22-gauge needle. Negative suction should be performed at all times while entering deeper tissues in order to notice accidental blood vessel injury. Aspiration of free-flowing pleural fluid is indicative of the needle reaching the pleural space—a quick mental note is

made of the direction and depth of the finder needle. The finder needle is withdrawn after adequate analgesia of the deeper tissues including the pleura. If the “catheter over the needle” device is used, a small skin puncture is made with a scalpel. The puncture should be deep enough to traverse the entire thickness of the skin. This step is not necessary with the “catheter within the needle” device. The thoracentesis needle is now prepared for entry into the pleural space—the 60-mL syringe is attached to the distal end of the thoracentesis needle, and care must be taken to align the 3-way stopcock such that pleural fluid flows into the syringe (see Figures 108–2 and 108–3). The thoracentesis needle is then slowly inserted through the skin puncture site, while maintaining negative suction pressure through the syringe. After pleural fluid is aspirated, the needle is further inserted by 2 to 3 mm to ensure the entire bevel of the needle is within the pleural space. The catheter is then slid into the pleural space while maintaining the needle still and in position. Once the catheter is in the pleural space, the needle is withdrawn. Serial pleural manometry may be performed to measure the pleural pressure or pleural elastance (change in pleural pressure/volume removed). Unless this is of diagnostic value or a large-volume thoracentesis is planned, there is no routine indication to perform pleural manometry

FIGURE 108–4 Ultrasound identification of pleural effusion.

in ICU patients. Patients on mechanical ventilation are at low risk of reexpansion pulmonary edema, and pleural fluid manometry tests may not be useful on mechanical ventilation. A collection tube connected to either a collection bag or vacutainer bottle is attached to the side port of the 3-way stopcock and the pleural fluid drained. Fluid is drained until one of the following end points is reached:

1. Fluid stops draining despite slightly pulling back the catheter.
2. The patient starts coughing or complains of chest discomfort (nonventilated patients).
3. Pleural fluid manometry indicates a pleural pressure of -20 cm H_2O has been reached, as the risk of reexpansion pulmonary edema is higher with further drop in pleural pressure.¹³
4. About 1- to 1.5-L fluid is drained (although potentially more fluid can be drained if pleural manometry is used).

The catheter is then withdrawn while asking the patient to hum or in the expiratory phase if the patient is on a ventilator. Pressure with gauze is maintained on the skin for a few minutes until there is no pleural fluid or blood seepage from the puncture site.

An adhesive dressing or Band-Aid is placed over the puncture site. We recommend performing a postprocedure CXR to rule out pneumothorax. Although this is not considered a mandatory practice for non-ICU patients, the procedure is riskier in this population and therefore every effort must be made to preempt any complications and take action early. It is a good practice to perform a localized ultrasound immediately after the procedure to look for lung sliding, the absence of which suggests a pneumothorax. However, localized ultrasound for detection of pneumothorax has limitations. Besides pneumothorax may develop hours after the procedure.

Sample Handling

It depends on the local laboratory preferences and guidelines. Ideally at least 50 to 60 mL of pleural fluid should be aspirated for diagnosis. Approximately 30 mL is sent for cytology in a methanol-based solution (CytoLyt bottle) or a plain or heparinized container. If immunocytochemistry is needed, the sample should also be collected in formalin for cellblock. If the sample needs to be sent for flow cytometry, 2 lavender-top bottles (ethylenediaminetetraacetic acid [EDTA]) are used for sample collection. Furthermore, there should be no delay in transporting flow cytometry samples to the laboratory in order to prevent cell degradation. Routine biochemical testing (lactate dehydrogenase, cholesterol, glucose, total protein), cell type, and cell count need about 5 mL each and samples are sent in sterile plain or heparinized containers. Microbiological testing requires about 10 mL of the sample. About 2-mL fluid is collected in a heparinized syringe for pH testing. Based on the clinical scenario, tests such as triglyceride and chylomicron levels, amylase, and lipase levels may be sent.

COMPLICATIONS

ICU patients are especially vulnerable to complications because of the critical nature of their illness. Mechanical ventilation and coagulopathy are particularly challenging considerations. Lastly, patient positioning in the ICU can be suboptimal leading to unsuccessful attempts at thoracentesis or complications.

Table 108–3 lists the potential complications of thoracentesis in the ICU. Pneumothorax is the most

TABLE 108–3 Complications of ICU thoracentesis.

Pneumothorax
Bleeding/hemothorax
Hematoma at injection site
Visceral (usually liver or spleen) injury
Soft tissue infection
Pleural infection
Vasovagal episode
Reexpansion pulmonary edema

common complication. Positive pressure ventilation, whether mechanical or noninvasive, renders the patient more susceptible to pneumothorax. The incidence of pneumothorax after thoracentesis while on mechanical ventilation prior to routine ultrasound guidance was 9% to 13%.¹⁴ The use of ultrasound has resulted in a significant reduction in pneumothorax incidence ranging from 1% to 6%.¹⁰ Coagulopathy and bleeding risk from anticoagulant/antiplatelet use have been traditionally considered relative contraindications in the ICU (Table 108–4). Patel et al demonstrated the safety of ultrasound-guided thoracentesis in patients with an international normalized ratio (INR) greater than 3 or a platelet count less than 25,000.¹⁵ Puchalski et al found that the

TABLE 108–4 Key points with thoracentesis.

Coagulopathy is a relative contraindication.
Risk of pneumothorax is higher with mechanical ventilation.
Assemble all equipment, including specimen containers, before the start of procedure.
Ultrasound-guided thoracentesis reduces complications.
Always insert the needle “above the rib” to avoid neurovascular injury.
Thoracentesis generally relieves symptoms, but length of ICU stay and mortality do not improve.
Occasionally chest tube/pigtail catheter insertion may be a safer alternative.

incidence of bleeding with thoracentesis was not any higher even in the presence of multiple bleeding risks such as elevated INR, thrombocytopenia, or use of anticoagulants.¹⁶ However, none of these studies advocating safety of thoracentesis with uncorrected bleeding risks specifically studied ICU patients.¹⁷ Blood products such as fresh frozen plasma and platelet transfusions can be administered to make the procedure safer when coagulopathy is a concern. Use of prophylactic anticoagulation is not considered a contraindication to thoracentesis. However, we recommend holding therapeutic anticoagulation before the procedure, and if this is not feasible inserting a chest tube instead.

Reexpansion pulmonary edema is not a major concern in mechanically ventilated patients as the positive pressure ventilation makes occurrence of reexpansion pulmonary edema unlikely. However, this remains a concern in nonventilated patients or those on noninvasive modes of ventilation. Use of pleural manometry or limiting the amount of fluid drained to 1.5 L reduces the chances of reexpansion pulmonary edema.¹³

CONCLUSIONS

Pleural effusions are rarely the main cause for admission of patients to the ICU. Thoracentesis is a safe procedure, particularly under ultrasound guidance, and has diagnostic utility that helps in management decisions.

Controversies: Early Tracheotomy

Bradley A. Schiff

INTRODUCTION

Tracheotomy is a common procedure with almost 1 in 4 ICU patients receiving a tracheotomy.¹ While a tracheotomy is a relatively straightforward surgical procedure, the medical complexity of patients requiring tracheotomy, and the debate about its timing and indications, make its utilization complex. Despite its common and widespread use there remains considerable debate in the literature regarding tracheotomies risks, benefits, and indications.

INDICATIONS AND BENEFITS

The indications for tracheotomy have evolved throughout the history of the procedure. With improved understanding of the disease processes affecting the airway, the indications have become more standardized and rigorous in recent years. Today there are numerous indications recognized in the adult population. These indications were defined by the American Academy of Otolaryngology and Head and Neck surgery in the 2010 Clinical Indicators Compendium,² and fall into 4 broad categories: to relieve a mechanical obstruction (or potential obstruction), to manage aspiration (and promote improved pulmonary toilet), to provide long-term ventilation (and avoid the complications of long-term translaryngeal intubation), and to promote weaning from the ventilator. The last 2 categories constitute the vast majority of patients included in studies on ET.

Tracheotomy offers a number of potential benefits over endotracheal intubation. Tracheotomy has been shown to decrease the mechanical workload of ventilator-dependent patients,^{3,4} and patients with tracheotomies can be placed on and off the ventilator without any significant risk to the patient, potentially facilitating earlier extubation. Tracheotomy improves comfort level when compared with

translaryngeal intubation. Patients with tracheotomies have improved tracheal suctioning, oral care, mobility, ability to take oral nutrition and articulate speech,^{5,6} and decreased oropharyngeal and laryngeal trauma compared to intubated patients.⁷

RISKS

Different clinicians have different opinions on the risks and timings of tracheotomy. The risk of tracheotomy has decreased over time and varies depending on the skill and experience of the person performing the procedure. In 1833 Trousseau reported a 75% mortality rate for tracheotomy patients, compared with current mortality rates of approximately 1%.⁸⁻¹⁰ Today, while tracheotomy is a relatively safe procedure, complications still occur. A recent study looking at 113,653 tracheotomies performed in the United States in 2006 showed a 3.2% complication rate and 0.6% mortality rate.¹¹ However, the experience and expertise of the physician performing the procedure can greatly impact the risk of tracheotomy. A recent study showed that surgeons performing the fewest tracheotomies demonstrated the highest complication rates, and that intraoperative complication rates varied greatly among practitioners with otolaryngologists having an intraoperative complication rate is 0.39% compared to 3.5% with tracheotomies done by nonotolaryngologists.¹²

TIMING

The optimal timing for a tracheotomy is dependent on the patient and the situation. There is significant controversy regarding the timing of surgery for those patients undergoing an elective tracheotomy after intubation, and it is the timing of tracheotomy in patients undergoing prolonged intubation that is the most debated, and is the focus of this chapter.

Physicians of the 1960s promoted the placement of ET tubes, as high pressure cuffs and rigid endotracheal tubes lead to significant complications rates.¹³ With the arrival of the more flexible endotracheal tubes with low-pressure cuffs in the 1970s, combined with the reported high complication rate of tracheotomy, delayed tracheotomy, 3 to 4 weeks after intubation, became the rule. Since the mid-1980s, with the introduction of percutaneous tracheotomy and the decreased complication rates associated with open tracheotomy, there has been a shift toward earlier tracheotomy placement.

The ideal time for tracheotomy in ventilated patients has not been established, despite many studies addressing this topic. The risks of prolonged intubation must be weighed against the benefits of tracheotomy as well as the risks of the procedure.¹⁴ Earlier recommendations suggested that tracheotomy be performed in patients requiring mechanical ventilation for more than 21 days.⁶ More recent guidelines advise that translaryngeal intubation be used only for patients requiring fewer than 10 days of artificial ventilation, and that tracheotomy be performed for those requiring artificial ventilation for more than 21 days. The decision is left to the physician for those patients falling between 10 and 21 days.¹⁵ A commonly used method of determining the need and timing of a tracheotomy is the “anticipatory approach.” This involves initially stabilizing the patient and treating the primary disease process. If extubation is felt to be possible in the first several days of mechanical ventilation then tracheotomy is not considered necessary. If after a week of translaryngeal intubation the patient is felt (1) likely to benefit from a tracheotomy and (2) likely to require extended intubation (more than 7 additional days), then a tracheotomy should be performed.^{13,16} As the clinician’s ability to predict the duration of intubation improves, even earlier tracheotomy can be considered. However, despite its widespread use, this approach has yet to be determined to improve the morbidity and mortality of patients requiring prolonged mechanical ventilation.

There are many studies examining the appropriate timing for tracheotomy that typically fall into 3 general categories: (1) nonrandomized retrospective reviews, (2) prospective studies, (3) meta-analysis (of either retrospective reviews or

prospective studies). Observational studies retrospectively comparing patients who received a tracheotomy early after intubation with those who received a tracheotomy sometime after intubation are common. However, it is very difficult to extrapolate meaningful conclusions from these observational papers as the patient populations in the 2 groups may be very different, and the difference in management in regards to the timing of tracheotomy may be reflective of differences in perceived outcomes of the patients.

A study by Arabi looked at 531 consecutive non-randomized patients.¹⁷ They found that the time to tracheotomy was associated with increased duration of ventilation, length of ICU and hospital stay, but not survival. A similar retrospective study by Tong et al, looked at 592 patients, 128 ET patients who received a tracheotomy by day 7, and 464 LT patients who received a tracheotomy after day 7, demonstrating decreased days of mechanical ventilation, length of ICU stay, and length of hospital stays in patients receiving an ET, but no improvement in survival and ventilator-associated pneumonia (VAP).¹⁸

Shan et al¹⁹ performed a meta-analysis of observational studies comparing ET (< 7 days) with LT (7 or more days) in ICU patients. They combined the data from 6 studies (Armstrong,²⁰ Arabi,¹⁷ Moller,²¹ Flaatten,²² Zalgi,²³ and Tong¹) looking at a total of 2037 subjects. They found that the mortality in the early tracheotomy group was significantly lower than the late group at 1 year (26.1% vs 29.8% $P = 0.02$). In addition the duration of mechanical ventilation was shorter in the early group than the late group (mean difference 10.04 days, $P = 0.001$), the ICU stay was shorter in the early tracheotomy group (mean difference 8.8 days, $P < 0.001$), the hospital stay was shorter in the early tracheotomy group (mean 12.18 days, $P < 0.001$), and there was no difference in the incidence of VAP between the 2 groups.

A more recent observational study, looking at tracheotomies in the American College of Surgeon’s Trauma Quality Improvement program, used a well-balanced propensity matched cohort of 1154 patients in an attempt to decrease bias and compared early (≤ 8 days) versus late (> 8 days) tracheotomy. They found that ET was associated with fewer mechanical ventilation days (10 vs 16), shorter ICU stay (13 vs 19 days), shorter hospital length of stay (20 vs

27 days), and lower incidence of pneumonia (41.7% vs 52.7%), deep venous thrombosis (DVT) (8.2% vs 14.4%), and decubitus ulcer (4.0% vs 8.9%). Hospital mortality was similar between the 2 groups.²⁴

A number of larger observational studies exist, which, like these smaller single-center studies, usually show a benefit for early tracheotomy and contributed to the interest in performing early tracheotomy. A study by Freeman et al²⁵ looked at the data from 43,916 patients of whom 2473 had tracheotomy. It showed that tracheotomy timing correlated significantly with duration of mechanical ventilation, ICU stay, and hospital stay. A similar study looked at tracheotomy in acute care hospitals in Ontario hospitals.²⁶ Between 1992 and 2004 10,927 patients received tracheotomy: 3758 received early tracheotomy (≤ 10 days) and 7169 patients received late tracheotomy. Patients receiving early tracheotomy had lower 90 day, 1 year, and study mortality. On multivariate analysis each delay of 1 day was associated with increased mortality. While these observational studies are an excellent starting point, there are a number of reasons why their findings cannot be extrapolated to prospective tracheotomy management. Most important among these is the potential selection biases in determining who received an early versus a late tracheotomy. However, at a minimum, these observational studies promoted the concept that ET might be beneficial, and encouraged larger prospective studies.

A number of prospective studies have been performed comparing early and late tracheotomy. Significant differences in definitions, methodologies, and conclusions exist between studies. A study by Koch et al²⁷ examined 100 predominately surgical patients in the university hospital in Geiben Germany, prospectively randomized to early (≤ 4 days, average 2.8 days) or late (≥ 6 days, average 8.1 days) tracheotomy. They found no change in mortality between the ET and LT groups, but did find a statistically significant decrease in VAP incidence, duration of mechanical ventilation, ICU and hospital stay in the ET group. A study by Terragni et al²⁸ in JAMA compared ET patients (day 6-8) and LT patients (day 13-15) as part of a randomized control trial across 12 Italian ICUs. Six hundred patients were randomized to early or late tracheotomy after 48 hours: 145/209 ET group patients received tracheotomy and 119/210

LT group patients received tracheotomy. They found a 14% incidence of VAP (measured at 28 days from randomization) in the ET group compared to a 21% incidence in the LT group that approached, but did not reach, statistical significance ($P = 0.07$). The number of ventilator-free days and ICU-free days were statistically significantly decreased in the ET group, but there was no change in hospital stay or mortality between the 2 groups.

Blot et al²⁹ performed a prospective and randomized study in 2008 evaluating 25 ICUs in France comparing ET (day 4) with prolonged intubation. The study was halted after 2 years because of difficulty accruing patients, and only 123 patients were enlisted in the study. There were no difference in mortality, duration of ventilation, or VAP between the ET and LT group, but there were improvements in patient comfort and late laryngeal symptoms in the ET group. This study was underpowered and fell well short of its recruitment goal partially due to what the authors thought was recruitment bias and therefore it is difficult to draw meaningful conclusions from the study. Trouillet et al³⁰ performed a prospective randomized controlled study looking at patients after heart surgery at a single French academic hospital expected to need more than 7 days of ventilation. They randomized patients to immediate ET ($< \text{day } 5$) or prolonged intubation with tracheotomy ($> \text{day } 14$). Two hundred sixteen patients were enrolled, 109 in the ET group and 107 in the LT group. There were some differences in the characteristics of the 2 groups with higher rates of heart transplantation, repeat surgery, and renal replacement in the ET group. Only 27% of LT group received tracheotomies. There was no significant difference in ventilation-free days, survival ICU or hospital stay, or rates of VAP between the groups, but more sedation-free days in the ET group with patients in the ET group having more time calm awake or lightly sedated and more days comfortable with easy care, earlier nutrition, and mobilization.

Rumbak et al³¹ performed a prospective randomized trial looking at 120 patients in a Florida hospital MICU comparing early percutaneous tracheotomy (48 hours) or delayed tracheotomy (day 14-16). They found that patients in the early group had statistically significant decreased mortality (31.7% vs 61.7%) rates of pneumonia (5% vs

25%), less time in ICU (4.8 vs 16.2 days), and days on mechanical ventilation (7.6 vs. 17.4). This paper has fewer patients than other papers; however, it also stratified patients to the widest difference between ET and LT (< 48 hours vs > 2 weeks).

The TracMan trial³² is a recent prospective study that was highly anticipated. It was an open multicentered randomized clinical trial at both university and nonuniversity hospitals in the United Kingdom that identified people within the first 4 days of admission that were likely to require 7 days of ventilator support. ETs were done by day 4 and LTs were done by day 10 or later. Of the people in the LT group over half did not get a tracheotomy (37% were extubated). There was an average of 13.6 days of mechanical ventilation in the ET group versus 15.2 days of mechanical ventilation in the LT group, this approached but did not reach statistical significance ($P = 0.06$). There was no difference in the length of ICU stay and mortality, but less sedation was used in the ET group. This study highlights the limited ability of clinicians to predict which patients would require ventilatory support as over half of the patients in the LT group did not need tracheotomy.

While most of these prospective studies are well designed it is difficult to power a prospective study that would pick up small changes between ET and LT groups. Because of this a number of meta-analysis exists attempting to increase the patient population and the power of the study. A study by Griffiths in 2005¹⁵ looked at 5 studies with 406 participants: the combined studies by Rumbak,³¹ Boudierka,³³ Dunham,³⁴ Rodriguez,³⁵ and Saf e.³⁶ They did not find any changes in morality, although the tracheotomy had a slightly lower relative risk (RR), and no change in hospital-acquired pneumonia, (although the tracheotomy had a slighter lower RR). They found that tracheotomy patients had 8.5 fewer days of mechanical ventilation and 15.3 fewer days in the ICU. A recent (2014) meta-analysis by Wang et al³⁷ looks at all randomized controlled trials regarding early versus late tracheotomy. They analyzed 7 trials (Saf e,³⁶ Boudierka,³³ Rumbak,³¹ Barquist,³⁸ Blot,²⁹ Terragni,²⁸ and Trouillet³⁰) encompass 1044 patients. They found no change in mortality (although there again was a lower RR in the ET group) and no change in VAP (although again there was an early with lower RR in the ET group). There

was no appreciable change in length of mechanical ventilation or ICU stay.

DISCUSSION

Despite the numerous studies looking at the timing of tracheotomy no definitive conclusions can be reached. There are a number of potential explanations for the lack of consensus regarding timing of tracheotomy despite numerous papers. First tracheotomy patients are a varied patient population who might require tracheotomy secondary to trauma, general medical issue, respiratory issues both acute (such as pneumonia) and chronic (such as chronic obstructive pulmonary disease [COPD]), and complications from surgery, neurologic injury, etc. It is possible that ET may benefit one type of patient while not benefiting others. Additionally, ET has many different definitions. Some studies compared people who received a tracheotomy within 48 hours versus those who did not receive a tracheotomy until 2 weeks passed, while others compared those earlier than 7 days versus those 7 days or later. It is possible that there are some cutoffs when early tracheotomy may be beneficial, but these were not measured in these studies, or if they were measured then they were underpowered. A comprehensive study would have to randomize people to every day to find ideal timing (and this could vary by disease).

Additionally the decision to perform an ET is based on the clinician's impression that prolonged intubation will be needed while also believing that the patient has a chance of recovery. The studies examining ET are therefore evaluating clinician's ability to determine which patients will need prolonged intubation but have a chance of recovery as much as whether ET is useful. Perhaps in the right patient population early tracheotomy is beneficial, but we are not yet able to accurately determine which patients fit these criteria. A number of studies exist examining clinician's ability to predict ET,^{39,40} but as of yet no applicable guidelines exist to determine which patients will need prolonged intubation.

When analyzing the data some studies suggest benefits for ET and some do not. Many studies find a benefit for some aspects of ET (such as increased comfort, or incidence of VAP) but not for others. However, care must be taken when drawing

conclusions on some characteristics such as length of mechanical ventilation, ICU stay, and hospital stay as these data may be more indicative of system issues, or of how these patients were managed and triaged, rather than actual medical differences. For example, patients with a tracheotomy may have easier access to step down units or hospice facilities thus decreasing their length of stay. While the data do not find conclusively for or against the use of ET, more of the data suggest benefits for ET and none of the data suggest harm for ET. The meta-analysis did not find a statistically significant benefit in terms of mortality and days of mechanical ventilation, but in both cases the RR of ET was less than that of LT patients.

CONCLUSIONS

Many studies have been written examining the benefits of ET, but as of yet there is no clear consensus on ET. The heterogeneity of the many studies and the patient population receiving tracheotomy makes drawing definitive conclusions difficult. While it cannot be conclusively stated that ET is beneficial there are a number of studies that suggest that it may be (and none that suggest it is harmful). At a minimum more larger and better defined studies are needed before we can say for certain when, and in which patients, ET is conclusively beneficial.

Antimicrobial Prophylaxis for Surgery

Jun Makino, MD and
John M. Oropello, MD, FACP, FCCP, FCCM

CHAPTER

110

INTRODUCTION

A surgical site infection (SSI) is an infection related to an operative procedure that occurs at or near the surgical incision within 30 days of the procedure, or within 90 days if prosthetic material is implanted at surgery.¹ SSIs are classified into incisional (superficial/deep) or organ/space infections ([Table 110–1A](#)).¹ According to the Centers for Disease Control and Prevention (CDC), prevalence survey in 183 acute care hospitals in the United States, SSIs and pneumonia were the most common health-care-associated infections.² Also the National Healthcare Safety Network (NHSN) data for 2006 to 2008 reported the overall SSI rate was 1.9% (16,147 SSIs following 849,659 operative procedures).³ The aim of antimicrobial prophylaxis is to prevent SSI by reducing the burden of microorganisms at the surgical site during the operative procedure,⁴ and ultimately to prevent related morbidity and mortality. Indications for antimicrobial prophylaxis, antibiotic selection, timing, and dosing are reviewed.

Surgical wound infections are historically classified into 4 groups based on the degree of expected microbial contamination during surgery ([Table 110–1B](#)).⁵ Antimicrobial treatment (vs prophylaxis) is required for dirty procedures or established infections. Antimicrobial prophylaxis is justified for contaminated or most clean-contaminated procedures and in certain clean procedures (eg, prosthetic implants).⁶ Also, antimicrobial prophylaxis may be justified for any procedure if the patient has an underlying

medical condition associated with a high risk of SSI ([Table 110–2](#)).⁶

ANTIMICROBIAL SELECTION, TIMING, DOSING AND DURATION

When antimicrobial prophylaxis is initiated, appropriate antimicrobials should be administered with appropriate timing, dose, and duration to minimize adverse effects, emergence of resistance, and cost.¹

Antimicrobial agents are selected according to the comparative efficacy for the procedure (eg, *Staphylococcus aureus* and coagulase-negative staphylococci in clean procedures; gram-negative rods and enterococci in abdominal procedures and transplantation of heart, kidney, and liver), the safety

TABLE 110–1A Classification of surgical site infection (SSI).¹

Type		Description
Incisional SSI	Superficial	Skin and subcutaneous tissue of the incision
	Deep	Deep tissue of the incision (eg, fascial and muscle layers)
Organ/space SSI		Infection involving any part of the body excluding incisional SSIs

Data from Centers for Disease Control. Surgical Site Infection (SSI) Event.

TABLE 110–1B Wound classif cation.⁵

Class	Def nition	SSIRate (%)	Microbiology
Clean	An uninfected operative wound in which no inf ammation is encountered and the wound is primarily closed.	1.3-2.9	Skin f ora; gram-positive cocci
Clean-contaminated	Operative wounds in which a viscus ^a is entered under controlled conditions and without unusual contamination.	2.4-7.7	Gram-negative rods; enterococci
Contaminated	Operative wounds in which the respiratory, alimentary, genital (including reproductive organs), or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered.	6.4-15.2	polymicrobial
Dirty	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera	7.1-40	polymicrobial

^aRespiratory, alimentary, genital (including reproductive organs), or urinary tracts.
Data from Culver DH, Horan TC, Gaynes RP, et al: Surgical wound infection rates by wound class, operative procedure, and patient risk index. National Nosocomial Infections Surveillance System, Am J Med 1991 Sep 16;91(3B):152S-157S.

profile, cost, and the patient’s allergic history.⁶ T ere is little evidence that broad-spectrum antimicrobi- als will lower the rate of SSI compared to narrow- spectrum ones. T erefore, cefazolin is generally chosen for its desirable duration of action, spectrum of activity against organisms commonly encoun- tered in surgery, reasonable safety, and low cost.¹ When patients have known Methicillin-resistant Staphylococcus aures (MRSA) colonization or high risk for MRSA colonization without surveillance data, vancomycin should be considered.⁷ However, because vancomycin is less effective for MSSA, cefazolin is sometimes combined with vancomy- cin to cover both MRSA and Methicillin-sensitive Staphylococcus aureus (MSSA).

TABLE 110–2 Patient-related factors associated with an increased risk for SSI.⁶

<ul style="list-style-type: none">• Age (elderly)• Malnutrition• Obesity• Diabetes mellitus• Tobacco use• Recent surgical procedure• Length of preoperative hospitalization• Colonization with microorganisms• Receiving immunosuppressants

Data from Bratzler DW1, Dellinger EP, Olsen KM, et al: Clinical practice guidelines for antimicrobial prophylaxis in surgery, Am J Health Syst Pharm 2013 Feb 1;70(3):195-283

Also, if the patient is documented or presumed to have IgE-mediated penicillin allergy, cephalo- sporins and carbapenems should be avoided, and vancomycin, clindamycin, gentamicin, tobramycin, ciprofloxacin, levofloxacin, or aztreonam should be used instead.^{6,8} Recommended antimicrobial agents and alternatives for each surgical procedure are listed in Table 110–3.⁶

In order to achieve successful antimicrobial prophylaxis, providing serum and tissue concentra- tions exceeding the minimum inhibitory concentra- tion at the time of incision and for the duration of the procedure is essential.^{9,10}

In the previous studies, patients who received prophylactic antimicrobials 60 to 120 minutes before the initial incision had lower rates of SSI than patients who received prophylaxis outside of this window (Table 110–4).^{11,12} T erefore, administration of the first dose of antimicrobials is recommended within 60 minutes before surgical incision.^{9,13,14} Van- comycin and fluoroquinolones should begin within 120 minutes before surgical incision because these drugs need more time for infusion. If the duration of the procedure exceeds 2 half-lives of the drug or there is excessive blood loss (> 1500 mL) during the procedure, intraoperative redosing is necessary and the dosing interval will be measured from the time of the initial dosing.⁶ Recommended doses and

TABLE 110–4 Timing of prophylactic antibiotic administration and subsequent rates of surgical site infections (SSIs).^{11,12}

Time of Administration	Percent with SSI	Odds Ratio (95% CI)
Early (2-24 h before incision)	3.8	4.3 (1.8-10.4)
Preoperative (0-2 h before incision)	0.6	1.0 (-)
Perioperative (within 3 h after incision)	1.4	2.1 (0.6-7.4)
Postoperative (> 3 h after incision)	3.3	5.8 (2.4-13.8)

Data from Classen DC, Evans RS, Pestotnik SL, Horn SD, Menlove RL, Burke JP. The timing of prophylactic administration of antibiotics and the risk of surgical-wound infection. *N Eng J Med* 1992;326:281-286; van Kasteren ME, Manniën J, Ott A, et al. Antibiotic prophylaxis and the risk of surgical site infections following total hip arthroplasty: timely administration is the most important factor. *Clin Infect Dis* 2007;44:921.

redosing intervals for commonly used antimicrobials are shown in [Table 110–5](#).⁶

Repeat antimicrobial dosing following wound closure is not necessary and may increase antimicrobial resistance.^{8,15-16} Also, there is no difference in the rate of SSI with single dose compared with multiple-dose regimens given for less than or more

than 24 hours (combined odds ratio 1.04, 95% confidence interval [CI] 0.86-1.25).¹⁵ Therefore, antimicrobial prophylaxis can be stopped within 24 hours after the surgery. There are no data to support the continuation of antimicrobial prophylaxis until all indwelling drains and intravascular catheters are removed.⁶

TABLE 110–5 Recommended doses and redosing intervals for commonly used antimicrobials for surgical prophylaxis.⁶

Antimicrobial	Recommended Doses		Half-Life in Adults with Normal Renal Function (h)	Recommended Redosing Interval (h)
	Adult	Pediatrics		
Ampicillin-sulbactam	3 g (ampicillin 2 g/sulbactam 1 g)	50 mg/kg of the ampicillin component	0.8-1.3	2
Ampicillin	2 g	50 mg/kg	1-1.9	2

INTRODUCTION

The International System of Units (abbreviated SI from the French phrase, *Système International d’Unités*), or SI, is the standard system of measurement.

Metric Prefixes

Pref x	Symbol	10 ⁿ
exa	E	10 ¹⁸
peta	P	10 ¹⁵
tera	T	10 ¹²
giga	G	10 ⁹
mega	M	10 ⁶
kilo	k	10 ³
hecto	h	10 ²
deca	da	10 ¹
		10 ⁰
deci	d	10 ⁻¹
centi	c	10 ⁻²
milli	m	10 ⁻³
micro	μ	10 ⁻⁶
nano	n	10 ⁻⁹
pico	p	10 ⁻¹²
femto	f	10 ⁻¹⁵
atto	a	10 ⁻¹⁸

Length

Symbol	Known Quantity	Multiply	Metric Symbol	Known Quantity
in	inches	2.54	cm	centimeters
ft	feet	30	cm	centimeters
ft	feet	0.3	m	meters
yd	yards	0.9	m	meters
—	miles	1.6	km	kilometers

Area

Symbol	Known Quantity	Multiply	Metric Symbol	Known Quantity
sq in	square inches	6.5	cm ²	square centimeters
sq ft	square feet	0.09	m ²	square meters
sq yd	square yard	0.8	m ²	square meters
—	square miles	2.6	km ²	square kilometers

Volume

Symbol	Known Quantity	Multiply	Metric Symbol	Known Quantity
tsp	teaspoons	5	mL	milliliters
tbssp	tablespoons	15	mL	milliliters
f oz	fluid ounces	30	mL	milliliters
c	cups	0.24	L	liters
pt	US pints	0.47	L	liters
qt	US quarts	0.95	L	liters
gal	US gallons	3.8	L	liters
cu ft	cubic feet	0.03	m ³	cubic meters
cu yd	cubic yard	0.76	m ³	cubic meters

Mass

Symbol	Known Quantity	Multiply	Metric Symbol	Known Quantity
oz	ounces	28	g	grams
lb	pounds	0.45	kg	kilograms

Energy^a

Symbol	Known Quantity	Multiply	Metric Symbol	Known Quantity
Kcal	kilocalories	4.184	kJ	kilojoules

^aThe kilocalorie (kcal) is still most commonly used to express the energy content of macronutrients, energy expenditure, and energy requirements, although kilojoules (kJ) is the SI unit.

Pressure or Mechanical Stress

Symbol	Known Quantity	Multiply	Metric Symbol	Known Quantity
cm H ₂ O ^a	centimeter of water (4°C)	0.01	Pa	Pascal
mm Hg	millimeter of mercury (0°C)	7.5006	kPa	kilopascal
mm Hg	millimeter of mercury (0°C)	1.36	cm H ₂ O	centimeter of water (4°C)

^aIn clinical practice arterial blood pressure is still measured in mm Hg, cerebrospinal fluid pressure in mm H₂O, and blood gases (P_{co₂} and P_{o₂}) in mm Hg.

Temperature^a

Symbol	Known Quantity	Calculation	Metric Symbol	Known Quantity
°F	degree Fahrenheit	([°F] – 32)/1.8	°C	degree Celsius
°C	degree Celsius	[°C] + 273.15	K	Kelvin
°F	degree Fahrenheit	([°F] + 459.67) × 5/9	K	Kelvin

^aTemperature is normally expressed in degrees Celsius (°C), although the SI base unit for temperature is the Kelvin.

Common Laboratories

Analyte	Specimen	Conventional Unit (Reference Range)	Conversion Factor (Multiply)	SI Unit (Reference Range)
Albumin	Serum	g/dL(3.5-5.0)	10	g/L(35-50)
Alkaline Phosphatase	Serum	U/L(30-120)	0.0167	μkat/L(0.5-2.0)
Alanine aminotransferase (ALT)	Serum	U/L(10-40)	0.0167	μkat/L(0.17-0.68)
Aspartate aminotransferase (AST)	Serum	U/L(10-30)	0.0167	μkat/L(0.17-0.51)
Bicarbonate	Serum	mEq/L(21-28)	1	mmol/L(21-28)
Bilirubin, total	Serum	mg/dL(0.3-1.2)	17.104	μmol/L(5.0-21.0)
Bilirubin, direct	Serum	mg/dL(0.1-0.3)	17.104	μmol/L(1.7-5.1)
Blood urea nitrogen (BUN)	Serum	mg/dL(8-23)	0.357	mmol/L(2.9-8.2)
Carbon dioxide P _{co₂}	Arterial blood	mmHg (35-45)	0.133	kPa (4.7-5.9)
Oxygen, P _{o₂}	Arterial blood	mmHg (80-100)	0.133	kPa (11-13)
Calcium, total	Serum	mg/dL(8.2-10.2)	0.25	mmol/L(2.05-2.55)
Chloride	Serum, plasma	mEq/L(96-106)	1	mmol/L(96-106)
Cholesterol (total)	Serum, plasma	mg/dL(< 200)	0.0259	mmol/L(< 5.18)
Cortisol	Serum, plasma	μg/dL(5-25)	27.588	nmol/L(140-690)
Creatinine	Serum, plasma	mg/dL(0.6-1.2)	88.4	μmol/L(53-106)
GlutaminyI-transferase (GGT)	Serum	U/L(2-30)	0.0167	μkat/L(0.03-0.51)
Glucose	Serum	mg/dL(70-110)	0.0555	mmol/L(3.9-6.1)
Lactate	Plasma	mg/dL(5.0-15)	0.111	mmol/L(0.6-1.7)
Lactate dehydrogenase (LDH)	Serum	U/L(100-200)	0.0167	μkat/L(1.7-3.4)
Magnesium	Serum	mEq/L(1.3-2.1)	0.5	mmol/L(0.65-1.05)
Phosphorus (inorganic)	Serum	mg/dL(2.3-4.7)	0.323	mmol/L(0.74-1.52)
Potassium	Serum	mEq/L(3.5-5.0)	1	mmol/L(3.5-5.0)
Protein (total)	Serum	g/dL(6.0-8.0)	10	g/L(60-80)
Sodium	Serum	mEq/L(136-142)	1	mmol/L(136-142)
Uric acid	Serum	mg/dL(4.0-8.0)	59.485	μmol/L(240-480)

Medication Dosing During Renal Replacement Therapy

Jun Makino, MD and John M. Oropello, MD, FACP, FCCP, FCCM

INTRODUCTION

The aim of drug dosing is to maintain pharmacokinetics (a similar peak, trough, or average steady-state drug concentration) to achieve a desired pharmacodynamic response without adverse side effects.¹ In critically ill patients receiving renal replacement therapy (RRT), however, determining appropriate drug dosing is challenging because pharmacodynamic target attainment is determined by a complex interplay between drug dosing, pharmacokinetic changes within the critically ill patient, and the type of RRT selected ([Table 112–1](#)).² A stepwise approach for patients with chronic kidney disease and acute kidney injury has been proposed ([Table 112–2](#)).³ For assessment of kidney function, estimation by equation is generally more accurate than measured creatinine clearance, given errors in urine collection.⁴ Therefore, the National Kidney Disease Education Program in the United States recommends estimation of the glomerular filtration rate from the Cockcroft and Gault equation for adults: urinary creatinine clearance = $(140 - \text{age [years]}) \times \text{weight (kg)} \times 0.85$ (for female)/serum creatinine (mg/dL) $\times 72$ or the Schwartz equation for children.^{5,6}

[Table 112–3](#) contains guidelines by the American College of Physicians for drug dosing in renal failure requiring RRT.⁷ There are a variety of RRTs including hemodialysis, continuous RRT, and peritoneal dialysis. When applying these or other guidelines it should be understood that dosing recommendations for one form of RRT usually cannot be applied to other forms of RRT.⁸ Dialysis filter type, surface area; the blood, dialysate, and ultrafiltration rates; and interruptions due to circuit clotting influence drug clearance and affect drug dosing.

Drug dosing studies in renal failure have not been conducted in most marketed drugs.^{8,9} In addition, the evidence level is weak as most of these studies are small and also the dose of RRT is not uniform. Finally, technological advances in RRT over the last several years have resulted in greater drug clearances; consequently, drug dosing recommendations may be outdated. Therefore, the most effective dosing optimization strategy is to estimate renal function and begin dosing according to the guidelines, followed by closely monitoring drug levels (if possible) or the clinical response, and adjusting the dosing accordingly ([Table 112–2](#)).

[Table 112–1](#) Factors to alter pharmacodynamics of critically ill patients.²

TABLE 112–1 Factors to alter pharmacodynamics of critically ill patients.²

Factors	Pharmacokinetic Change	Response to Change
Fluid overload	Increased volume of distribution	Give a larger loading dose
Increased capillary permeability	Increased volume of distribution	Give a larger loading dose
Hypoalbuminemia	Increased drug availability to exert pharmacologic effect or increased drug elimination	Potential dosage adjustment for highly protein-bound drugs
Augmented renal clearance	Increased drug elimination	More frequent dosing interval
AKI	Decreased drug elimination	Adjust doses on drugs eliminated by the kidney
AKI requiring RRT	Increased drug elimination	Dose adjust as RRT modality chosen
Preserved nonrenal clearance in AKI	Preserved drug elimination in face of AKI in selected drugs	More frequent dosing interval
Increased cardiac output	Increased drug elimination	More frequent dosing interval
Impaired GI motility/reduced GI blood flow	Decreased oral drug absorption	Avoid oral medication

AKI, acute kidney injury; GI, gastrointestinal; RRT, renal replacement therapy.
Reproduced with permission from Scoville BA, Mueller BA: Medication dosing in critically ill patients with acute kidney injury treated with renal replacement therapy, Am J Kidney Dis. 2013 Mar;61(3):490-500.

TABLE 112–2 Stepwise approach to adjust drug dosage regimens for patients with CKD and AKI.³

Step 1	Obtain history and relevant demographic/clinical information	Assess demographic information, past medical history, current clinical, and laboratory data.
Step 2	Estimate GFR	Use most appropriate tools based on age, body size, ethnicity, and concomitant disease status.
Step 3	Review current medications	Is it really necessary or not?
Step 4	Calculate individualized treatment regimen	Calculate dosage regimen based on pharmacokinetic characteristics of the drug and the patient’s volume status and eGFR or CLcr.
Step 5	Monitor	Monitor parameters of drug response and toxicity; monitor levels if available/applicable.
Step 6	Revise regimen	Adjust regimen based on step 5.

AKI, acute kidney injury; CKD, chronic kidney disease; CLcr, urinary creatinine clearance; eGFR, estimated glomerular filtration rate; GFR, glomerular filtration rate.
Reproduced with permission from Matzke GR, Aronoff GR, Murray P, et al. Drug dosing consideration in patients with acute and chronic kidney disease—a clinical update from kidney disease: improving global outcomes (KDIGO), Kidney Int 2011 Dec;80(11):1122-1137.

TABLE 1 12–3 Drug dosing in patients treated with RRT.

Drug	Major Excretion Route (percentage of total drug excreted unchanged in the urine for patients with normal renal function)	Dose for Normal Renal Function	Adjustment for Renal Failure GFR > 50	Adjustment for Renal Failure GFR 10-50	Adjustment for Renal Failure GFR < 10	Supplement for Dialysis
Analgesics						
Codeine	Hepatic	30-60 mg q4-6	100% [D]	75% [D]	50% [D]	Intermittent Hemodialysis (IHD): No data PD: No data CRRT: Dose for GFR 10-50 [D]
Fentanyl	Hepatic	Individualized	100% [D]	75% [D]	50% [D]	IHD: Not applicable Peritoneal Dialysis (PD): Not applicable CRRT: Dose for GFR 10-50 [B]
Meperidine	Hepatic	50-100 mg q3-4h	100% [D]	75% [D]	50% [D]	IHD: Avoid PD: Avoid CRRT: Avoid [D]
Methadone	Hepatic	2.5-10 mg q6-8h	100% [D]	100% [D]	50%-75% [D]	IHD: None PD: None CRRT: Dose for GFR: 10-50 [D]
Morphine	Hepatic	20-25 mg q4h	100% [A]	75% [A]	50% [A]	IHD: None PD: None CRRT: Dose for GFR 10-50 [D]
Naloxone	Hepatic	2 mg IV	100% [D]	100% [D]	100% [D]	IHD: Not applicable PD: Not applicable CRRT: Dose for GFR: 10-50 [D]
Acetaminophen	Hepatic	650 mg q4h	q4h [D]	q6h [D]	q8h [D]	IHD: None PD: None CRRT: Dose for GFR: 10-50 [B]
Aspirin	Hepatic	650 mg q4h	q4h [B]	q4-6h [B]	Avoid [B]	IHD: Dose after dialysis PD: None CRRT: Dose for GFR: 10-50 [D]
Antihypertensive and Cardiovascular Agents						
Clonidine	62	0.1-0.6 mg bid	q 12h [B]	q 12-24h [B]	q24h [B]	IHD: Dose after dialysis [B] PD: Dose for GFR < 10 [B] CRRT: Dose for GFR 10-50 [D]
Methyldopa	25-40	250-500 mg q8	q8h [B]	q8-12h [B]	q 12-24h [B]	IHD: Dose after dialysis [D] PD: Dose for GFR < 10 [D] CRRT: Dose for GFR 10-50 [D]
Prazosin	< 5	1-15 mg bid-tid	100% [A]	100% [D]	100% [D]	IHD: None PD: None [D] CRRT: Not applicable

(Continued)

TABLE 1 12–3 Drug dosing in patients treated with RRT. (Continued)

Drug	Major Excretion Route (percentage of total drug excreted unchanged in the urine for patients with normal renal function)	Dose for Normal Renal Function	Adjustment for Renal Failure GFR > 50	Adjustment for Renal Failure GFR 10-50	Adjustment for Renal Failure GFR < 10	Supplement for Dialysis
Terazosin	20-30	1 mg hs Second dose: 1-20 mg q24h	100% [A]	100% [A]	100% [A]	IHD: None [D] PD: None [D] CRRT: Not applicable
Candesartan	52	16-32 mg q24	100% [A]	100% [A]	100% [A]	IHD: No dose adjustment [A] PD: No dose adjustment [A] CRRT: Dose for GFR 10-50 [D]
Irbesartan	< 5	150-300 mg q24	100% [A]	100% [A]	100% [A]	IHD: No dose adjustment [A] PD: No dose adjustment [D] CRRT: Dose for GFR 10-50 [D]
Losartan	4-10	25-100 mg q24	100% [A]	100% [A]	100% [A]	IHD: None [A] PD: None [A] CRRT: Dose for GFR 10-50 [D]
Valsartan	13	80-320 mg q24h	100% [B]	100% [B]	100% [D]	IHD: None [A] PD: None [D] CRRT: Dose for GFR 10-50 [D]
Benazepril	54	10 mg q24h Second dose: 10-40 mg q12-24h	100% [A]	50%-75% [A]	25%-50% [D]	IHD: None [D] PD: None [D] CRRT: Dose for GFR 10-50 [D]
Captopril	40-50	25-50 mg q8h Second dose: 50-150 mg q8-12h	100% q8-12h [A]	75% q12-18h [A]	50% q24h [A]	IHD: Dose after dialysis [A] PD: Dose for GFR 10-50 [A] CRRT: Dose for GFR 10-50 [D]
Enalapril	88	5-20 mg q12-24h	100% [A]	50%-100% [A]	25% [A]	IHD: Dose after dialysis [A] PD: Dose for GFR < 10 [D] CRRT: Dose for GFR 10-50 [D]
Enalaprilat	88	1.25-5 mg IV over 5 min q6h	100% [A]	50%-100% [A]	25%-50% [D]	IHD: Dose after dialysis [A] PD: Dose for GFR < 10 [D] CRRT: Dose for GFR 10-50 [D]
Lisinopril	88-100	5-10 mg q24h Second dose: 20-40 mg q24h	100% [A]	50%-75% [A]	25%-50% [A]	IHD: Dose after dialysis [A] PD: None [D] CRRT: Dose for GFR 10-50 [D]

Ramipril	35	2.5 mg q24h Second dose: 5-10 mg q24h	100% [A]	25%-50% [A]	25% [A]	IHD: Dose after dialysis [A] PD: Dose for GFR < 10 [D] CRRT: Dose for GFR 10-50 [D]
Atenolol	85	50-100 mg q24h	50-100 mg q24h [A]	25-50 mg q24h [A]	25 mg q24h [A]	IHD: 25-50 mg after dialysis [A] PD: Dose for GFR < 10 [A] CRRT: Dose for GFR 10-50 [D]
Carvedilol	< 2	3.125-6.25 mg q12-24h Second dose: 6.25-25 mg q12-24h	100% [A]	100% [A]	100% [A]	IHD: None [A] PD: None [D] CRRT: Dose for GFR 10-50 [D]
Esmolol	< 10	0.5 mg/kg infused over 1 min Second dose: 0.05 mg mg/kg/min for the next 4 min	100% [A]	100% [A]	100% [A]	IHD: None [A] PD: None [A] CRRT: Dose for GFR 10-50 [D]
Labetalol	< 5	100 mg bid Second dose: 200-400 mg bid	100% [A]	100% [A]	100% [A]	IHD: None [A] PD: None [A] CRRT: Dose for GFR 10-50 [D]
Metoprolol	8-13	50-400 mg q24h	100% [A]	100% [A]	100% [A]	IHD: None [A] PD: None [A] CRRT: Dose for GFR 10-50 [D]
Nadolol	90	40 mg q24h Second dose: 40-240 mg q24h	q24h [A]	q24-48h [A]	q40-60h [A]	IHD: Dose after dialysis [A] PD: Dose for GFR < 10 [A] CRRT: Dose for GFR 10-50 [D]
Propranolol	< 5	80-160 mg bid	100% [A]	100% [A]	100% [A]	IHD: None [A] PD: None [D] CRRT: Dose for GFR 10-50 [D]
Timolol	15	10-30 mg bid	100% [A]	100% [A]	100% [A]	IHD: No dose adjustment [A] PD: No dose adjustment [D] CRRT: Dose for GFR 10-50 [D]
Hydralazine	25	25-50 mg tid	q8h [A]	q8h [A]	q8h [A]	IHD: Dose after dialysis [D] PD: Dose for GFR < 10 [D] CRRT: Dose for GFR 10-50 [D]
Minoxidil	15-20	5-30 mg bid	100% [A]	100% [A]	100% [A]	IHD: Dose after dialysis [D] PD: Dose for GFR < 10 [D] CRRT: Dose for GFR 10-50 [D]

Drug	Major Excretion Route (percentage of total drug excreted unchanged in the urine for patients with normal renal function)	Dose for Normal Renal Function	Adjustment for Renal Failure GFR > 50	Adjustment for Renal Failure GFR 10-50	Adjustment for Renal Failure GFR < 10	Supplement for Dialysis
Primaquine	1	15 mg (base) q24h	No data; 100% [D]	No data; 100% [D]	No data; 100% [D]	IHD: No data, None PD: No data, None CRRT: Dose for GFR 30-50 [D]
Pyrimethamine	15-30	50-75 mg q24h	100% [D]	100% [D]	100% [D]	IHD: None PD: None CRRT: Dose for GFR 30-50 [D]
Acyclovir	40-70	5-10 mg/kg q8h	100% q8 [D]	100% q 12-24h [D]	50% q24h [D]	IHD: Dose after dialysis PD: Dose for GFR < 10 CRRT: 5-10 mg/kg q24h [A]
Famciclovir	50-65	500 mg q8h for herpes zoster; 125 mg q12h for genital herpes	100% [D]	q12-24h [D]	50% q24h [D]	IHD: Dose after dialysis PD: No data CRRT: Not applicable, recommend IV ganciclovir
Foscarnet	85	40-60 mg/kg q8h Second dose: to 90 mg/ kg q12h	28 mg/kg [A]	15 mg/kg [A]	6 mg/kg [A]	IHD: Dose after dialysis PD: Dose for GFR < 10 CRRT: Cytomegalovirus (CMV) induct; 60 mg q24h; CMV main; 60 mg q48 [B]
Ganciclovir	90-100	5 mg/kg q12h	50% q12-24h [D]	25%-50% q24h [D]	25% 3 wk [D]	IHD: 25% 3×/wk PD: Dose for GFR < 10 CRRT: Induction: 2.5 mg/kg q24h, main: 1.25 mg/kg q24h [B]
Valacyclovir	< 1	500 mg q12h Second dose: to 1000 mg q8h	100% [D]	Full dose q 12- 24h [D]	0.5 g q24h [D]	IHD: Dose after dialysis PD: Dose for GFR < 10 CRRT: Not applicable, recommend IV form
Valganciclovir	> 90	900 mg bid (induction) 900 mg daily (maintenance)	Induction GFR 40-59; 450 mg bid GFR 25-39; 450 mg qd GFR 10-24 450 mg q2d [A]	Maintenance GFR 40-59; 450 mg qd GFR 25-39 450 mg q2d GFR 10-24 450 mg twice weekly [A]		IHD: Avoid PD: Avoid CRRT: based on GFR

Anticoagulants						
Alteplase	No data	60 mg over 1 h, then 20 mg/h for 2 h	100% [D]	100% [D]	100% [D]	IHD: No data [D] PD: No data [D] CRRT: Dose for GFR 10-50 [D]
Dipyridamole	No data	50 mg tid	100% [D]	100% [D]	100% [D]	IHD: None [D] PD: Dose for GFR < 10 [D] CRRT: Not applicable
Heparin	None	75 U/kg load, then 0.5 U/kg/min	100% [A]	100% [A]	100% [A]	IHD: None [A] PD: None [A] CRRT: Dose for GFR 10-50 [D]
Low molecular weight heparin (LMWH)	No data	30-40 mg bid	100% [B]	100% [B]	50% [B]	IHD: Not applicable [D] PD: Dose for GFR < 10 [D] CRRT: 50% and monitor Xa [D]
Streptokinase	None	250,000 U load, then 100,000 U/h	100% [B]	100% [B]	100% [B]	IHD: Not applicable [D] PD: Not applicable [D] CRRT: Dose for GFR 10-50 [D]
Urokinase	No data	4400 U/kg load, then 4400 U/kg qh	100% [B]	100% [B]	100% [B]	IHD: None [D] PD: None [D] CRRT: Dose for GFR 10-50, not available [D]
Warfarin	None	10-15 mg load, then 2-10 mg q24h	100% [A]	100% [A]	100% [A]	IHD: None [B] PD: None [B] CRRT: 100% [D]
Anticonvulsants						
Carbamazepine	2-3	200 mg bid Second dose: to 1200 mg q24h	100% [A]	100% [A]	75% [D]	IHD: Dose for FR < 10 give after dialysis [B] PD: Dose for GFR < 10 [D]CRRT: 100% [B]
Clonazepam	< 1	0.5 mg tid	100% [D]	100% [D]	100% [D]	IHD: None [D] PD: No data CRRT: Not applicable
Fosphenytoin	2	15-20 mg PE/kg at 100-150 mg PE/min	100% [B]	100% [B]	100% [B]	IHD: None [A] PD: None [B] CRRT: 100% [B]
Gabapentin	90	300-600 mg tid	400 mg tid [A]	300 mg q12-24h [A]	300 mg qod [A]	IHD: 300 mg load, then 200-300 mg post HD [A] PD: 300 mg qod [D] CRRT: Dose for GFR 10-50 [D]

(Continued)

TABLE 112–3 Drug dosing in patients treated with RRT. (Continued)

Drug	Major Excretion Route (percentage of total drug excreted unchanged in the urine for patients with normal renal function)	Dose for Normal Renal Function	Adjustment for Renal Failure GFR > 50	Adjustment for Renal Failure GFR 10-50	Adjustment for Renal Failure GFR < 10	Supplement for Dialysis
Lamotrigine	10	50 mg q 12-24h (initially) 100- 500 mg q24h (maintenance)	100% [D]	75% [D]	10 mg qod [A]	IHD: 100 mg after dialysis [A] PD: Dose for GFR < 10 [D] CRRT: Decrease dose by 50% [B]
Levetiracetam	66	500-1500 mg q 12h	500-1000 mg q 12h [A]	250-750 mg q 12h [A]	500-1000 mg q 24h [A]	IHD: 250-500 mg after dialysis [B] PD: Dose for GFR < 10 [D] CRRT: 250-750 mg q 12h [D]
Oxcarbazepine	30	300-600 mg bid	100% [A]	75%-100% [A]	50% [A]	IHD: Dose for GFR < 10, give after dialysis [D] PD: Dose for GFR < 10 [D] CRRT: Decrease dose by 50%, monitor levels [D]
Phenobarbital	19-31	50-100 mg q 8-12h	q 8-12h [D]	q 8-12h [D]	q 12-16h [D]	IHD: Dose before dialysis, 1/2 dose after dialysis [D] PD: 1/2 normal dose [B] CRRT: Normal dose and measure levels [B]
Phenytoin	2	100 mg tid	100% [B]	100% [B]	100% [B]	IHD: None [A] PD: None [B] CRRT: 100% [B]
Topiramate	70-97	200 mg q 12h	100% [A]	50% [A]	25% [D]	IHD: Dose for normal renal function after dialysis [D] PD: Dose for GFR 10-50 [D] CRRT: Dose for GFR 10-50 [B]
Valproic acid	< 5	500 mg q24h for 1 wk Second dose: 500-1000 mg q24h	100% [D]	100% [D]	100% [D]	IHD: Dose after dialysis [D] PD: Dose for GFR < 10 [B] CRRT: None [D]
Antihistamines						
Diphenhydramine	2	25 mg tid-qid	100% [D]	100% [D]	100% [D]	IHD: None [D] PD: None [D] CRRT: 100% [D]
Famotidine	65-80	20-40 mg qhs	50%-75% [D]	10%-50% [D]	10% [D]	IHD: Dose after dialysis [A] PD: Dose for GFR < 10 [A] CRRT: Dose for GFR 10-50 [B]
Ranitidine	80	150-300 mg qhs	75% [A]	150 mg q 12- 24h [A]	75-150 mg q 24h [A]	IHD: Dose after dialysis [D] PD: Dose for GFR < 10 [D] CRRT: Dose for GFR 10-50 [D]

Antiparkinson Agents						
Carbidopa	30	1 tab tid Second dose: to 6 tabs daily	100% [D]	100% [D]	100% [D]	IHD: No data PD: No data CRRT: Dose for GFR 10-49 [D]
Levodopa	None	250-500 mg bid Second dose: to 8 g q24h	100% [B]	50%-100% [B]	50%-100% [B]	IHD: Dose after dialysis [D] PD: Dose for GFR < 10 [D] CRRT: Dose for GFR 10-50 [D]
Antithyroid Drugs						
Methimazole	7	5-20 mg tid	100% [B]	100% [B]	100% [B]	IHD: None [D] PD: None [D] CRRT: Dose for GFR 10-50 [D]
Propylthiouracil	< 10	100 mg tid	100% [A]	100% [A]	100% [A]	IHD: None [D] PD: None [D] CRRT: Dose for GFR 10-50 [D]
Arthritis and Gout Agents						
Allopurinol	30	300 mg q24h	75% [B]	50% [B]	25% [B]	IHD: 1/2 dose [B] PD: No data [D] CRRT: Dose for GFR 10-50 [D]
Colchicine	5-17	Acute: 2 mg then 0.5 mg q6h Chronic: 0.5-1 mg q24h	100% [B]	50%-100% [B]	25% [B]	IHD: None [D] PD: Dose for GFR < 10 [D] CRRT: Dose for GFR 10-50 [D]
Diclofenac	< 1	25-75 mg bid	50%-100% [D]	25%-50% [D]	25% [D]	IHD: None [D] PD: None [D] CRRT: Not applicable
Ibuprofen	1	800 mg tid	100% [A]	100% [A]	100% [B]	IHD: None [D] PD: None [D] CRRT: Dose for GFR 10-50 [D]
Indomethacin	30	25-50 mg tid	100% [A]	100% [A]	100% [A]	IHD: None PD: None [D] CRRT: Not applicable
Ketorolac	30-60	30-60 mg load, then 15-30 mg q6h	100% [D]	50% [B]	25%-50% [B]	IHD: None [D] PD: None [D] CRRT: Dose for GFR 10-50 [D]
Naproxen	< 1	500 mg bid	100% [A]	100% [A]	100% [A]	IHD: None [D] PD: None [D] CRRT: Not applicable

TABLE 112–3 Drug dosing in patients treated with RRT. (Continued)

Drug	Major Excretion Route (percentage of total drug excreted unchanged in the urine for patients with normal renal function)	Dose for Normal Renal Function	Adjustment for Renal Failure GFR > 50	Adjustment for Renal Failure GFR 10-50	Adjustment for Renal Failure GFR < 10	Supplement for Dialysis
Bronchodilators						
Albuterol	28	2 inhalations q4-6h	100% [D]	100% [D]	100% [D]	IHD: None [D] PD: None [D] CRRT: 100% [D]
Ipratropium	No data	2 inhalations qid	100% [D]	100% [D]	100% [D]	IHD: None [D] PD: None [D] CRRT: 100% [D]
Salmeterol	< 1	1-2 inhalations bid	100% [D]	100% [D]	100% [D]	IHD: None [D] PD: None [D] CRRT: 100% [D]
Theophylline	< 10	6 mg/kg load, then 9 mg/kg q24h	100% [A]	100% [A]	100% [A]	IHD: 125% during dialysis [B] PD: None [D] CRRT: 100% [D]
Corticosteroids						
Dexamethasone	8	0.75-9 mg q24h	100% [D]	100% [D]	100% [D]	IHD: None [D] PD: None [D] CRRT: 100% [D]
Hydrocortisone	None	20-500 mg q24h	100% [A]	100% [A]	100% [A]	IHD: None [D] PD: None [D] CRRT: 100% [D]
Methylprednisolone	< 10	4-48 mg q24h	100% [A]	100% [A]	100% [A]	IHD: Yes [D] PD: None [D] CRRT: 100% [D]
Prednisone	34	5-60 mg q24h	100% [A]	100% [A]	100% [A]	IHD: Yes [B] PD: None [B] CRRT: 100% [D]
Hypoglycemic Agents						
Glipizide	4.5-7	2.5-15 mg q24h	100% [B]	50% [B]	50% [B]	IHD: None [D] PD: Dose for GFR < 10 [D] CRRT: Not applicable
Glyburide	50	1.25-20 mg q24h	No data	No data	100% [A]	IHD: None PD: None CRRT: Not applicable
Metformin	90-100	500-850 mg bid	50% [B]	25% [B]	Avoid [B]	IHD: Not applicable [D] PD: None [D] CRRT: Not applicable

Glipizide	4.5-7	2.5-15 mg q24h	100% [B]	50% [B]	50% [B]	IHD: None [D] PD: Dose for GFR < 10 [D] CRRT: Not applicable
Insulin	None	Variable	100% [A]	75% [A]	50% [A]	IHD: None [A] PD: None [A] CRRT: Dose for GFR 10-50
Hypolipidemic Agents						
Cholestyramine	None	4 g q4-6h	100% [D]	100% [D]	100% [D]	IHD: None [D] PD: None [D] CRRT: 100%[D]
Gemfibrozil	None	600 mg bid	100% [B]	75% [B]	50% [B]	IHD: None [D] PD: Dose for GFR < 10 [D] CRRT: Not applicable
Nicotinic acid	None	1-2 g tid	100% [B]	50% [B]	25% [B]	IHD: None [D] PD: Doses for GFR < 10 [D] CRRT: Dose for GFR 10-50 [D]
Pravastatin	< 10	10-40 mg q24	100% [A]	100% [A]	100% [A]	IHD: None [B] PD: None [B] CRRT: Dose for GFR 10-50 [D]
Simvastatin	< 0.5	5-40 mg q24h	100% [A]	100% [A]	100% [A]	IHD: None [D] PD: None [D] CRRT: Dose for GFR 10-50 [D]
Miscellaneous Drugs						
Metoclopramide	10-22	10-15 mg qid	100% [A]	75% [A]	50% [A]	IHD: None [D] PD: None [D] CRRT: Dose for GFR 10-50 [D]
Ondansetron	< 5	8-10 mg IV q6-12h	100% [A]	100% [A]	100% [A]	IHD: None [B] PD: None [B] CRRT: Dose for GFR 10-50 [D]
Neuromuscular Agents						
Atracurium	None	0.4-0.5 mg/kg load, then 0.08-0.1 mg/kg q15-25 min	100% [D]	100% [D]	100% [D]	IHD: Not applicable [D] PD: Not applicable [D] CRRT: Dose for GFR 10-50 [B]
Etomidate	2	0.2-0.6 mg/kg	100% [D]	100% [D]	100% [D]	IHD: Not applicable [D] PD: Not applicable [D] CRRT: Dose for GFR 10-50 [D]
Fentanyl	6-8	0.002-0.05 mg/kg	100% [D]	100% [D]	100% [D]	IHD: None [D] PD: None [D] CRRT: Dose for GFR 10-50 [B]

DRUGS IN PREGNANCY

The Food and Drug Administration (FDA) has established 6 categories (A, B, C, D, X, and N) to indicate the potential of a drug to cause birth defects if used during pregnancy.[†] The categories are determined

by the reliability of documentation and the risk to benefit ratio. They do not take into account any risks from pharmaceutical agents or their metabolites in breast milk.

Class of Medication	FDA Pregnancy Category Risk	Class of Medication	FDA Pregnancy Category Risk
Analgesics and sedative agents		Amiodarone	D
Acetaminophen	C	Digoxin	C
Acetylsalicylic acid*	D	Diltiazem	C
Fentanyl*	C	Esmolol	C
Hydromorphone*	C	Flecainide	C
Ibuprofen*	C (first and second trimester); D (third trimester)	Metoprolol	C
Indomethacin*	C (first and second trimester); D (third trimester)	Antimicrobial agents	
Ketorolac*	C (first and second trimester); D (third trimester)	Penicillins	B
Meperidine*	C	Cefazolin	B
Methadone*	C	Cefepime	B
Morphine*	C	Ceftriaxone	B
Oxycodone*	C	Imipenem-cilastatin	C
Oxymorphone*	C	Meropenem	B
Midazolam	D	Amikacin	D
Lorazepam	D	Gentamicin	D
Propofol	B	Tobramycin	D
Dexmedetomidine	C	Erythromycin	B
Anesthetic agents		Levofloxacin	C
Halothane	C	Clarithromycin	C
Isoflurane	C	Ciprofloxacin	C
Ketamine	N	Vancomycin	C
Lidocaine (local)	B	Linezolid	C
Propofol	B	Aztreonam	B
Antiarrhythmic agents		Clindamycin	B
Adenosine	C	Metronidazole	B
		Trimethoprim-sulfamethoxazole	D
		Tetracyclines	D

Notes:

Category A

Adequate and well-controlled studies have failed to demonstrate a risk to the fetus in the first trimester of pregnancy (and there is no evidence of risk in later trimesters).

Category B

Animal reproduction studies have failed to demonstrate a risk to the fetus and there are no adequate and well-controlled studies in pregnant women.

Category C

Animal reproduction studies have shown an adverse effect on the fetus and there are no adequate and well-controlled studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

Category D

There is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience or studies in humans, but potential benefits may warrant use of the drug in pregnant women despite potential risks.

Category X

Studies in animals or humans have demonstrated fetal abnormalities and/or there is positive evidence of human fetal risk based on adverse reaction data from investigational or marketing experience, and the risks involved in use of the drug in pregnant women clearly outweigh potential benefits.

Category N

FDA has not classified the drug.

Maastricht index (MI)	MI = 20.68 – (0.24 × albumin [g/L]) – 19.21 × prealbumin [g/L] – 1.86 × lymphocytes [10 ⁹ /L] – (0.04 × percentage ideal weight)	Patients with MI > are considered malnourished
Nutritional risk index (NRI)	NRI = (15.9 × plasma albumin [g/dL]) + 41.7 × (present weight/usual weight)	>100: subject is not malnourished 97.5-100: mildly malnourished 83.5 to <97.5: moderately malnourished <83.5: severely malnourished

Algorithms for Resuscitation

Natalie Kostecky, RN, BSN and
Stephen M. Pastores, MD, FACP, FCCP, FCCM

115

CPR Quality

- Push hard (at least 2 inches [5 cm]) and fast (100-120/min) and allow complete chest recoil.
- Minimize interruptions in compressions.
- Avoid excessive ventilation.
- Rotate compressor every 2 minutes, or sooner if fatigued.
- If no advanced airway, 30:2 compression-ventilation ratio.
- Quantitative waveform capnography
 - If $\text{PETCO}_2 < 10$ mm Hg, attempt to improve CPR quality.
- Intra-arterial pressure
 - If relaxation phase (diastolic) pressure < 20 mm Hg, attempt to improve CPR quality.

Shock Energy for Defibrillation

- **Biphasic:** Manufacturer recommendation (eg, initial dose of 120-200 J); if unknown, use maximum available. Second and subsequent doses should be equivalent, and higher doses may be considered.
- **Monophasic:** 360 J

Drug Therapy

- **Epinephrine IV/IO dose:**
1 mg every 3-5 minutes
- **Amiodarone IV/IO dose:** First dose: 300 mg bolus. Second dose: 150 mg.

Advanced Airway

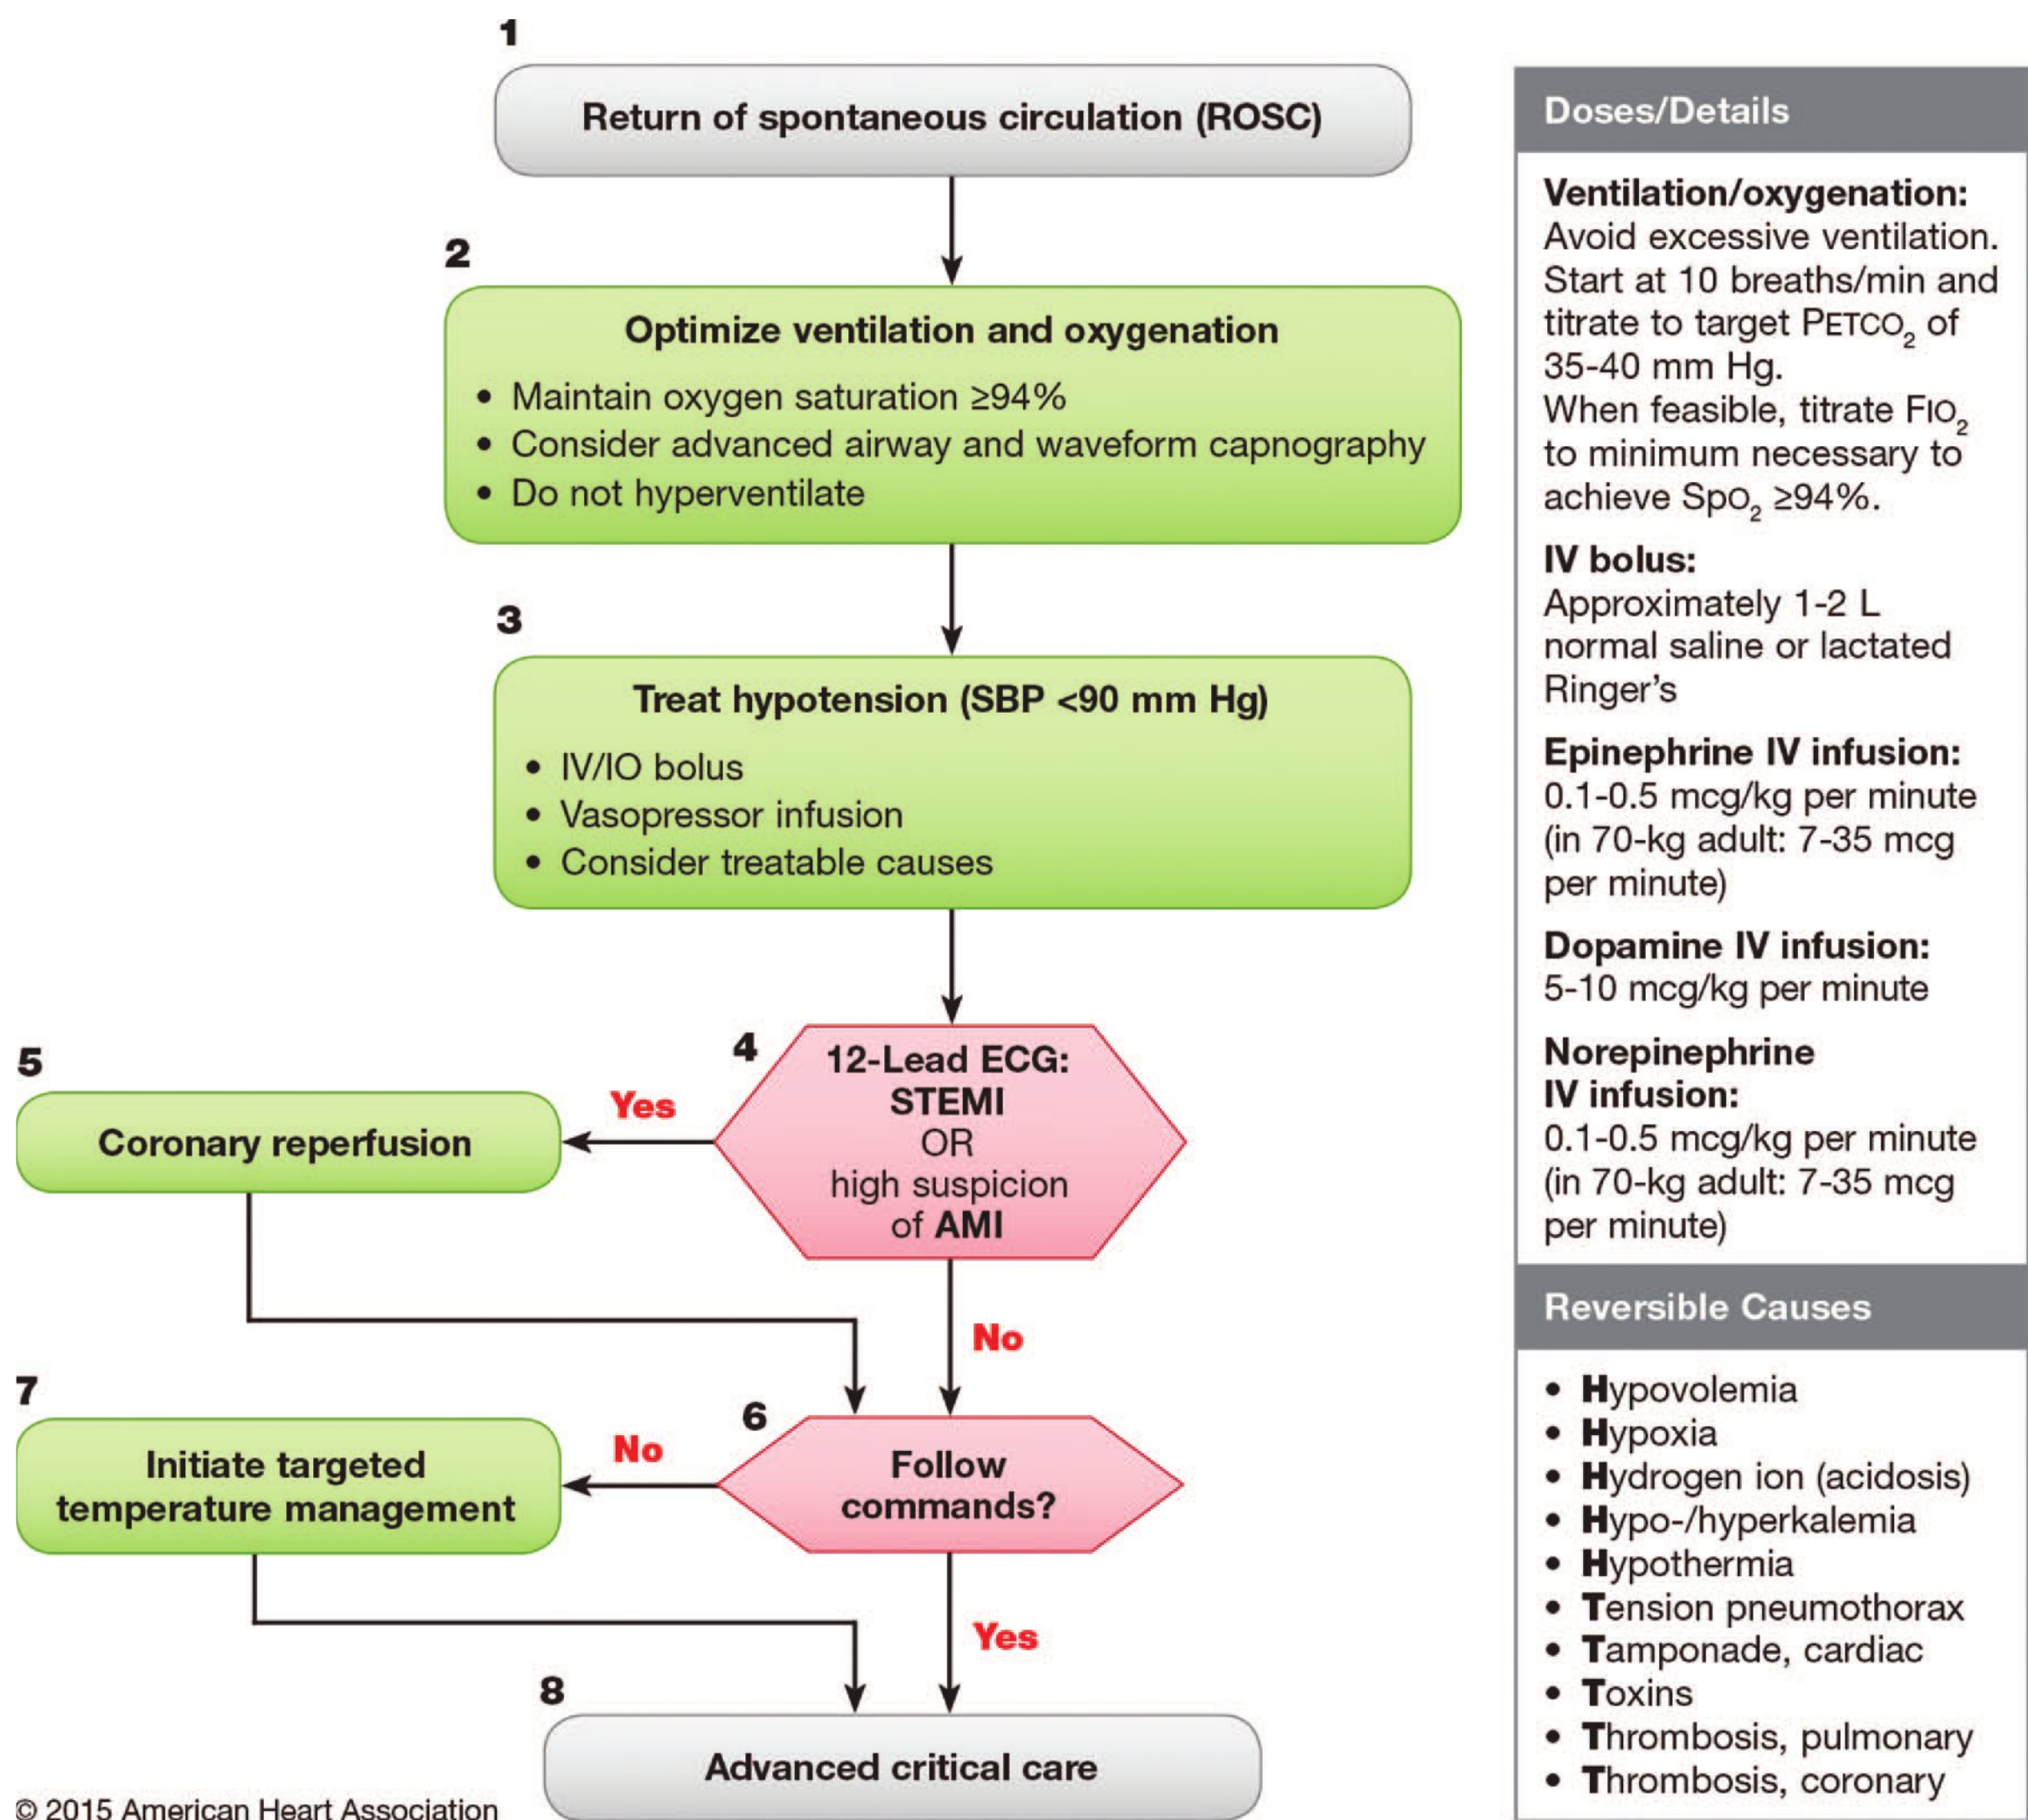

- Endotracheal intubation or supraglottic advanced airway
- Waveform capnography or capnometry to confirm and monitor ET tube placement
- Once advanced airway in place, give 1 breath every 6 seconds (10 breaths/min) with continuous chest compressions

Return of Spontaneous Circulation (ROSC)

- Pulse and blood pressure
- Abrupt sustained increase in PETCO₂ (typically ≥ 40 mm Hg)
- Spontaneous arterial pressure waves with intra-arterial monitoring

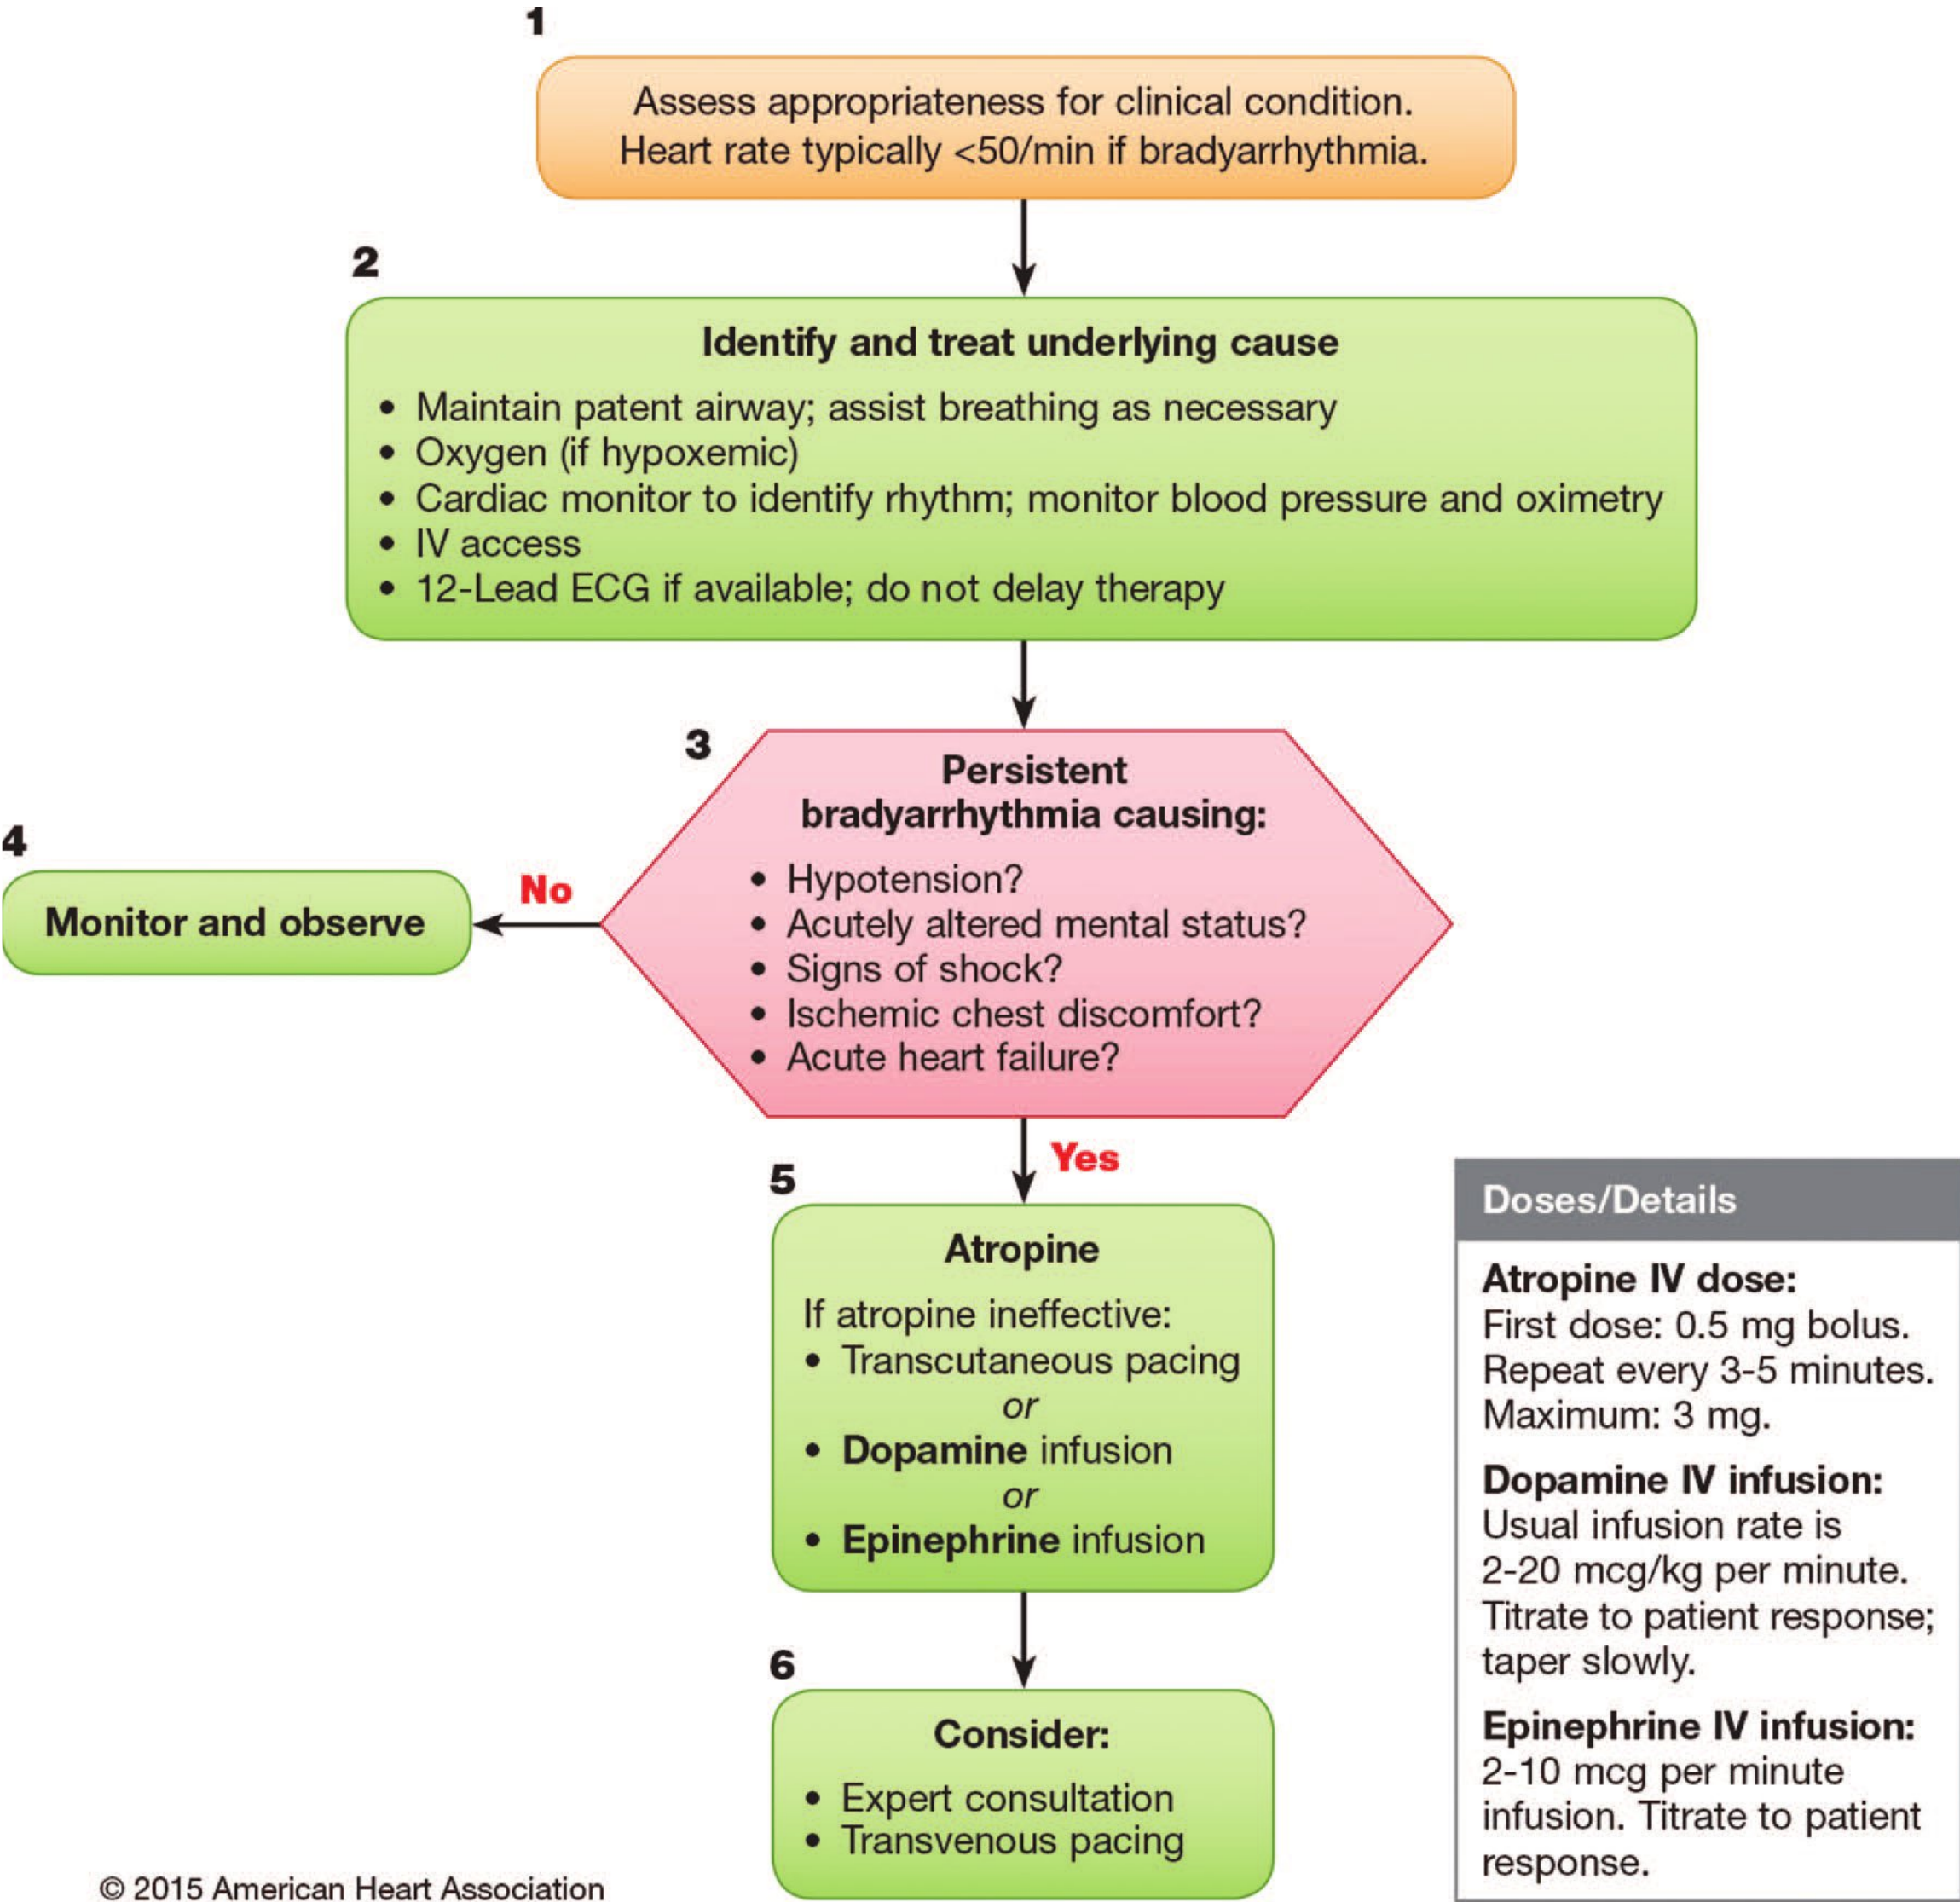

Reversible Causes

- **Hypovolemia**
- **Hypoxia**
- **Hydrogen ion (acidosis)**
- **Hypo-/hyperkalemia**
- **Hypothermia**
- **Tension pneumothorax**
- **Tamponade, cardiac**
- **Toxins**
- **Thrombosis, pulmonary**
- **Thrombosis, coronary**

Bedside Statistical Tools

John T. Doucette, PhD and Steven Krasnica, MD

INTRODUCTION

A primary goal for clinicians is to evaluate the benefits and harms from the treatment options before them. *Primum non nocere* is a basic principle of ethical practice. “Evidence-based medicine is the conscientious, explicit, and judicious use of the current best evidence in making decisions about the care of individual patients. The practice of evidence-based medicine means integrating the individual clinical expertise with the best available external evidence from systematic review.”¹ Since the 1990s, evidence-based medicine (EBM) has been gaining a strong foothold in most disciplines of medicine. In order to practice EBM, however, it is paramount that clinicians are capable of assessing and synthesizing medical literature. Effective physicians comprehend the balance between personal clinical experience and evidence from appropriately conducted research. Clinicians need to proficiently assess the quality of published studies with respect to design, conduct, and analysis, and then to determine the relevance and external validity to their specific patient. Not all evidence is equal, nor does it offer definite clinical plans of care. One needs to understand the basic threats to the validity of studies, namely bias, confounding, and chance. The randomized controlled trial (RCT) and meta-analysis are regarded as the gold standard of EBM. However, RCTs are difficult to perform in critical care medicine.

Critical care medicine is a rapidly evolving discipline that deals with a complex disease spectrum. Sepsis and ARDS, for example, are still poorly understood disease processes with multiple etiologies and phenotypes. Sepsis syndrome may arise from a number of sources all presenting differently in different patients. Consequently, there are many challenges in the conduct of sound clinical research

in this field: critical illness is difficult to precisely define; patient populations may differ drastically with respect to severity of disease, treatment modalities, and other characteristics; subject recruitment may be difficult.

A sound knowledge of fundamental statistics will lay the basis for critical appraisal of the literature, an imperative clinical tool in every practitioner’s armamentarium. Statistical tools can be used to describe the performance of diagnostic tests, characterize relationships between clinical decisions and outcomes, and estimate survival probabilities, just to name a few of their many uses. Ultimately, one would like to pair a critical appraisal of evidence with comprehensive clinical judgment at the bedside, where $n = 1$.

STUDY DESIGNS

Perhaps as important as an understanding of the methods of analysis used in clinical studies is an understanding of the various types of study designs, their defining characteristics, and the strengths and weaknesses of each. The most commonly used designs that involve collection and analysis of original data (“primary studies”) can be broken into 2 subtypes: experimental or intervention studies and observational studies. Yet another class of studies (“secondary studies”) seeks to synthesize information from multiple existing studies of the same research question. For experimental designs, we describe the RCT and other clinical trial designs. For observational studies, we consider cohort studies, case-control studies, cross-sectional studies, case series, and case reports. Finally, we discuss meta-analyses and systematic reviews as types of secondary studies.

EXPERIMENTAL STUDIES

Randomized Controlled Trials

Partly because of its desirable properties, the RCT is widely used in critical care medicine. In this design, patients who meet eligibility criteria are randomly assigned to 1 of 2 or more groups, called the arms of the trial. The groups are often defined by the treatment regimen to be received by the subjects in the group. This is an experimental design, meaning that the investigator actively chooses to give, for example, 1 treatment to 1 group of patients and another to a second group. Thus, the RCT is not suited to research questions where it is not practical or ethical to experimentally assign subjects to the exposure (treatment) of interest.

A key feature of the RCT is the randomization of subjects to the arms of the trial. The purpose of this randomization is to create groups of subjects that tend to be comparable on other prognostic factors related to outcome, thus ensuring a “fair” comparison. We stress that the groups tend to be comparable, because randomization does not guarantee this. For this reason, it is imperative to compare the subjects in each treatment arm with respect to other factors known to be related to outcome in order to either assure that the groups are similar or to account for any dissimilarities in the analysis of the trial data.

An important issue in the design of an RCT is blinding or masking. Blinding of a study keeps knowledge of the random treatment assignment of each subject hidden from 1 or more parties. In a so-called double-blind study, both the investigators and the study subjects are thus blinded. The purpose of blinding is to minimize the potential for bias in the study results. Bias can often occur in subtle, unintended ways from well-meaning individuals, and so blinding attempts to remove the potential for many types of bias. For some types of interventions (eg, surgery vs medical management), blinding is not feasible. When this occurs, to the extent possible it is advisable to blind the investigators who assess outcomes. This can be achieved by having outcomes assessed by members of the research team who are not involved in clinical care of the patient or administration of the intervention.

Another important factor, specific to experimental studies, and thus RCTs, is crossover, and

related to that, the intention-to-treat principle. In some studies, patients who are randomly assigned to 1 treatment group may, at some point during the trial, end up not receiving that treatment and possibly receiving a treatment associated with one of the other arms of the trial. These subjects are said to have crossed over, and the existence of such crossover complicates the analysis of the trial results. The intention-to-treat principle, which is the accepted method of dealing with crossover when it occurs, dictates that data collected from subjects should be analyzed with the group to which the subject was randomized, irrespective of what treatment the subject actually received. Although this may initially seem counterintuitive, this protects the validity of any observed differences between groups. Crossover cannot be assumed to occur at random, and thus to remove crossover subjects from the group to which they were randomly assigned would compromise the randomization, potentially leading to invalid results. Under the intention-to-treat principle, the crossover may dilute the degree of difference between the groups on whatever outcome measure is employed. But the integrity of any observed difference (that is found despite any such dilution) is intact. At the design phase of a trial, if a fair amount of crossover is expected, investigators may be wise to plan for somewhat larger sample sizes to compensate for the dilution of effect sizes due to crossover.

OBSERVATIONAL STUDIES

In observational studies, unlike in studies with an experimental design, the investigator does not decide who has which treatment or exposure but merely observes what happens within each exposure group. As such, extra care must be taken, usually in the analysis, to account for imbalances between the groups on factors related to outcome other than the exposure(s) of interest.

Cohort Studies

In a cohort design, a group of subjects (the “cohort”) is identified and followed forward over time to observe the rate of occurrence of the outcome(s) of interest. The cohort is typically divided into 2 or more groups based on exposure to a particular risk factor for the outcome (eg, treatment), with those

exposure groups being compared at the end of the study with respect to the outcome rate. Most cohort studies are prospective and proceed as described earlier. Occasionally, if reliable exposure data are available from an earlier time, an investigator can assemble the cohort retrospectively, by determining who had exposure at some specific earlier time and comparing outcomes over the time subsequent to that exposure. These latter studies are alternately referred to as retrospective cohort or historical cohort studies.

Case-Control Studies

In the case-control design, groups of subjects are chosen after the outcome of interest has already occurred. A case group of subjects with a particular disease (or other outcome) are selected, and a comparison group of subjects (the controls) without the disease are chosen. Information about past exposures and risk factors of interest is then collected and compared between the cases and controls. If the exposure data rely on self-report from the study subjects, and if case subjects recall their exposures differently from control subjects, these studies can suffer from a resulting bias known as recall bias. Nonetheless, case-control studies can often be a useful way of addressing a question that needs an observational design.

Cross-Sectional Studies

Another type of observational design is the cross-sectional study. This is sometimes simply called a survey. In a cross-sectional design, no time has passed between the assessment of exposure(s) and outcome(s). Rather, both are assessed or measured at the same point in time. As such, a major limitation of such studies is that the temporal relationship between one factor and the other cannot be established. Cross-sectional designs are often employed for large-scale, population-based surveys to look at the health characteristics of a population.

Case Reports and Case Series

As its name implies, a case report is a description of the characteristics of a single patient. A case series describes a usually small group (series) of patients. These types of studies do not typically involve any data analysis or comparison of subgroups, but merely

report on characteristics of interest in the case or series of cases. As such, they are especially useful when something out of the ordinary has occurred that may shed new light on existing knowledge or perhaps even identify a new disease type or syndrome.

SECONDARY STUDIES

In secondary studies, new data are not presented. Rather, existing data from other studies are collected and perhaps reanalyzed to synthesize the body of evidence on a particular topic. All such studies need to consider the possible role of what is known as publication bias, which stems from the belief that studies that find an effect (“positive studies”) are more likely to be published than studies that do not (“negative studies”). If this belief is warranted, a synthesis of only published studies will be biased toward finding an effect.

There are 3 main types of secondary studies: review articles, systematic reviews, and meta-analyses. In a review article, the authors identify as many studies as can be found related to a particular research question (and perhaps related topics). They then present in an organized way the key findings of those studies, and draw conclusions based on critical evaluation of the full body of evidence on the question.

Systematic reviews have largely taken the place of the basic review article. In a systematic review, the investigators must spell out the systematic approach used in identifying the research to be included in the review. Typically, a very wide net is cast and a very large number of studies need to be vetted for inclusion or exclusion from the review.

In a meta-analysis, investigators gather all the studies relevant to a particular question in a similar manner as one would do for a systematic review. They then do a new analysis of the combined set of data from those studies, in order to present an overall estimate of the effect of interest that is more precise due to the much larger number of subjects from all studies combined.

Statistical Analysis

Hypothesis Tests

Most clinical studies involve one or more statistical hypothesis tests to address the research question(s) at hand. There are many types of such

hypothesis tests. For complex questions or designs, a biostatistician should be consulted, but some of the basic tests used, and issues related to their proper use, are presented here. The types of tests can be grouped as those related to continuous outcomes, categorical or discrete outcomes, and time-to-event (survival) data.

Continuous outcomes—Many of the outcomes we measure are quantitative in nature and lend themselves to inference based on continuous distributions. Many of the tests of this type involve comparing the mean (or other measure of central tendency) of 2 or more populations. When only 2 groups are to be compared, a t-test for 2 independent samples is often employed. If a comparison group internal to the study is not available, sometimes the mean of a single group is compared to a known population value using a one-sample t-test. If the 2 samples of data to be compared are not from 2 independently selected groups, but are either from the same subjects (paired data) or a comparison group especially selected to match the first group on important characteristics (matched data), then a paired t-test is often employed. When more than 2 groups are to be compared to test for equality of means, a method called analysis of variance (ANOVA) can be used.

All of these types of t-tests and the ANOVA method make an assumption that the data within each population are (approximately) normally distributed. Minor deviations from this assumption can be tolerated, but when this assumption is not realistic, as is often the case, the analyst has 2 options: (1) the data can be transformed in a way that results in a more symmetric distribution (eg, positively skewed data may benefit from a logarithmic transformation) or (2) a nonparametric test may be employed instead of the t-test or ANOVA. These nonparametric tests, as their name implies, do not make distributional assumptions about the data. They are insensitive to extreme outliers as they make use of the rank ordering of the observations, not their actual values. So, for example, if the 5 oldest patients in a sample were 102, 64, 63, 59, and 56 years of age, in a nonparametric analysis these values would be converted to ranks of 1, 2, 3, 4, and 5 thus diminishing the influence of the extreme value of 102. Examples of nonparametric tests (not an exhaustive list) include the Mann-Whitney U test or the Wilcoxon rank-sum test in

place of the 2-sample t-test, the Wilcoxon signed rank test in place of the paired t-test, and Friedman's test in place of ANOVA.

Categorical outcomes—When the outcome of interest is a qualitative factor, we say it is a categorical variable, meaning that it can only take on a discrete set of possible values. Categorical variables may further be classified as either nominal (named categories, such as blood type) or ordinal (ordered categories, such as severity of pain if measured as none, mild, moderate, or severe).

Analysis of categorical outcomes often involves using one of a set of tests known collectively as chi-square tests. In the Pearson chi-square test, 2 or more groups are compared with respect to the proportion exhibiting the outcome. The data are often summarized in a contingency table or cross-tabulation, in which subjects are cross-classified by the combination of their exposure group and whether or not they have the outcome. The cross-tabulation presents counts and percentages for each possible combination of the 2 factors, with one factor listed on the rows and the other on the columns. The Pearson chi-square uses a continuous distribution to approximate the behavior of the categorical data; when the number of subjects in 1 or more of the groups (defined by either exposure or outcome) is small, however, the validity of that approximation is questionable, in that case a Fisher's exact test should be used instead. Most statistical software is programmed to warn users when use of a Fisher's exact test is preferred. Just as is the case with continuous outcomes, if the groups to be compared are not independently selected but are instead paired or matched, then the method of analysis needs to account for the interdependence within the pairs. In this case, one could use a McNemar's test for paired data. The contingency table is set up differently, however, as the unit of observation becomes the matched pairs instead of the individual subjects. Each pair is cross-classified with respect to the outcome for each of the 2 members of the pair.

Time-to-event outcomes (survival analysis)—When the outcome is an event that occurs over time, one is often interested in both whether subjects experience the event and how soon they experience the event. If the event is one for which all subjects can be observed completely with respect to either the fact or the timing of the event, then the methods

described earlier can be employed. Many studies, however, follow subjects for the occurrence of an event where, at the end of the study, some subjects have not experienced the event but have been at risk for that event for a period of time. The time to event for such subjects is said to be censored, in that we only partially observe it (ie, we know the time is at least as long as the amount of time they were at risk, but do not know how much longer). This arises often in studies where the event of interest is mortality, as such studies will often not be continued until all subjects have died. As such, the analytic methods for dealing with censored time-to-event data are often referred to as survival analysis. The survival (or event-free time) experience of 1 or more groups can be estimated using a variety of methods, including the Kaplan–Meier or product-limit method. This can be illustrated graphically with a Kaplan–Meier curve (actually a step function) that plots study time on the horizontal axis against survival (event-free) probability on the vertical axis. The survival experience of 2 or more groups can be compared with various methods, including the log-rank test.

P-values—Regardless of the type of statistical test used, a hypothesis test is performed by comparing the observed data to what would be expected to be observed under what is termed the null hypothesis which, generally speaking, represents the absence of a difference between groups, or an effect, association, etc. If what was observed would be unlikely under the null hypothesis, then that null hypothesis is rejected in favor of the alternative (eg, that there is a difference or an effect). Specifically, a test statistic is calculated (it may be a *t* statistic, a chi-square statistic, or some other) whose probability distribution under the null hypothesis is known. When “unlikely” values of the test statistic occur, that is, when we reject the null hypothesis. How we define unlikely is determined by the significance level of the test, denoted α , which is typically set by convention at 0.05. So, with $\alpha = 0.05$, if the test statistic falls in the range of values that are the 5% least likely to occur, that is, when we reject the null hypothesis. But, in addition to this reject or do not reject dichotomy, our statistical tests produce a measure of the likelihood of our test statistic known as the P value. Specifically, the P value is the chance of observing a test statistic as large (in absolute value) as the one observed if the

null hypothesis were true. Because the test statistic is a function of the observed data, one can think of the P value as the chances of observing as great a degree of difference as was observed if, in fact, the populations represented by the groups do not differ at all. One thing that the P value is not, though it is often misinterpreted as such, is the probability that a conclusion to reject or not reject is due to chance alone.

Measures of Disease Occurrence and Association

The aims of a study often include a desire to quantify the frequency with which, or the rate at which, a disease (or other outcome) occurs and/or the association of 1 or more risk factors with the occurrence of disease. For this, we need to have metrics to describe both disease occurrence and the associations between risk factors and outcomes.

Risks, Rates, and Odds

The proportion of a particular population that develops a particular disease is called the risk of disease. The risk is estimated simply as the number with the disease over the total number at risk of the disease. The proportion developing a disease per unit time is called the rate of disease. The numerator for the rate is still the same, but the denominator is no longer a count of the at-risk population, but the person-time of observation. To calculate person-time, say in years, the number of years that each subject in the at-risk group was followed is summed to get the total person-years for the rate calculation. The line between risks and rates may sometimes be fine, as a risk is often for a fixed period of time, for example, the 5-year risk of cancer recurrence. We do not often think of the odds of disease, but we sometimes need to calculate odds for measures of association (described later). If the probability of an outcome is *P*, then the odds of that outcome is $P/(1 - P)$, that is, the chance of it happening divided by the chance of it not happening. Note that if an outcome is rare (*P* close to zero), then the chance of it not happening is close to one, and the odds and the risk are almost the same.

Ratio Measures of Association

If 2 groups are being compared with respect to the occurrence of an outcome, they can be compared

with either ratio measures or difference measures. We first consider ratio measures. The relative risk is simply the risk in the group of interest divided by the risk in the comparison group. If rates rather than risks are being compared, one may instead compute a rate ratio. In the context of survival analysis, the rate of the event in one group divided by the rate in the other is called the hazard (rate) ratio. For the case-control study design, risk in each comparison group cannot be observed directly, and we instead calculate an odds ratio, defined as the odds of exposure in the cases over the odds of exposure in the controls. If the outcome is rare, one can exploit the fact that odds and risk are almost the same and employ the so-called rare-disease assumption to interpret an odds ratio as an estimate of relative risk. When outcomes are not rare, however, the odds ratio tends to overestimate the relative risk (ie, be further away from a null ratio of one).

Difference Measures of Association

Sometimes the absolute difference in risk or rate between 2 groups is of greater interest than the relative difference. In such cases, a difference measure would be preferred over a ratio measure. The risk difference is simply the risk in one group minus the risk in the other. In clinical studies, where the goal is often to test an experimental treatment to see if it reduces risk of an adverse outcome relative to a control treatment, these measures sometimes go by more specific names. The control event rate and the experimental event rate are simply the rates (or risks) of the outcome in the control group and experimental group, respectively. The difference between these is known as the absolute risk reduction (ARR), and is a measure of how much of the event (disease, mortality, etc) could be prevented (or cured) by replacement of the control treatment with the experimental treatment. Another measure of association, related to the ARR and often important in clinical studies, is the number needed to treat (NNT). It is defined as $NNT = 1/ARR$. It is an estimate of how many patients would need to be treated with the experimental treatment in order to prevent 1 adverse outcome (eg, death). So, for example, if a new treatment reduced mortality in a certain patient population from 10% to 4%, the relative risk (of death) would be 0.40 (4%/10%), the ARR would be 6% (10% – 4%), and

$NNT = 1/0.06 = 16.67$, suggesting that 17 patients would need to be treated to prevent 1 death. The number needed to harm is an analogous measure in studies where the groups are being compared with respect to a risk factor or exposure that increases, rather than decreases, the risk of the outcome. It is still calculated as 1 divided by the absolute difference in risk, but has an opposite interpretation because the group with the factor of interest is harmed rather than helped.

Confidence Intervals

Any of the measures mentioned earlier can be estimated from a given set of data. Such an estimate is called a point estimate. Because it is based on limited sample data, the point estimate will differ from the actual value it is intended to estimate due to sampling variability. To get a better idea of what the true value of a population parameter may be, one may calculate and present a confidence interval (CI) around the point estimate. A CI has a confidence level associated with it, denoted $(1 - \alpha)$ and usually expressed as a percent, corresponding to a significance level α for a related hypothesis test. Typically, $\alpha = 0.05$, corresponding to 95% CIs. Even though a CI gives us a better idea of what the true population value is than does the point estimate, any given CI from a single study may or may not contain that true value. But the formulas for calculating 95% CIs are constructed in such a way that, over repeated studies, they will contain the correct value 95% of the time. It is from this that CIs get their name, as we claim 95% confidence that the interval will contain the true value.

Diagnostic and Screening Test Performance Measures

Diagnostic and screening tests are used to classify patients with respect to the presence or absence of a disease, syndrome, or other condition. These tests are not always accurate, and their performance is described by various metrics that relate to the correct classification of those with and without disease. To define these measures, consider a population of N patients represented in the following “truth table.” The columns of the table represent the patients’ true presence or absence of disease while the rows represent their test result. In practice, when evaluating

TABLE 116–1 Truth table.

		True Disease Status		
		Disease	No Disease	Total
Test Result	Positive	a	b	a + b
	Negative	c	d	c + d
	Total	a + c	b + d	N

new tests, we may not know with absolute certainty the true disease status of a set of patients, but instead compare a new test to a “gold standard” that is assumed to represent true disease status (Table 116–1).

The sensitivity of a test refers to how well it correctly classifies those with disease, and is equal to $[a/(a + c)]$, the proportion of those with disease who test positive. The specificity of a test refers to how well it correctly classifies those without disease, and is equal to $[d/(b + d)]$, the proportion of those without disease who test negative. The positive predictive value (PPV) of a test refers to how likely it is that a positive test result indicates the presence of disease, and is equal to $[a/(a + b)]$, the proportion of all those with a positive test result who actually have disease. The negative predictive value (NPV) of a test refers to how likely it is that a negative test result indicates the absence of disease, and is equal to $[d/(c + d)]$, the proportion of all those with a negative test result who actually do not have disease.

The sensitivity and specificity of a test are characteristics of the test itself and thus do not change unless something about the test itself is changed (eg, by altering a cutoff for what is considered a positive test result). The PPV and NPV, however, depend

not only on how accurate the test is but also on how prevalent the disease is in the population to whom the test is applied. The prevalence of a disease is the proportion of the population that has the disease. In our truth table discussed earlier, the prevalence is $[(a + c)/N]$. In particular, if the prevalence is low in the population being tested, a test with fairly high sensitivity and specificity can still have very poor PPV. In such instances, more specific confirmatory tests may be needed in those who initially test positive.

CONCLUSION

The development of comprehensive expertise in statistical methods is beyond the scope of study for most physicians, and only basic methods have been presented here. But the clinician who is equipped with these tools is better prepared to critically appraise the medical literature, where innovations that have the potential to affect clinical practice may appear. The clinical investigator who is equipped with these tools is better prepared to design sound, unbiased studies, and to effectively communicate with coinvestigators (including biostatisticians) in order to make valid inferences from their data. Finally, the physician who can appreciate when the claims of published studies are validly supported by the available data, and when they are not, it is better prepared to treat patients in an optimal, evidence-based manner.
